Group-Theoretical Treatment of the Energy Bands in Metal Borides MeB_6

By Masatoshi YAMAZAKI

Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received August 8, 1956)

The tight-binding approximation is applied to a study of electronic energy bands in metal borides MeB_6. The 25×25 determinantal secular equation for the energy is reduced by a group-theoretical treatment of the spatial symmetry at certain special values of the wave vector $\boldsymbol{K}$. The results are that if metal atoms have two valence electrons the valence bands are all filled and the conduction bands are all empty, and in the case of calcium boride CaB_6 the narrowest gap between valence- and conduction-bands is at edges of the first Brillouin zone, the simple cube in the reciprocal space and its width is about 1.5 eV, in good agreement with empirical results that there exist only borides of elements having two valence *s* electrons in this type of structure.

§ 1. Introduction

According to the results of Kiessling's X-ray analysis[1)], structures of metal boride crystals MeB_6 are that six boron atoms *en bloc* make one octahedron the center of which makes a simple cube, and metal atoms which are at interstices of boron octahedra and enclosed by twenty-four boron atoms make another simple cube, and thus six boron atoms B_6 *en bloc* and metal atoms Me make a structure of cesium chloride type. Every boron atom has five other adjacent boron atoms at equal distances. The shortest boron-boron distances of MeB_6 are almost independent of the participating metals, as seen in Table I. It is significant that metals with a higher ionization potential than yttrium (8.71 eV) cannot form MeB_6 crystals. Thus in MeB_6 crystals parts of electrons are considered to be transferred to boron atoms, so the high stability of MeB_6 crystal very likely depends on the ionization of Me. After the results of another X-ray analysis of several boron hydrides by Lipscomb[2)], five boron atoms in B_5H_9 occupy almost five vertex sites of a octahedron (B–B (base) 1.80 and B–B (slant) 1.69 A), and five boron atoms in B_5H_{11} imperfectly occupy five vertex sites of a distorted octahedron (average B–B 1.74 A). It is thought to be characteristic that boron atoms make structures of octahedron type. Longuet-Higgins and de V. Roberts[3)] and Flodmark[4)] performed theoretical analysis of MeB_6 and reached the conclusions fairly agreeing with experimental results. It is the purpose of this paper to calculate more quantitatively the variation of energy with the wave vector in the reciprocal space for

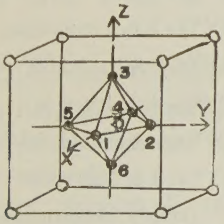

Fig. 1. Structure of the MeB_6 crystal. Six B atoms make one octahedron, whose center is situated at the body center of simple cube made by Me atoms. Every B atom has five nearest B atoms at equal distance, one of which belongs to the next octahedron. The coordination number of Me atom is 24.

MeB_6.

In this paper the energies of Bloch orbitals which are based on the four atomic orbitals 2*s*, 2*px*, 2*py*, and 2*pz* of the boron atom and one *ns* of the metal atom are calculated under the simplified periodic field at certain special values of the wave vector $\boldsymbol{K}$. Since there are six B atoms and one Me atom per unit cell, there are twenty-five basis atomic orbitals to be considered. The 25×25 determinantal secular equation for the energy based on twenty-five Bloch sums is factorized with respects to sets of basis of different irreducible representations for the subgroup of the rotation group of the lattice and the group of the wave vector, so leaving us with seculor equations of lower degree to solve. Because MeB_6 lattice is polyatomic, the cubic harmonics of von der Lage and Bethe⁵⁾ developed about different points in the lattice must be matched over the surface of subcells, resulting from the division of the unit cell and one surrounding each site, by the condition that the Bloch orbital is smooth throughout the crystal⁶⁾. Here we regard six boron atoms *en bloc* making one octahedron as to constitute one lattice site, and MeB_6 crystals are considered to have the structure of cesium chloride type, Me atoms making simple cube and B_6 atoms occupying its body centers. The twenty-four AO's of B_6 atoms are combined to form bases of different irreducible representations of the crystal symmetry, the octahedral group $\boldsymbol{O}_h$. In the following the band structure of calcium boride is calculated at certain points in the Brillouin zone.

§2. Method and Calculation

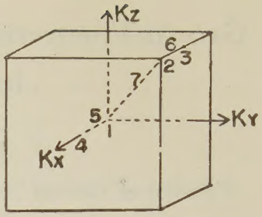

Fig. 2. The first Brillouin zone of the MeB_6 crystal (CsCl type) 1), 2), 3), 4), 5), 6) and 7) are the special points in the zone cited in the text.

The direct lattice vectors $\boldsymbol{a}_i$ and the reciprocal lattice vectors $\boldsymbol{b}_j$ are

$$\boldsymbol{a}_1=a(1,0,0)\,; \qquad \boldsymbol{b}_1=2\pi/a(1,0,0)\,;$$
$$\boldsymbol{a}_2=a(0,1,0)\,; \qquad \boldsymbol{b}_2=2\pi/a(0,1,0)\,;$$
$$\boldsymbol{a}_3=a(0,0,1)\,; \qquad \boldsymbol{b}_3=2\pi/a(0,0,1)\,.$$

Thus, the unit lattice cell is a cube of side *a* and the first Brillouin zone a cube of side $2\pi/a$. The MeB_6 lattice is *so-called diatomic*, made up of two interpenetrating simple cubic lattices of B_6 atoms and Me atoms based on the points (0, 0, 0) and $a/2(1,1,1)$, respectively, such that the potential has full cubic symmetry about each site. The *x*-, *y*-, and *z*-axes and the numbering of six boron atoms making one octahedron are taken as shown in Fig. 1. The coordinates of six boron atoms are with the center of octahedron as zero;

$$1,\ (a/(2+\sqrt{2}),0,0); \qquad 2,\ (0,a/(2+\sqrt{2}),0);$$
$$3,\ (0,0,a/(2+\sqrt{2})); \qquad 4,\ (-a/(2+\sqrt{2}),0,0);$$
$$5,\ (0,-a/(2+\sqrt{2}),0); \quad 6,\ (0,0,-a/(2+\sqrt{2})).$$

The twenty-four AO's, four on each atom, are combined to form bases of the crystal symmetry $\boldsymbol{O}_h$ as:

$$a_{1g}\ :\quad (1/6)^{1/2}(s_1+s_2+s_3+s_4+s_5+s_6)\,,$$
$$(1/6)^{1/2}(x_1-x_4+y_2-y_5+z_3-z_6);$$
$$e_g(1):\quad (1/12)^{1/2}(2s_1-s_2-s_3+2s_4-s_5-s_6)\,,$$
$$(1/12)^{1/2}(2x_1-y_2-z_3-2x_4+y_5+z_6);$$
$$e_g(2):\quad (1/4)^{1/2}(s_2-s_3+s_5-s_6)\,,$$
$$(1/4)^{1/2}(y_2-z_3-y_5+z_6)$$

(doubly degenerate):

$$f_{1u}(x):\quad (1/2)^{1/2}(s_1-s_4)\,,\quad (1/2)^{1/2}(x_1+x_4)\,,$$
$$(1/4)^{1/2}(x_2+x_3+x_5+x_6);$$
$$f_{1u}(y):\quad (1/2)^{1/2}(s_2-s_5)\,,\quad (1/2)^{1/2}(y_2+y_5)\,,$$
$$(1/4)^{1/2}(y_3+y_4+y_6+y_1);$$
$$f_{1u}(z):\quad (1/2)^{1/2}(s_3-s_6)\,,\quad (1/2)^{1/2}(z_3+z_6)\,,$$
$$(1/4)^{1/2}(z_1+z_2+z_4+z_5)$$

(triply degenerate):

$$f_{1g}(x):\quad (1/4)^{1/2}(z_2-y_3-z_5+y_6);$$
$$f_{1g}(y):\quad (1/4)^{1/2}(x_3+z_4-x_6-z_1);$$
$$f_{1g}(z):\quad (1/4)^{1/2}(y_1-x_2-y_4+x_5)$$

(triply degenerate):

$$f_{2g}(x):\quad (1/4)^{1/2}(z_2+y_3-z_5-y_6);$$
$$f_{2g}(y):\quad (1/4)^{1/2}(x_3-z_4-x_6+z_1);$$
$$f_{2g}(z):\quad (1/4)^{1/2}(y_1+x_2-y_4-x_5)$$

(triply degenerate):

$$f_{2u}(x):\quad (1/4)^{1/2}(x_2-x_3+x_5-x_6);$$
$$f_{2u}(y):\quad (1/4)^{1/2}(y_3-y_4+y_6-y_1);$$
$$f_{2u}(z):\quad (1/4)^{1/2}(z_1-z_2+z_4-z_5)$$

(triply degenerate):

here s_i, x_i, y_i, and z_i means $2s$, $2px$, $2py$, and $2pz$ AO's of B atom i, respectively. The overlapping of atomic orbitals are all neglected.

For AO's of Me atoms we consider only valence s orbitals which belong to a_{1g} representation of $\boldsymbol{O}_h$ group. These Me orbitals match the boron AO's at special values of the wave vector as:

1) $\boldsymbol{K}=(0, 0, 0)$ Γ_1

2) $K=\pi/a(1, 1, 1)$ R_2',

so there is none in our treatment

3) $K=\pi/a(0, 1, 1)$ M_3

4) $K=\pi/a(1, 0, 0)$ X_4'

5) $K=\pi/a(\alpha, 0, 0)$, $0<\alpha<1$ Δ_1

6) $K=\pi/a(\alpha, 1, 1)$, $0<\alpha<1$ T_2'

7) $K=\pi/a(\alpha, \alpha, \alpha)$, $0<\alpha<1$ Λ_1

8) $K=\pi/a(0, \alpha, \alpha)$, $0<\alpha<1$ Σ_1

9) $K=\pi/a(1, \alpha, \alpha)$, $0<\alpha<1$ S_3

10) $K=\pi/a(\alpha, 0, 1)$, $0<\alpha<1$ Z_4.

Following Bloch's method, the one electron wave functions in the periodic potential field are written as

$$\Psi_N(\boldsymbol{K})=\sum(\boldsymbol{R}_i)\exp(i\boldsymbol{K}\boldsymbol{R}_i)\bar{\chi}_N(\boldsymbol{r}-\boldsymbol{R}_i),$$

where $\boldsymbol{R}_i$ is the position vector of the crystal lattice site, $\boldsymbol{K}$ is the wave vector, and $\bar{\chi}_N$'s are linear combinations of several AO's χ_n of one lattice site. ($\bar{\chi}_N(\boldsymbol{K})=\sum(n)\lambda_{Nn}(\boldsymbol{K})\chi_n$; λ_{Nn}'s are functions of $\boldsymbol{K}$). We make Bloch sums φ_n for every same kinds of AO's on each same lattice site as

$$\varphi_n=\sum(\boldsymbol{R}_i)\exp(i\boldsymbol{K}\boldsymbol{R}_i)\chi_n(\boldsymbol{r}-\boldsymbol{R}_i),$$

so we obtain $\Psi_N(\boldsymbol{K})=\sum(n)\lambda_{Nn}(\boldsymbol{K})\varphi_n$. For simplification we assume the Bloch sums are orthogonal to each other.

In the case of general K values we have secular equations for the energy as

$$|H_{nm}-E\delta_{nm}|=0,$$

where $\boldsymbol{H}$ is the one electron hamiltonian operator in the crystal and

$$H_{nm}=\int\varphi_n^*\boldsymbol{H}\varphi_m d\tau.$$

Factorizations of secular equations at special points in the first Brillouin zone are tabulated in the appendix.

The matrix elements H_{nm}'s are expressed as (Bloch sums are normalized over the cyclic domain, and N is the number of atoms in the cyclic domain):

$$\begin{aligned}H_{nm}&=\int\varphi_n^*\boldsymbol{H}\varphi_m d\tau\\&=N^{-1}\sum(\boldsymbol{R}_i)\sum(\boldsymbol{R}_j)\exp(i\boldsymbol{K}(\boldsymbol{R}_j-\boldsymbol{R}_i))\\&\quad\times\int\chi_n^*(\boldsymbol{r}-\boldsymbol{R}_i)\boldsymbol{H}\chi_m(\boldsymbol{r}-\boldsymbol{R}_j)d\tau\\&=\sum(\boldsymbol{R}_j)\exp(i\boldsymbol{K}(\boldsymbol{R}_j-\boldsymbol{R}_i))\\&\quad\times\int\chi_n^*(\boldsymbol{r}-\boldsymbol{R}_i)\boldsymbol{H}\chi_m(\boldsymbol{r}-\boldsymbol{R}_j)d\tau.\end{aligned}$$

For arbitrary B atoms interactions with five atoms within that octahedron and shortest distance one within next one are considered and for B–Me, Me–Me only the nearest neighbour interactions are taken into account. Coulomb energies

$$\int\chi_n^*(\boldsymbol{r}-\boldsymbol{R}_i)\boldsymbol{H}\chi_n(\boldsymbol{r}-\boldsymbol{R}_i)d\tau$$

are approximated by one-electron orbital energies of the free atom given by Slater[7], i.e., -14.01, -5.71, and -6.12 eV for $2s$, $2p$ of B, and $4s$ of Ca, respectively, and resonance energies are approximated to be proportional to the corresponding overlap integrals[8] of Slater atomic orbitals[9], the proportional constant being taken as -10.153 eV determined from the ratio of the resonance energy for carbon-carbon neighbour in benzene, -2.39 eV, the value suggested by Pariser and Parr[10], to the corresponding overlap integral, 0.2354, calculated from formulas by Mulliken et al.[8]*. The effective nuclear charge of boron $2s$, $2p$ AO's is first taken as $2\delta=2.60$ (5 electrons per atom), but after preliminary calculations it is decided to be $2\delta=2.482$ ($5+\frac{1}{3}$ electrons per atom). The calculated energy bands are shown in Fig. 3.

If the metal atom has two valence s electrons, the valence bands are completely filled and the conduction bands are completely empty. The shortest gap between valence-

---

* The overlap integrals for B atoms are:

$$\begin{aligned}&S_{s1s2}=0.452, \quad S_{s1\sigma2}=0.442,\\&\qquad\qquad\qquad\quad S_{\sigma1\sigma2}=0.322, \quad S_{\pi1\pi2}=0.282,\\&S_{s1s4}=0.216, \quad S_{s1\sigma4}=0.257,\\&\qquad\qquad\qquad\quad S_{\sigma1\sigma4}=0.274, \quad S_{\pi1\pi4}=0.105;\end{aligned}$$

with effective nuclear charge $2\delta=2.482$.

The overlap integral for Ca atoms is approximated to be $S_{ss}=0.395$ with effective nuclear charge $3.7\delta=3.2$, and those between nearest Ca–B neighbours are approximated to be $S_{ss}=0.275$ and $S_{s\sigma}=0.165$.

and conduction-bands is at edges of the first Brillouin zone, the simple cube in the reciprocal space and its width is proved to be about 1.5 eV.

The assumptions we have used are undoubtedly crude by quantitative standards, but we feel fairly confident of our obtained results qualitatively.

Appendix

The factorizations of secular equations for the energy at certain special points in the first Brillouin zone:

S_i, X_i, Y_i, Z_i, and S_M means the Bloch sum constructed from the atomic orbital $2s$, $2px$, $2py$, and $2pz$ of the i-site of B atom, and the $4s$ atomic orbital of the metal-site of Ca atom. Unnormalized forms of Bloch sums and notations of different irreducible representations about the B-site are described.

1) $K=(0, 0, 0)$ and 2) $K=\pi/a(1, 1, 1)$ (symmetry type: O_h)

In case 1) three 1st order-(each triply degenerated), one second order-(doubly degenerated), and two third order-secular equations (one of which is triply degenerated) are obtained.

In case 2) four 1st order-(three of which are triply degenerated), two second order-(one of which is doubly degenerated), and one third order-(triply degenerated) secular equations are obtained.

Γ_1 : $(S_1+S_2+S_3+S_4+S_5+S_6)$, $(X_1-X_4+Y_2-Y_5+Z_3-Z_6)$, S_M(for case 1));
$\Gamma_{12}(1)$: $(2S_1-S_2-S_3+2S_4-S_5-S_6)$, $(2X_1-Y_2-Z_3-2X_4+Y_5+Z_6)$;
$\Gamma_{12}(2)$: $(S_2-S_3+S_5-S_6)$, $(Y_2-Z_3-Y_5+Z_6)$;
$\Gamma_{15}(x)$: (S_1-S_4), (X_1+X_4), $(X_2+X_3+X_5+X_6)$;
$\Gamma_{15}(y)$: (S_2-S_5), (Y_2+Y_5), $(Y_3+Y_4+Y_6+Y_1)$;
$\Gamma_{15}(z)$: (S_3-S_6), (Z_3+Z_6), $(Z_1+Z_2+Z_4+Z_5)$;
$\Gamma_{15}'(x)$: $(Z_2-Y_3-Z_5+Y_6)$; $\Gamma_{25}'(x)$: $(Z_2+Y_3-Z_5-Y_6)$;
$\Gamma_{15}'(y)$: $(X_3+Z_4-X_6-Z_1)$; $\Gamma_{25}'(y)$: $(X_3-Z_4-X_6+Z_1)$;
$\Gamma_{15}'(z)$: $(Y_1-X_2-Y_4+X_5)$; $\Gamma_{25}'(z)$: $(Y_1+X_2-Y_4-X_5)$;
$\Gamma_{25}(x)$: $(X_2-X_3+X_5-X_6)$; Γ_2' : S_M(for case 2)).
$\Gamma_{25}(y)$: $(Y_3-Y_4+Y_6-Y_1)$;
$\Gamma_{25}(z)$: $(Z_1-Z_2+Z_4-Z_5)$;

3) $\boldsymbol{K}=\pi/a(0, 1, 1)$ and 4) $\boldsymbol{K}=\pi/a(1, 0, 0)$ (symmetry type: $\boldsymbol{D}_{4h}$)

In case 3) two first order-, three second order-(one of which is doubly degenerated), one third order-, and two fourth order-(one of which is doubly degenerated) secular equations are obtained.

In case 4) three 1st order-, two 2nd order-(one of which is doubly degenerated), and three fourth order-(one of which is doubly degenerated) sec. equ. are obtained.

On the Period of Out-of-step of Ordered Alloys with Anti-phase Domain Structure

By Kunio FUJIWARA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received September 13, 1956)

The period of out-of-step of ordered alloys with anti-phase domain structure, measured in atomic distance, is generally not an integer, in spite of sharp splits of superlattice reflections. This fractional property of the period has theoretically been examined. The general treatment of this problem has shown that a regular and uniform arrangement of the different periods of anti-phase domains can explain the fractional value of the period, M. The results of numerical calculations in some models of arrangement have suggested, however, that complete regularity in arrangement is not always necessary but only uniformity is essential for the interpretation of the diffraction patterns.

§1. Introduction

Recently, many X-ray and electron diffraction studies[1] have been made on the ordered alloys with anti-phase domain structure, such as CuAu, Cu_3Pd, etc., and even a fairly complex type of anti-phase domain has been discovered[2]. The writer has also studied the anti-phase domain structure of Ag_3Mg in single crystal as well as polycrystal[3]. The diffraction patterns of such alloys show sharp splits of superlattice reflections, due to anti-phase domains, and the period of out-of-step or the length of anti-phase domain, measured in atomic distance, M, can be calculated from the separation of split spots. The value of M is, however, generally not an integer* in spite of sharpness of the splitting. This curious property may be interpreted, if M means a mean length of anti-phase domains. Namely, we consider that a crystal contains several sorts of anti-phase domains whose lengths correspond to different integers respectively and that these domains are mixed in such a manner that M is given as a mean length. The type of arrangement of anti-phase domains can be classified as follows:

i) Regular arrangement with uniform mixing,
ii) Regular arrangement with not uniform mixing,
iii) Irregular arrangement with almost uniform mixing,
iv) Irregular arrangement with not uniform mixing.

To explain the sharpness of split diffraction spots, it seems to be necessary that some regularities are contained in the arrangements. Models of regular arrangement which correspond to the same value of M are, however, innumerable and it is difficult to decide which model is realized in a real crystal. Such a problem will much more complicate the image of the anti-phase domain structure. On the other hand, the idea that no regularity is contained in the arrangements seems to be attractive for its simplicity. In this case, however, it should be examined whether this model can explain the sharpness of splitting of spots or not. Some calculations have been made in the present work, in order to interpret the fractional values of M, and the results are believed to give a fairly clear conclusion on the period of out-of-step.

§2. The Regular Arrangements of the Anti-phase Domains

Let us now deal with an ordered crystal lattice of Cu_3Au type as shown in Fig. 1. Its dimensions parallel to the x, y, z-axes are N_1a_1, N_2a_2 and N_3a_3 respectively, where a_1, a_2 and a_3 are the lattice constants and N_1, N_2 and N_3 the numbers of the unit cells. An

---

* For example,

Cu_3Pd(2)—	$M_1=5.5$,	$M_2=3.7$	(25 at. % Pd)
	$M_1=3.5$,	$M_2=3.2$	(28 at. % Pd)
Ag_3Mg(3)—	$M=1.77$		(25 at. % Mg)
	$M=1.83$		(24. 3 at. % Mg)

anti-phase domain structure is assumed to occur along the z-direction in this lattice. The arrows in the figure show the positions of anti-phase domain boundaries, where a displacement $(\vec{a}_1+\vec{a}_2)/2$ takes place. This type of anti-phase domain structure can be observed in Cu_3Pd, Ag_3Mg[1),3)], an incompletely ordered lattice of Cu_3Au and so on. In such a crystal the unit cell* in terms of a disordered lattice is considered in two ways, as shown in Fig. 2. If the structure factor of the left cell in the figure is given by Φ, that of the right cell becomes $\Phi\cdot\exp\{\pi i(h+k)\}$, if h, k and l represent the coordinates in reciprocal space. It can easily be shown that only superlattice reflections with odd $h+k$ split along the l-direction. As we are mainly interested in the split reflections, we shall restrict our calculations only to the case of odd $h+k$. Thus, the structure factors of two unit cells become Φ and $-\Phi$ respectively, and the intensity distribution in reciprocal space is given by

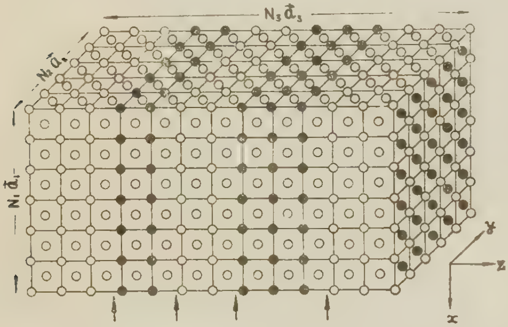

Fig. 1. An ordered lattice of Cu_3Au type with anti-phase domains along the z-direction.

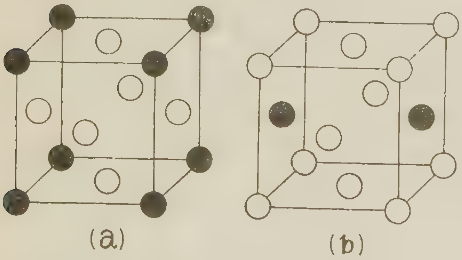

Fig. 2. (a) unit cell of positive type
(b) unit cell of negative type

$$I(hkl)=\left|\sum_{n_1=0}^{N_1-1}\sum_{n_2=0}^{N_2-1}\sum_{n_3=0}^{N_3-1}\Phi\cdot f(n_3)\cdot\exp\{2\pi i(n_1h+n_2k+n_3l)\}\right|^2$$
$$=\Phi^*\Phi\cdot\frac{\sin^2 N_1\pi h}{\sin^2 \pi h}\cdot\frac{\sin^2 N_2\pi k}{\sin^2 \pi k}\cdot\left|\sum_{n_3=0}^{N_3-1} f(n_3)\cdot\exp(2\pi i n_3 l)\right|^2, \qquad (1)$$

where a set of (n_1, n_2, n_3) represents the number of a unit cell contained in this crystal. $f(n)$ is a factor which takes either value, $+1$ or -1, according as the type of the n-th unit cell along the z-axis is positive or negative, and so it will be called 'anti-phase factor.' It is the factor

$$F\equiv\sum_{n=0}^{N-1} f(n)\cdot\exp(2\pi inl) \qquad (2)$$

that gives splitting of spots in the l-direction, and in the following calculations, therefore, we shall concern ourselves only with this factor. If a functional form of $f(n)$ is given, then the corresponding arrangement of anti-phase domains in crystal will be determined, and the factor F can be calculated at once.

a) *Regular arrangements with uniform mixing*

If it could be proved that several models of regular arrangement give acceptable intensity distributions, a complete solution of the problem would not be obtained unless the general law could be found which give an acceptable regular arrangement corresponding to a given value of M. Thus, the present problem is to find the general form of $f(n)$ corresponding to a regular arrangement with uniform mixing. If n is replaced, for convenience, by a continuous variable, ξ, the following periodic function $f_M(\xi)$ with the period $2M$ can be obtained as a solution:

$$f_M(\xi)=\begin{cases}1 & \text{for}\quad 2kM\leq\xi<(2k+1)M\\ -1 & \text{for}\quad (2k+1)M\leq\xi<(2k+2)M\end{cases}$$
$$(k=0,\,1,\,2,\,\cdots)\,. \qquad (3)$$

Fig. 3-(a) shows the form of $f_{1.70}(\xi)$ as an examale. Of course, $f_M(\xi)$ has a physical meaning only when $\xi=n$, and, hereafter, such functions as $f_M(\xi)$ will be called 'anti-phase function.' When $M=1.80$, for example, $f_{1.80}(\xi)$ gives the arrangement

$$(2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}\cdots)$$

and when $M=1.70$, $f_{1.70}(\xi)$ gives the arrange-

---

* If there is a complete regularity in the arrangement of anti-phase domains, a larger unit cell should be adopted as an actual one, as described later,

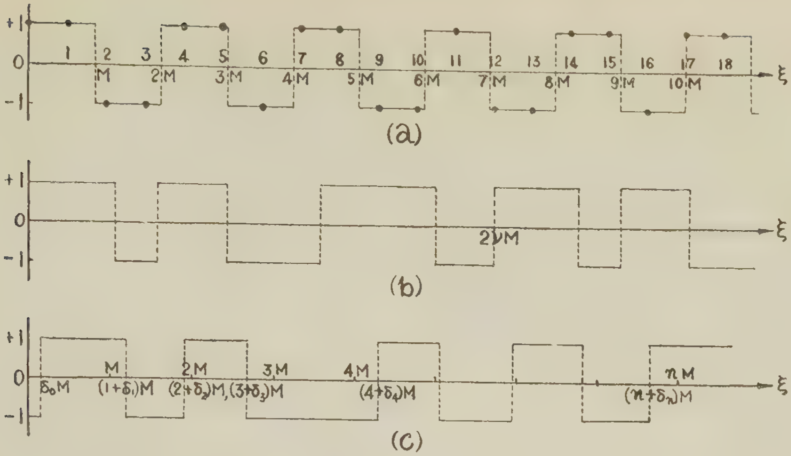

Fig. 3. Anti-phase functions in various cases.
(a) $f_{1.70}(\xi)$ (b) An example of $\varphi_M(\xi)$ (c) An example of $\psi_M(\xi)$

ment

$$(2\bar{2}2\bar{1}2\bar{2}1\bar{2}2\bar{1}\cdots),$$

where each number represents the length of an anti-phase domain in the z-direction, measured in atomic distance, and upper bars mean the domains of negative type. As to the regular arrangements with $M=1.80$, other models may be considered;

$$(2\bar{2}2\bar{1}2\bar{2}2\bar{2}2\bar{1}\cdots),$$

$$(2\bar{2}2\bar{2}2\bar{2}2\bar{2}1\bar{1}\cdots),$$

$$(2\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{1}2\bar{2}2\bar{1}2\bar{2}2\bar{2}2\bar{1}\cdots)$$

and so on. None of them, however, can be more uniform than the arrangement

$$(2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}\cdots)$$

corresponding to $f_{1.80}(\xi)$. It should be noticed that the arrangement arising from $f_M(\xi)$ is periodically repeated every m_0 unit cells, where m_0 is a minimum value of the integer, m, which satisfies the next condition,

$$2\nu M=m \qquad (\nu,\ m\text{: positive integers}). \tag{4}$$

For example, when $M=1.80$ and 1.83, $m_0=18$ and 183 respectively. In other words, the lattice has a large unit cell whose dimensions along the three axes are a_1, a_2 and m_0a_3 respectively. To calculate the factor F in a general way, $f_M(\xi)$ is expanded in Fourier series:

$$f_M(\xi)=\frac{4}{\pi}\sum_{m=0}^{\infty}\frac{1}{2m+1}\sin\frac{(2m+1)\pi}{M}\xi. \tag{5}$$

Thus, the following expression is obtained as the intensity distribution in reciprocal space:

$$\begin{aligned}F^*F&=\left|\sum_{n=0}^{N-1}f_M(n)\exp(2\pi inl)\right|^2\\&=\frac{4}{\pi^2}\left|\sum_{m=0}^{\infty}\frac{1}{2m+1}\left[\exp\left\{i\pi\left(l+\frac{2m+1}{2M}\right)(N-1)\right\}\cdot\frac{\sin N\pi(l+(2m+1)/2M)}{\sin\pi(l+(2m+1)/2M)}\right.\right.\\&\qquad\left.\left.-\exp\left\{i\pi\left(l-\frac{2m+1}{2M}\right)(N-1)\right\}\cdot\frac{\sin N\pi(l-(2m+1)/2M)}{\sin\pi(l-(2m+1)/2M)}\right]\right|^2.\end{aligned}\tag{6}$$

The right hand side of formula (6) shows that the intensity distribution in reciprocal space has sharp maxima only when $l=n\pm(2m+1)/2M$ (n, $m=0$ or integers). It can be said, therefore, that the regular arrangement with uniform mixing corresponding to $f_M(\xi)$ explains the diffraction patterns quite well.

b) *Regular arrangements with not uniform mixing*

The anti-phase function, $\varphi_M(\xi)$, leading to a regular arrangement with not uniform mixing is illustrated in Fig. 3-(b). In this case, the period of $\varphi_M(\xi)$ is not $2M$ but $2\nu M$ which satisfies the condition (4), and so its Fourier expansion takes the following form:

$$\varphi_M(\xi)=\sum_{k=-\infty}^{\infty}A_k(M)\exp(i\pi k\xi/\nu M), \tag{7}$$

where $A_k(M)=A_{-k}^*(M)$.

Thus we obtain

$$F^*F=\left|\sum_{k=-\infty}^{\infty} A_k(M)\exp\left\{i\pi\left(l+\frac{k}{2\nu M}\right)(N-1)\right\}\times\frac{\sin N\pi(l+k/2\nu M)}{\sin \pi(l+k/2\nu M)}\right|^2. \tag{8}$$

Now, it follows that appreciable peaks take place not only at $l=n\pm(2m+1)/2M$ but also at $l=n\pm k/2\nu M$ $(k=0, 1, 2, \cdots)$ unless the modulus of Fourier coefficient, $|A_k(M)|$, is negligibly small. Such a situation is well illustrated in Fig. 4. Here, the results of numerical calculations on two models of regular arrangement corresponding to $M=1.80$ and $N=72$,

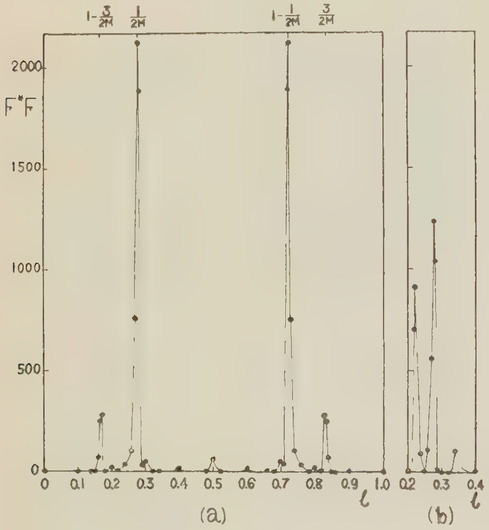

Fig. 4. The intensity distribution along the l-direction, given by numerical calculation.
(a) Uniform regular arrangement $M=1.80$, $N=72$
(b) Not uniform regular arrangement $M=1.80$, $N=72$

$$(2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1})$$

and

$$(2\bar{2}2\bar{2}2\bar{2}2\bar{2}1\bar{1}2\bar{2}2\bar{2}2\bar{2}2\bar{2}1\bar{1}2\bar{2}2\bar{2}2\bar{2}2\bar{2}1\bar{1}2\bar{2}2\bar{2}2\bar{2}2\bar{2}1\bar{1})$$

are shown. The former model is uniform, while the latter not uniform. It should be noticed that the latter gives an excessive peak at $l=k/2\nu M=4/18$. Since such an excessive peak has never been observed, the regular arrangements with not uniform mixing is hardly realized in the actual alloys.

§ 3. The Irregular Arrangements and Their Statistical Assembly

So far as anti-phase domains are almost uniformly mixed, irregularities in their arrangement may be allowed to some extent. To exemplify this conjecture, the results of numerical calculations are shown in Fig. 5, three models of irregular arrangement being adopted.

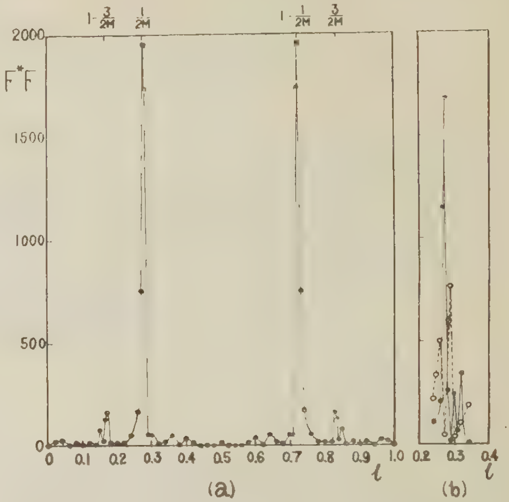

Fig. 5 The intensity distribution along the l-direction, given by numerical calculation.
(a) uniform irregular arrangement $M=1.80$, $N=72$
(b) not uniform irregular arrangements
1) $M=1.85$, $N=72$ —●——●—
2) $M=1.76$, $N=72$ ----○-------○---

It is really wonderful that an irregular arrangement such as

$$(2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}2\bar{2}1\bar{2}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2})$$

$$\cdots M=1.80,\ N=72$$

can still give the intensity distribution which fits well in actual diffraction patterns. On the other hand, two models of irregular arrangement with not uniform mixing,

$$(2\bar{2}2\bar{1}2\bar{2}2\bar{2}1\bar{2}2\bar{2}2\bar{2}1\bar{2}2\bar{2}3\bar{1}2\bar{2}2\bar{1}2\bar{1}2\bar{2}1\bar{2}2\bar{4}1\bar{2}2\bar{2}2\bar{1}2)$$

$$\cdots M=1.85,\ N=72$$

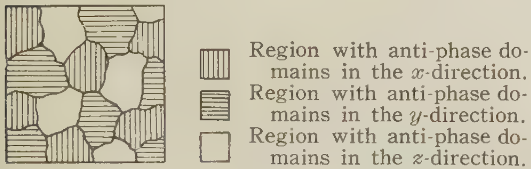
and

$$(2\bar{2}2\bar{1}2\bar{2}1\bar{1}2\bar{1}2\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}2\bar{1}2\bar{2}2\bar{2}2\bar{1}1\bar{2}2\bar{1}2\bar{2}2\bar{2}2\bar{1}2\bar{2}2)$$

$$\cdots M=1.76,\ N=72$$

give many excessive peaks and, therefore, are not acceptable. Then, the question arises to what extent irregularity and non-uniformity can be allowed. The general treatment of this problem is considered to require some 'short range theory' instead of 'long range theory' based on the concept of anti-phase function. But the construction of such theory seems fairly troublesome, and the larger M becomes, the more complexity will arise. For simplicity, therefore, only 'long range theory' will be developed, and the problem mentioned above will thus be treated in terms of statistics applied to the anti-phase function.

It was considered at the beginning that a single crystal forms a coherent region for superlattice reflections as well as mainlattice reflections. But such a view is not correct in real crystals. For, from the aspects of diffraction photographs, it is evident that a single crystal itself is divided into many small coherent regions in which the directions of anti-phase are different from one another, as shown in Fig. 6. Therefore, as to superlattice reflections, a single crystal behaves as if it were polycrystalline[†]. Here an assumption is made, for convenience, that each region has the same form and dimensions and that the number of regions in which anti-phase occurs along the z-directions is W. In this case, the total intensity distribution corresponding to formula (1) is given by



▥ Region with anti-phase domains in the x-direction.
▤ Region with anti-phase domains in the y-direction.
□ Region with anti-phase domains in the z-direction.

Fig. 6. A model of an ordered single crystal of Cu_3Au type.

$$I(hkl)=\Phi^*\Phi\,\frac{\sin^2 N_1\pi h}{\sin^2 \pi h}\cdot\frac{\sin^2 N_2\pi k}{\sin^2 \pi k}\cdot\sum_{j=1}^{W}F_j{}^*F_j\,, \tag{9}$$

where F_j is the F-factor of j-th region, and the summation must be taken over whole regions in which anti-phase occurs along the z-direction. Thus, the new object of calculation is to evaluate

$$I(l)=\sum_{j=1}^{W}F_j{}^*F_j\,. \tag{10}$$

When the regular arrangement corresponding to $f_M(\xi)$ takes place in each region, $I(l)$ becomes

$$I(l)=W\cdot\frac{4}{\pi^2}\left|\sum_{m=0}^{\infty}\frac{1}{2m+1}\left[\exp\left\{i\pi\left(l+\frac{2m+1}{2M}\right)(N-1)\right\}\cdot\frac{\sin N\pi(l+(2m+1)/2M)}{\sin\pi(l+(2m+1)/2M)}\right.\right.$$
$$\left.\left.-\exp\left\{i\pi\left(l-\frac{2m+1}{2M}\right)(N-1)\right\}\cdot\frac{\sin N\pi(l-(2m+1)/2M)}{\sin\pi(l-(2m+1)/2M)}\right]\right|^2. \tag{11}$$

When some irregular arrangement with almost uniform mixing takes place in each region, on the other hand, it is shown, using statistics, that the total intensity distribution also coincides with actual diffraction patterns. That is,

$$\begin{aligned}I(l)&=\sum_{j=1}^{W}F_j{}^*F_j\\&=\sum_{j=1}^{W}\sum_{m=0}^{N-1}f^{(j)*}(m)\exp(-2\pi iml)\sum_{n=0}^{N-1}f^{(j)}(n)\exp(2\pi inl)\\&=\sum_{m=0}^{N-1}\sum_{n=0}^{N-1}\exp\{2\pi il(n-m)\}\sum_{j=1}^{W}f^{(j)}(m)f^{(j)}(n)\\&=W\cdot\sum_{m=0}^{N-1}\sum_{n=0}^{N-1}\exp\{2\pi il(n-m)\}\cdot\langle f^{(j)}(m)\rangle\cdot\langle f^{(j)}(n)\rangle\\&\quad+W\sum_{m=0}^{N-1}\sum_{n=0}^{N-1}\exp\{2\pi il(n-m)\}\cdot(\langle f^{(j)}(m)\cdot f^{(j)}(n)\rangle-\langle f^{(j)}(m)\rangle\cdot\langle f^{(j)}(n)\rangle)\,,\end{aligned}$$

where $f^{(j)}(n)$ is the anti-phase factor of j-th region and $\langle\ \rangle$ represents the mean value. By putting $s\equiv n-m$, we obtain

$$I(l)=W\cdot\left|\sum_{n=0}^{N-1}\langle f^{(j)}(n)\rangle\exp(2\pi inl)\right|^2+W\cdot\sum_{n=0}^{N-1}(1-\langle f^{(j)}(n)\rangle^2)$$

---

[*] In most ordered alloys with anti-phase domains, such as CuAu, Cu_3Pd, Ag_3Mg, etc., the crystal lattice distorts more or less as the anti-phase domain structure is completed, e.g., the maximum tetragonality, c/a, amounts to 1.006 in Ag_3Mg. The crystal, therefore, is not single even in a true sense.

$$+2W\sum_{s=1}^{N-1}\cos 2\pi sl\cdot\sum_{n=0}^{N-1-s}(\langle f^{(j)}(n)\cdot f^{(j)}(n+s)\rangle-\langle f^{(j)}(n)\rangle\langle f^{(j)}(n+s)\rangle)\,. \tag{12}$$

To calculate $I(l)$ further, the following assumptions are made:

1. Anti-phase function of $f^{(j)}(n)$, $\psi_M^{(j)}(\xi)$, is of the form

$$\psi_M^{(j)}(\xi)=\begin{cases}+1 & \text{for}\quad (2k+\delta_{2k}^{(j)})M\le\xi<(2k+1+\delta_{2k+1}^{(j)})M\\ -1 & \text{for}\quad (2k+1+\delta_{2k+1}^{(j)})M\le\xi<(2k+2+\delta_{2k+2}^{(j)})M\end{cases}\qquad (k=0,\,1,\,2,\,\cdots)\,. \tag{13}$$

as shown in Fig. 3-(c).

2. In each $\psi_M^{(j)}(\xi)$, $\delta_m^{(j)}$ is independent of all other $\delta_n^{(j)}$'s $(n\neq m)$.
3. Each set of $\delta_m^{(j)}$'s with the same m and different j has a normal distribution, $N(0,\sigma^2)$†, as its 'population distribution.' Therefore, a standard distribution, σ, represents the degree of disturbance in a regular arrangement.

Thus the following expression is obtained as a final result:

$$\begin{aligned}I(l)=W\cdot\frac{4}{M^2}\Bigg|\sum_{m=0}^{\infty}&\left\{\int_0^{M/2}\operatorname{erf}\,(\eta/\sqrt{2}\,\sigma M)\cdot\sin\frac{(2m+1)\pi\eta}{M}\,d\eta\right\}\\&\times\left[\exp\left\{i\pi\left(l+\frac{2m+1}{2M}\right)(N-1)\right\}\cdot\frac{\sin N\pi(l+(2m+1)/2M)}{\sin\pi(l+(2m+1)/2M)}\right.\\&\left.-\exp\left\{i\pi\left(l-\frac{2m+1}{2M}\right)(N-1)\right\}\frac{\sin N\pi(l-(2m+1)/2M)}{\sin\pi(l-(2m+1)/2M)}\right]\Bigg|^2\\&+W\cdot K_0+2W\sum_{s=1}^{[M]}K_s\cos 2\pi sl\,,\end{aligned} \tag{14}$$

where $[M]$ is the maximum integer smaller than M, and

$$K_0=\sum_{n=0}^{N-1}(1-\langle f^{(j)}(n)\rangle^2)$$

$$K_s=\sum_{n=0}^{N-1-s}(\langle f^{(j)}(n)\cdot f^{(j)}(n+s)\rangle-\langle f^{(j)}(n)\rangle\cdot\langle f^{(j)}(n+s)\rangle)\,.$$

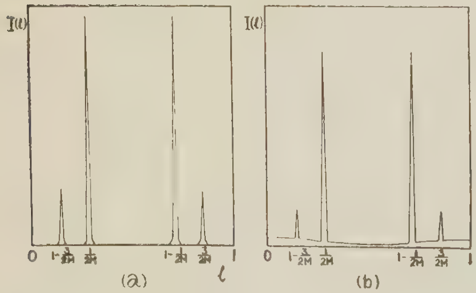


Fig. 7. Intensity distribution along the l-direction in reciprocal space. $(M<2)$
(a) regular arrangement
(b) statistical arrangement

These are constants independent of l. The first term of (14) gives sharp peaks only for $l=n\pm(2m+1)/2M$, but their heights decrease as σ grows larger, or as the arrangement in each region becomes more irregular. The second and third terms of (14) do not make any peaks. So far as σ is small, these terms are much smaller than the first. Even if they give very weak streaks in diffraction patterns, we can hardly observe them. Schematic diagrams of (11) and (14) are illustrated in Fig. 7. As σ grows larger, the said terms increase more and more, and, finally, they will become comparable with the first term of (14). Such irregular, not uniform arrangements corresponding to large σ, however, seem not to have been observed.

§ 4. Discussion

From the above calculations two acceptable types of arrangement of anti-phase domains can be concluded. They are

1. regular arrangements with uniform mixing

and

2. incomplete, or disturbed, regular arrangements with uniform mixing.

It should be noticed that the essential condition consists not in regularity but in uniformity. The reason why uniformity is re-

---

† The normal distribution $N(0,\sigma^2)$ is defined by the following probability density function:

$$g(\delta)=\exp(-\delta^2/2\sigma^2)/\sqrt{2\pi}\cdot\sigma\,.$$

quired in actual arrangements of anti-phase domains is not clear at the present stage. There seems to be not any conclusive answer to the question whether a complete regularity exists or not in atomic arrangements of real alloys. For, an exceedingly exact observation of diffraction intensity will be required to examine the problem and it is very difficult according to the present experimental technique.

Study of Simultaneous Reflexion in Electron Diffraction by Crystals

I. Theoretical Treatment*

By Kyozaburo KAMBE**

Tokyo Institute of Technology, Oh-Okayama, Meguro-ku, Tokyo

(Received September 22, 1956)

The simultaneous reflexion by two lattice planes (with indices h and h') in electron diffraction has been treated by the dynamical theory in order to investigate how it is influenced by the phases of structure amplitudes. For convenience of treatment, a modified formulation of the theory has been developed using particular cross sections of the dispersion surface in reciprocal space. Applying the theory to a lamellar crystal, it was proved that the intensities of transmitted and diffracted waves depend in a relatively simple way on the value of $|\Phi_{hh'}|=|\varphi_h-\varphi_{h'}+\varphi_{h'-h}|$, where φ_h, $\varphi_{h'}$, and $\varphi_{h'-h}$ are the phase angles of structure amplitudes for the indices h, h', and $h'-h$. It was shown that the phase effect can be most easily demonstrated by observing fine structures of reflexion spectra which are obtained by rotating the crystal in a specified manner. The determination of the value of $|\Phi_{hh'}|$ is most simple when the coupling reflexion $h'-h$ is strong compared with the reflexions h and h', and the crystal is centrosymmetric.

§ 1. Introduction

The simultaneous reflexion of X-ray, electron, or neutron waves by a crystal takes place when the orientation of the crystal relative to the direction of incident beam satisfies Bragg conditions for two or more lattice planes at the same time. The simultaneous reflexion is usually accompanied by intensity anomalies, such as the phenomenon of *Aufhellung*,2) *Umweganregung* (Renninger effect),3) and peculiar structures of Kossel lines or Kikuchi lines at their cross points.4)5)6)7) Some anomalous effects due to simultaneous reflexion have been also found in reflexion patterns7)8)9) and convergent-beam patterns10)11)12) in electron diffraction.

---

* Cf. previous short notes of this paper.1)

** Now at Electrotechnical Laboratory, Nagata-cho, Chiyoda-ku, Tokyo.

In the present paper we treat the simultaneous reflexion by the dynamical theory to study how the intensity anomaly is related to the phases of structure amplitudes. The existence of this relation was previously pointed out by Lipscomb[13)] by the consideration as follows.

When two reflexions with indices $h(h_1h_2h_3)$ and $h'(h_1'h_2'h_3')$ occur simultaneously, the wave-number vectors of the primary and the two reflected waves, denoted by $\boldsymbol{k}_0$, $\boldsymbol{k}_h$, and $\boldsymbol{k}_h'$ respectively, satisfy the conditions

$$\boldsymbol{k}_h=\boldsymbol{k}_0+\boldsymbol{b}_h\,,\qquad \boldsymbol{k}_{h'}=\boldsymbol{k}_0+\boldsymbol{b}_{h'}\,,$$

where $\boldsymbol{b}_h$ and $\boldsymbol{b}_{h'}$ are the reciprocal lattice vectors. We have immediately a relation

$$\boldsymbol{k}_{h'}=\boldsymbol{k}_h-\boldsymbol{b}_h+\boldsymbol{b}_{h'}=\boldsymbol{k}_h+\boldsymbol{b}_{h'-h}\,,$$

which shows that the two reflected waves mutually satisfy the Bragg condition for the lattice plane $h-h'$.

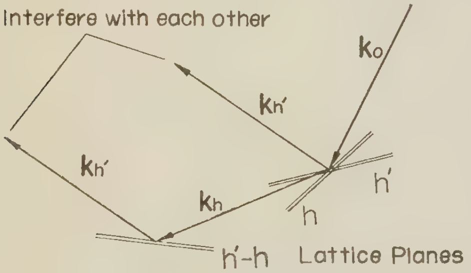

Fig. 1. Interference between singly and doubly reflected waves.

Thus the reflected wave having the wave-number vector $\boldsymbol{k}_{h'}$ is obtained not only through the direct reflexion of the primary wave by the lattice plane h', but also through the successive reflexions first by the lattice plane h and then by the lattice plane $h'-h$ (Fig. 1). As is well known, the wave reflected by a lattice plane is accompanied by a phase depending on the phase of the associated structure amplitude. Accordingly, the component obtained through the direct reflexion has a phase determined by $\varphi_{h'}$, and the component obtained through the successive reflexions has a phase determined by φ_h and $\varphi_{h'-h}$, where φ_h, $\varphi_{h'}$, $\varphi_{h'-h}$ are the phase angles of the structure amplitudes with indices h, h', $h'-h$ respectively. As the result of superposition of the above two components, the intensity of the wave with the wave-number vector $\boldsymbol{k}_{h'}$ depends on the phase angles φ_h, $\varphi_{h'}$, and $\varphi_{h'-h}$.

Although the above consideration is not rigorous, the same conclusion is obtained, as shown in this paper, by a more exact treatment on the basis of dynamical theory.

Lipscomb[13)] and others[14)] have tried to detect experimentally the phase effect in X-ray diffraction, but so far the successful results have not been obtained. It is perhaps on account of severe requirements for the parallelity and monochromatism of the incident beam and for the perfectness of crystals.* It is expected however, that the phase effect can be detected more readily in the case of electron diffraction by virtue of stronger coupling between the reflected waves. Actually, Fues[16)] and Hoerni[12)] have shown a few examples of the phase effect in convergent-beam patterns.

In this paper (Part I) we first develope the dynamical theory of electron diffraction in a particular form which is convenient to treat the phase problem. Then, applying the theory to the case of a lamellar crystal, the effect of the phases of structure amplitudes on the intensities of the diffracted waves is discussed. An experimental verification of the theory by means of the convergent-beam electron diffraction using graphite crystal is described in Part II.

§ 2. The Dynamical Theory of the Simultaneous Reflexion by Two Lattice Planes

The Schrödinger equation for an electron in a crystal is given by

$$\Delta\psi+\frac{8\pi^2me}{h^2}(E+V)\psi=0\,. \tag{1}$$

In (1) eE is the total energy, and V is the periodic potential of the crystal which is expressed by

$$V=\sum_h V_h\exp(-2\pi i\boldsymbol{b}_h\boldsymbol{r})\,, \tag{2}$$

$$V_h=V_{-h}{}^*\,, \tag{2a}$$

where the index h represents the triple indices $(h_1h_2h_3)$.

The solution of (1) is given by Bloch function

---

* Recent work of Renninger[15)] which obtained angular aperture of 2″ using triple-crystal method seems to make promising the phase-effect investigations by X-rays.

$$\psi=\sum_h u_h\psi_h\,, \tag{3}$$

where

$$\psi_h=\exp(-2\pi i\boldsymbol{k}_h\boldsymbol{r})\,, \tag{3a}$$

$$\boldsymbol{k}_h=\boldsymbol{k}_0+\boldsymbol{b}_h\,. \tag{3b}$$

ψ_h is a plane wave having unit amplitude.

The simultaneous reflexion by two lattice planes with indices h and h' occurs provided

$$|\boldsymbol{k}_0|\approx|\boldsymbol{k}_h|\approx|\boldsymbol{k}_{h'}|\,. \tag{4}$$

Let us assume that only three amplitudes u_0, u_h, $u_{h'}$ are appreciable. Then, (3) is reduced to a combination of three plane waves

$$\psi=u_0\psi_0+u_h\psi_h+u_{h'}\psi_{h'}\,. \tag{5}$$

Substituting (5) into (1), multiplying $\psi_0{}^*$, $\psi_h{}^*$, and $\psi_{h'}{}^*$, and finally integrating over the whole crystal, we get a set of equations

$$\left.\begin{aligned}
&(\kappa^2-|\boldsymbol{k}_0|^2)u_0+\frac{2me}{h^2}V_{-h}u_h+\frac{2me}{h^2}V_{-h'}u_{h'}=0\,,\\
&\frac{2me}{h^2}V_hu_0+(\kappa^2-|\boldsymbol{k}_h|^2)u_h+\frac{2me}{h^2}V_{h-h'}u_{h'}=0\,,\\
&\frac{2me}{h^2}V_{h'}u_0+\frac{2me}{h^2}V_{h'-h}u_h+(\kappa^2-|\boldsymbol{k}_{h'}|^2)u_{h'}=0\,,
\end{aligned}\right\} \tag{6}$$

where

$$\kappa^2=\frac{2me}{h^2}(E+V_0)\,. \tag{6a}$$

Let us define the quantities x_0, x_h and $x_{h'}$ by

$$x_0=\kappa-|\boldsymbol{k}_0|\,,\quad x_h=\kappa-|\boldsymbol{k}_h|\,,\quad x_{h'}=\kappa-|\boldsymbol{k}_{h'}|\,. \tag{7}$$

Then, with the conditions (4) and $V\ll E$, (6) can be rewritten as

$$\left.\begin{aligned}
&x_0u_0+\alpha V_{-h}u_h+\alpha V_{-h'}u_{h'}=0\,,\\
&\alpha V_hu_0+x_hu_h+\alpha V_{h-h'}u_{h'}=0\,,\\
&\alpha V_{h'}u_0+\alpha V_{h'-h}u_h+x_{h'}u_{h'}=0\,,
\end{aligned}\right\} \tag{8}$$

where

$$\alpha=\frac{1}{2\kappa}\,\frac{2me}{h^2}\,. \tag{8a}$$

We get a secular equation

$$\begin{vmatrix} x_0 & \alpha V_{-h} & \alpha V_{-h'}\\ \alpha V_h & x_h & \alpha V_{h-h'}\\ \alpha V_{h'} & \alpha V_{h'-h} & x_{h'}\end{vmatrix}=0\,. \tag{9}$$

(9) determines the dispersion surface[6)12)17)] in reciprocal space. In Fig. 2, O is the origin of reciprocal space, and H and H' are the reciprocal lattice points corresponding to the indices h and h'. A point P lying on the dispersion surface is the wave point associated with a set of wave-number vectors $\boldsymbol{k}_0=\overrightarrow{PO}$, $\boldsymbol{k}_h=\overrightarrow{PH}$, $\boldsymbol{k}_{h'}=\overrightarrow{PH'}$. The values of x_0, x_h, $x_{h'}$ obtained from these vectors using (7) satisfy (9). By their definition, x_0, x_h, $x_{h'}$ are the distances from P to the spheres Σ_0, Σ_h, $\Sigma_{h'}$ of radius κ having the centers at O, H, H' respectively. As $\alpha V_h\ll\kappa$ (from $V\ll E$ in (1)), the dispersion surface deviates appreciably from the spheres only near the intersections of the spheres.

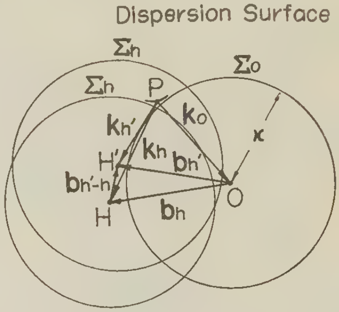

Fig. 2. Geometrical construction of wave vectors in reciprocal space.

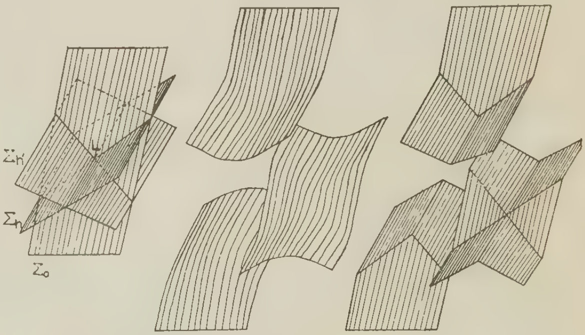

(a) (b) (c)

Fig. 3. (a) Three spheres meeting at the point L.
(b) Three sheets of dispersion surface.
(c) Three component surfaces of (a), roughly approximating the components in (b).

Fig. 3 (a) shows the three spheres meeting at the point L by approximating them by planes. As was studied in detail by Fues,[6)17)] the dispersion surface determined by (9) is made up of three curved sheets as shown in Fig. 3 (b). They approach asymptotically to the three surfaces shown in Fig. 3 (c) which are divided components of the combination of the spheres shown in Fig. 3 (a).

To investigate the shape of the dispersion surface it is useful to examine first a special case where $V_h = V_{h'} = 0$ and $V_{h'-h} \neq 0$. This case is of course trivial because the amplitudes of the reflected waves are zero, but it serves as a convenient basis for later considerations. In this case (8) becomes

$$x_0 u_0 = 0\,, \tag{10a}$$

$$\left.\begin{aligned} x_h u_h + \alpha V_{h-h'} u_{h'} &= 0\,, \\ \alpha V_{h'-h} u_h + x_{h'} u_{h'} &= 0\,, \end{aligned}\right\} \tag{10b}$$

and (9) becomes

$$x_0 = 0\,, \tag{11a}$$

$$\begin{vmatrix} x_h & \alpha V_{h-h'} \\ \alpha V_{h'-h} & x_{h'} \end{vmatrix} = 0\,. \tag{11b}$$

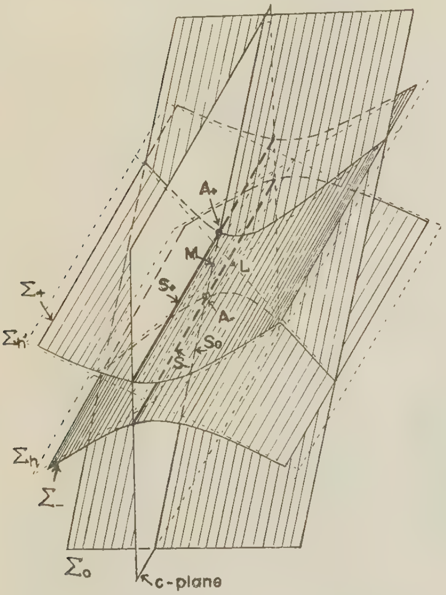

Fig. 4. Surfaces Σ_0, Σ_+, Σ_- and c-plane, with lines of intersection S_0, S_+, and S_-.

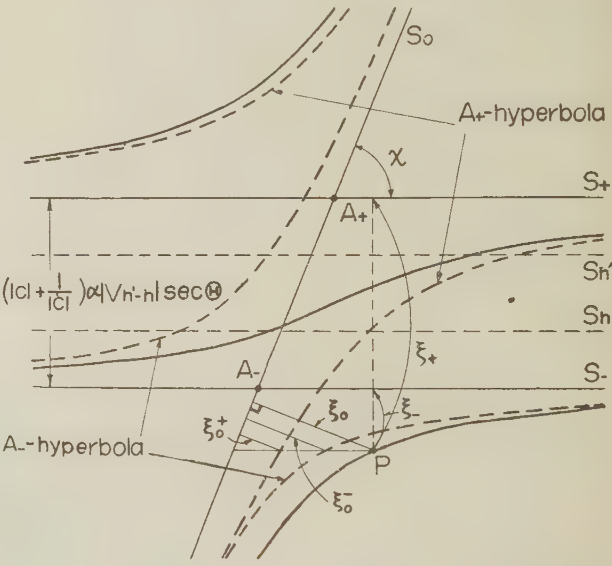

Fig. 5. Dispersion curve, a cross section of dispersion surface, obtained by combining two hyperbolae. ($|c|>1$)

We have a dispersion surface which is made up of Σ_0, in accordance with (11a), and two surfaces Σ_+ and Σ_-, in accordance with (11b) (Fig. 4). The latter two surfaces are cylindrical surfaces having a hyperbolic section; Σ_h and $\Sigma_{h'}$ are their asymptotic surfaces. Σ_+ and Σ_- lie respectively outside and inside of the two spheres Σ_h and $\Sigma_{h'}$, therefore x_h and $x_{h'}$ are negative on Σ_+ and positive on Σ_-. The combination of the surfaces Σ_0, Σ_+, and Σ_- is obviously the limiting form to which the dispersion surface of the general case shown in Fig. 3 (b) approaches when V_h and $V_{h'}$ approach zero from finite values.

Let us next consider the general case where V_h, $V_{h'}$, and $V_{h'-h}$ are all finite. To investigate the shape of the dispersion surface we make use of its cross section by a plane which is perpendicular to the line HH', i.e., parallel to the lattice plane $h'-h$. We call this plane hereafter the 'c-plane' (Fig. 4). Since in what follows we are concerned only with the region of reciprocal space near the intersection of Σ_h and $\Sigma_{h'}$, the c-plane can be expressed by an equation

$$x_{h'} - x_h = \delta\,, \tag{12}$$

where δ is a constant determining the position of the c-plane; for instance, the c-plane for $\delta=0$ contains the intersection of Σ_h and $\Sigma_{h'}$, and bisects the line HH' (Fig. 2).

Fig. 5 shows the cross section of the dispersion surface made by a c-plane. S_0, S_h, and $S_{h'}$ are the cross sections of the spheres Σ_0, Σ_h, and $\Sigma_{h'}$ respectively, and S_+ and S_- are the cross sections of the surfaces Σ_+ and Σ_- respectively. The four lines S_h, $S_{h'}$, S_+, and S_- are parallel to each other. The 'dispersion curve,' or the cross section of the dispersion surface, is composed of three branches corresponding to the three sheets shown in Fig. 3 (b). As shown in Fig. 5 the asymptotes of these curves are not S_0, S_h, and $S_{h'}$, but S_0, S_+, and S_-. This can be proved by putting (12) into (9).

§ 3. A Modified Treatment of the Simultaneous Reflexion

In (9) the dispersion surface is expressed in terms of the variables x_0, x_h, and $x_{h'}$. As mentioned before, these variables are defined with reference to the spheres Σ_0, Σ_h, and $\Sigma_{h'}$. On the other hand, in the end of the preceding section we have seen that the asymptotes for the dispersion curve on a c-plane are S_+ and S_-, instead of S_h and $S_{h'}$. This indicates the fact that Σ_+ and Σ_- are closer asymptotic surfaces of the dispersion surface than Σ_h and $\Sigma_{h'}$. Hence, a more convenient expression of the dispersion surface (or curve) may be obtained when the surface is expressed in terms of some new variables which are defined with reference to the surfaces Σ_0, Σ_+, and Σ_-. We can introduce such variables by the following modified theory.

Let us define the functions ψ_+ and ψ_- as follows:

$$\psi_+=\frac{1}{N}(\psi_h+c\psi_{h'})\,, \quad \psi_-=\frac{1}{N}(c^*\psi_h-\psi_{h'})\,, \tag{13}$$

where ψ_h and $\psi_{h'}$ are given by (3a), c a constant, and N the normalizing factor given by

$$N=\sqrt{1+cc^*}\,. \tag{13a}$$

Then, (5) is rewritten as

$$\psi=u_0\psi_0+u_+\psi_++u_-\psi_-\,, \tag{14}$$

with

$$u_+=\frac{1}{N}(u_h+c^*u_{h'})\,, \qquad u_-=\frac{1}{N}(cu_h-u_{h'})\,. \tag*{(15)*}$$

Since ψ_+ and ψ_- are orthogonal to each other and normalized, we get from (1) and (14), by applying the same procedure as adopted to give (6), the relations

$$\left.\begin{aligned}
&x_0u_0 \qquad\qquad +\frac{\alpha}{N}(V_{-h}+cV_{-h'})u_+ \\
&\qquad\qquad\qquad\qquad\qquad +\frac{\alpha}{N}(c^*V_{-h}-V_{-h'})u_- \;=0\,, \\
&\frac{\alpha}{N}(V_h+c^*V_{h'})u_0+\frac{1}{N^2}[x_h+cc^{**}x_{h'}+\alpha(cV_{h-h'}+c^*V_{h'-h})]u_+ \\
&\qquad\qquad\qquad +\frac{1}{N^2}[c^*(x_h-x_{h'})-\alpha(V_{h-h'}-c^{*2}V_{h'-h})]u_-=0\,, \\
&\frac{\alpha}{N}(cV_h-V_{h'})u_0+\frac{1}{N^2}[c(x_h-x_{h'})+\alpha(c^2V_{h-h'}-V_{h'-h})]u_+ \\
&\qquad\qquad\qquad +\frac{1}{N^2}[cc^*x_h+x_{h'}-\alpha(cV_{h-h'}+c^*V_{h'-h})]u_-=0\,.
\end{aligned}\right\} \tag{16}$$

The secular equation of (16) is equivalent to (9), being nothing but another form of expression for the dispersion surface.

In order to obtain the expression for the dispersion curve on a c-plane, we must take account of the relation (12) between x_h and $x_{h'}$. Let us now rewrite (12) in the form

$$\delta=x_{h'}-x_h=\left(|c|-\frac{1}{|c|}\right)\alpha|V_{h'-h}|\,, \tag{17}$$

defining thus the absolute value of the parameter c which has been an arbitrary number up to here. Let us further assume that c has the same phase angle $\varphi_{h'-h}$ with $V_{h'-h}$,

$$c=|c|\exp i\varphi_{h'-h}\,. \tag{18}$$

Then, by (17) and (18) the third term in the second equation and the second term in the third equation in (16) vanish, and (16) becomes

$$\left.\begin{aligned}
x_0u_0 &+\alpha V_+^*u_+ + \alpha V_-^*u_-=0\,, \\
\alpha V_+u_0 &+ \quad x_+u_+ \qquad\qquad\;\; =0\,, \\
\alpha V_-u_0 & \qquad\qquad\qquad + x_-u_-=0\,,
\end{aligned}\right\} \tag{19}$$

where

$$V_+=\frac{1}{N}(V_h+c^*V_{h'})\,, \quad V_-=\frac{1}{N}(cV_h-V_{h'})\,, \tag{20}$$

and

$$\left.\begin{aligned}
x_+&=x_h+|c|\alpha|V_{h'-h}|=x_{h'}+\frac{1}{|c|}\alpha|V_{h'-h}|\,, \\
x_-&=x_h-\frac{1}{|c|}\alpha|V_{h'-h}|=x_{h'}-|c|\alpha|V_{h'-h}|\,.
\end{aligned}\right\} \tag{21}$$

The secular equation for (19) can thus be written in a quite simple form

---

[*] In a previous note[1] $1/N$ was erroneously replaced by N.

$$x_0=\frac{|\alpha V_+|^2}{x_+}+\frac{|\alpha V_-|^2}{x_-}. \tag{22}$$

Since this equation is derived under the condition (17), it represents the dispersion curve on the c-plane. It should be noted that (22) has only two independent variables, because from (21) x_+ and x_- are related by

$$x_+-x_-=\left(|c|+\frac{1}{|c|}\right)\alpha|V_{h'-h}|. \tag{23}$$

The geometrical meaning of the newly introduced variables x_+ and x_- is illustrated in Fig. 6, which shows the cross section of reciprocal space by a plane containing the three points H, H', and P. The cross sections of the spheres Σ_h and $\Sigma_{h'}$ are approximated by the two straight lines, which make the angle $2\Theta=2\sin^{-1}(|\boldsymbol{b}_{h'-h}|/2\kappa)$. In accordance with (11b), the cross sections of Σ_+ and Σ_- make a hyperbola with the inter-vertex distance between their branches equal to $2\alpha|V_{h'-h}|\sec\Theta$. The vertical line $c-c$ is the cross section of the c-plane. The points S_h, $S_{h'}$, S_+, and S_- are the cross points of the corresponding lines shown in Fig. 5.

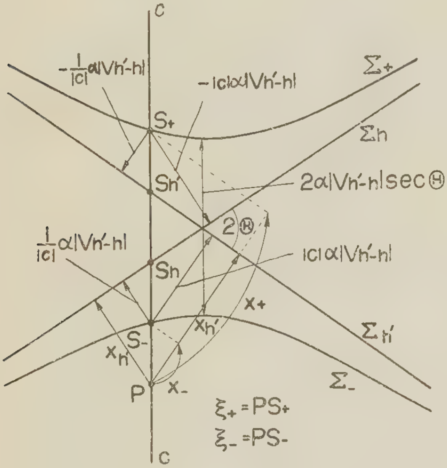

Fig. 6. Cross section by a plane which contains the points H, H', and P, showing the geometrical meaning of x_+ and x_-. ($|c|>1$)

Since the surfaces Σ_+ and Σ_- are derived from (11b), the values of x_h and $x_{h'}$ appropriate for the points S_+ and S_- are obtained from (11b) and (17) as follows:

$$\left.\begin{aligned}
&x_h=-|c|\alpha|V_{h'-h}|, \quad x_{h'}=-\frac{1}{|c|}\alpha|V_{h'-h}| && \text{for } S_+,\\
&x_h=\frac{1}{|c|}\alpha|V_{h'-h}|, \quad x_{h'}=|c|\alpha|V_{h'-h}| && \text{for } S_-.
\end{aligned}\right\} \tag{24}$$

These are the distances from the points S_+ and S_- to Σ_h and $\Sigma_{h'}$. From (21) and (24) we have

$$x_+=\xi_+\cos\Theta, \quad x_-=\xi_-\cos\Theta, \tag{25}$$

where $\xi_+=PS_+$ and $\xi_-=PS_-$ (Fig. 6). Since S_+ and S_- lie on Σ_+ and Σ_- respectively, x_+ and x_- can be regarded as the variables defined with respect to Σ_+ and Σ_-, as expected in the beginning of this section.

When the values of x_+ and x_- for a specified point on the dispersion curve are found, the values of u_+/u_0 and u_-/u_0 are determined from (19) as

$$\frac{u_+}{u_0}=-\frac{\alpha V_+}{x_+}, \quad \frac{u_-}{u_0}=-\frac{\alpha V_-}{x_-}. \tag{26}$$

The values of u_h/u_0 and $u_{h'}/u_0$ are obtained from (15) and (26) as

$$\left.\begin{aligned}
\frac{u_h}{u_0}&=-\frac{1}{N}\left(\frac{\alpha V_+}{x_+}+c^*\frac{\alpha V_-}{x_-}\right),\\
\frac{u_{h'}}{u_0}&=-\frac{1}{N}\left(c\frac{\alpha V_+}{x_+}-\frac{\alpha V_-}{x_-}\right).
\end{aligned}\right\} \tag{27}$$

In passing, it is to be noted here that the functions ψ_+ and ψ_- are intimately related to the surfaces Σ_+ and Σ_- respectively. In the limiting problem treated in § 2, in which it is assumed that $V_h=V_{h'}=0$, and $V_{h'-h}\neq 0$, the dispersion surface is composed of Σ_0, Σ_+, and Σ_-. When the wave point lies on the surface Σ_+ or Σ_- the wave function (the Bloch function) has the form

$$\psi=u_h\psi_h+u_{h'}\psi_{h'}, \tag{28}$$

because we have $u_0=0$ from (10a). The ratio between u_h and $u_{h'}$ in (28) is obtained from (10b) as

$$\frac{u_{h'}}{u_h}=-\frac{x_h}{\alpha V_{h-h'}}=-\frac{\alpha V_{h'-h}}{x_{h'}}. \tag{28a}$$

When the wave point lies particularly on the lines S_+ and S_- the values of x_h and $x_{h'}$ are given by (24). Hence, we have

$$\left.\begin{aligned}
\frac{u_{h'}}{u_h}&=c && \text{for } S_+,\\
&=-\frac{1}{c^*} && \text{for } S_-.
\end{aligned}\right\} \tag{29}$$

We can see from (13), (28), and (29) that ψ_+ and ψ_- are the normalized wave functions associated respectively with the surfaces Σ_+ and Σ_-, or more accurately, with the lines S_+ and S_-. This circumstance is just like ψ_0, ψ_h, and $\psi_{h'}$ are the functions associated with the spheres Σ_0, Σ_h, and $\Sigma_{h'}$ in the case $V_h=V_{h'}=V_{h'-h}=0$.

§ 4. The Form of Dispersion Curve on the *c*-plane

With the aid of the expression (22) we explain briefly the main features of the dispersion curve on the *c*-plane (Fig. 5). The distances ξ_+ and ξ_- from a wave point P on the *c*-plane to the lines S_+ and S_- are given by (25). The distance ξ_0 from P to the line S_0 is given by

$$\xi_0=x_0 \operatorname{cosec} \Phi\,, \tag{30}$$

where Φ is the angle between the sphere Σ_0 and the *c*-plane which is given by

$$\Phi=\cos^{-1}[||\boldsymbol{b}_h|^2-|\boldsymbol{b}_{h'}|^2|/2\kappa|\boldsymbol{b}_{h'-h}|]\,.$$

Thus (22) is written in the form

$$\xi_0=\frac{\beta|\alpha V_+|^2}{\xi_+}+\frac{\beta|\alpha V_-|^2}{\xi_-}\,, \tag{31}$$

where

$$\beta=\sec\Theta \operatorname{cosec}\Phi\,. \tag{31a}^*$$

On the basis of the expression (31) the dispersion curve can be drawn in the following way. Writing (31) in the form

$$\xi_0=\xi_0{}^+ + \xi_0{}^-\,, \tag{32a}$$

$$\xi_0{}^+=\frac{\beta|\alpha V_+|^2}{\xi_+}\,,\quad \xi_0{}^-=\frac{\beta|\alpha V_-|^2}{\xi_-}\,, \tag{32b}$$

we draw first the two hyperbolae defined by (32b), which are called hereafter the A_+ and A_--hyperbola respectively. The asymptotic lines of these hyperbolae are the lines S_0 and S_+, and the lines S_0 and S_-, respectively (Fig. 5). The inter-vertex distances are $2\sqrt{\beta}\,\alpha|V_+|\sec\chi$ and $2\sqrt{\beta}\,\alpha|V_-|\sec\chi$ respectively, where χ is the angle between S_0 and S_+ or S_- (Fig. 5). From (32a) the dispersion curve can be drawn quite easily by graphical procedure as illustrated in Fig. 5.

From this procedure it is clear that the shape of the dispersion curve has more or less the characteristics of the combination of the two hyperbolae. When, especially, $|V_{h'-h}|$ is much larger than $|V_h|$ and $|V_{h'}|$, the distance between S_+ and S_- given by

$$\xi_+-\xi_-=(x_+-x_-)\sec\Theta$$
$$=\left(|c|+\frac{1}{|c|}\right)\alpha|V_{h'-h}|\sec\Theta \tag{33}$$

becomes much larger than the inter-vertex distances of the hyperbolae. In this case, the dispersion curve can be approximated satisfactorily by the combination of the two independent hyperbolae (Fig. 9).

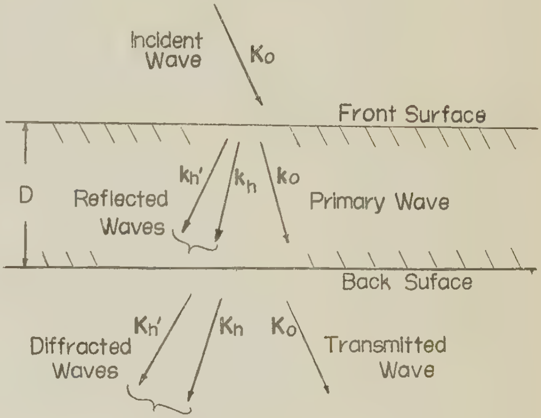

Fig. 7. Arrangement of wave-number vectors in Laue case.

§ 5. Application of the Theory to a Lamellar Crystal

(a) General consideration

In this section we apply the above theory to the electron diffraction by a parallel crystal slab. Fig. 7 shows schematically the waves inside and outside the crystal, representing them by wave-number vectors. The incident wave and the transmitted wave have the same vector $\boldsymbol{K}_0$. We assume that the simultaneously diffracted waves $\boldsymbol{K}_h$ and $\boldsymbol{K}_{h'}$ emerge from the back surface of the crystal, corresponding to the so-called 'Laue case.'

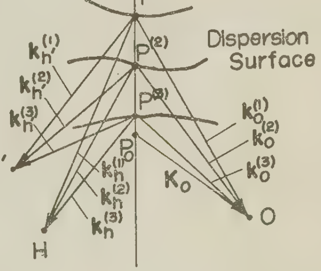

Fig. 8. Three sets of wave-number vectors inside the crystal determined by the boundary condition.

---

* In usual conditions of electron diffraction, $\kappa\approx 20$ Å^{-1}, $|\boldsymbol{b}_h|\approx 1$ Å^{-1}, hence $\sec\Theta\approx 1$, $\operatorname{cosec}\Phi\approx 1$. Thus (31) may be replaced by (22).

The wave number vectors of the waves inside and outside the crystal should satisfy the continuity of tangential components on the crystal surface. In accordance with this requirement, the three wave points $P^{(1)}$, $P^{(2)}$, and $P^{(3)}$ for the waves inside the crystal are obtained as the intersecting points of the dispersion surface with the line (the ν-normal) which is drawn perpendicular to the surface of the crystal through the point P_0 for which $\overrightarrow{P_0O}=\boldsymbol{K}_0$ (Fig. 8). Corresponding to each of the three wave points the wave-number vectors $\boldsymbol{k}_0$, $\boldsymbol{k}_h$, and $\boldsymbol{k}_{h'}$ are determined as

$$\left.\begin{aligned} &\boldsymbol{k}_0^{(i)}=\overrightarrow{P^{(i)}O}\,, \qquad \boldsymbol{k}_h^{(i)}=\overrightarrow{P^{(i)}H}\,, \\ &\boldsymbol{k}_{h'}^{(i)}=\overrightarrow{P^{(i)}H'} \qquad (i=1,2,3)\,. \end{aligned}\right\} \tag{34}$$

The wave function ψ in the crystal is given by a superposition of three Bloch functions relating to these wave points,

$$\psi=\psi^{(1)}+\psi^{(2)}+\psi^{(3)}\,, \tag{35}$$

where $\psi^{(i)}(i=1, 2, 3)$, the Bloch function corresponding to the i-th wave point, is given by

$$\begin{aligned} \psi^{(i)}&=u_0^{(i)}\psi_0^{(i)}+u_h^{(i)}\psi_h^{(i)}+u_{h'}^{(i)}\psi_{h'}^{(i)} \\ &=u_0^{(i)}\exp(-2\pi i\boldsymbol{k}_0^{(i)}\boldsymbol{r}) \\ &\quad+u_h^{(i)}\exp(-2\pi i\boldsymbol{k}_h^{(i)}\boldsymbol{r}) \\ &\quad+u_{h'}^{(i)}\exp(-2\pi i\boldsymbol{k}_{h'}^{(i)}\boldsymbol{r})\,. \\ &(i=1, 2, 3) \end{aligned} \tag{36}$$

Since the ratios $u_0^{(i)}$: $u_h^{(i)}$: $u_{h'}^{(i)}$ $(i=1, 2, 3)$ are determined by (8) or (27), ψ is obtained when the values of $u_0^{(1)}$, $u_0^{(2)}$, $u_0^{(3)}$ are determined by the boundary condition, or the conditions requiring the continuity of ψ and of its normal derivative on the crystal surfaces. Under the condition $V\ll E$, however, the continuity of normal derivative can be discarded because it is equivalent to the continuity of ψ, provided the wave-number vectors shown in Fig. 7 do not make too small angles with the crystal surfaces.

When the origin of coordinates is taken on the front surface and the amplitude of the incident wave is taken to be unity, the boundary condition on the front surface is given by

$$1=u_0^{(1)}+u_0^{(2)}+u_0^{(3)} \tag{37a}$$

$$\left.\begin{aligned} 0&=u_h^{(1)}+u_h^{(2)}+u_h^{(3)}\,, \\ 0&=u_{h'}^{(1)}+u_{h'}^{(2)}+u_{h'}^{(3)}\,, \end{aligned}\right\} \tag{37b}$$

and on the back surface by

$$\left.\begin{aligned} U_0\exp(-2\pi i\Gamma_0 D)&=u_0^{(1)}\exp(-2\pi i\gamma_0^{(1)}D)+u_0^{(2)}\exp(-2\pi i\gamma_0^{(2)}D)+u_0^{(3)}\exp(-2\pi i\gamma_0^{(3)}D)\,, \\ U_h\exp(-2\pi i\Gamma_h D)&=u_h^{(1)}\exp(-2\pi i\gamma_h^{(1)}D)+u_h^{(2)}\exp(-2\pi i\gamma_h^{(2)}D)+u_h^{(3)}\exp(-2\pi i\gamma_h^{(3)}D)\,, \\ U_{h'}\exp(-2\pi i\Gamma'_{h'} D)&=u_{h'}^{(1)}\exp(-2\pi i\gamma_{h'}^{(1)}D)+u_{h'}^{(2)}\exp(-2\pi i\gamma_{h'}^{(2)}D)+u_{h'}^{(3)}\exp(-2\pi i\gamma_{h'}^{(3)}D)\,, \end{aligned}\right\} \tag{38}$$

where D is the thickness of the crystal, and U_0, U_h, $U_{h'}$ are the amplitudes of the waves leaving the crystal with the wave-number vectors $\boldsymbol{K}_0$, $\boldsymbol{K}_h$, $\boldsymbol{K}_{h'}$ respectively. Γ'_0, $\gamma_0^{(1)}$ etc. are the normal components of $\boldsymbol{K}_0$, $\boldsymbol{k}_0^{(1)}$ etc..

Using (27) the ratios $u_0^{(1)}$: $u_0^{(2)}$: $u_0^{(3)}$ are determined from (37b) as

$$\begin{aligned} u_0^{(1)}:u_0^{(2)}:u_0^{(3)}&=\frac{1}{x_+^{(2)}x_-^{(3)}}-\frac{1}{x_+^{(3)}x_-^{(2)}}:\frac{1}{x_+^{(3)}x_-^{(1)}}-\frac{1}{x_+^{(1)}x_-^{(3)}}:\frac{1}{x_+^{(1)}x_-^{(2)}}-\frac{1}{x_+^{(2)}x_-^{(1)}} \\ &=\frac{1}{\xi_+^{(2)}\xi_-^{(3)}}-\frac{1}{\xi_+^{(3)}\xi_-^{(2)}}:\frac{1}{\xi_+^{(3)}\xi_-^{(1)}}-\frac{1}{\xi_+^{(1)}\xi_-^{(3)}}:\frac{1}{\xi_+^{(1)}\xi_-^{(2)}}-\frac{1}{\xi_+^{(2)}\xi_-^{(1)}}\,. \end{aligned} \tag{39}$$

The values of $u_0^{(1)}$, $u_0^{(2)}$, $u_0^{(3)}$ are determined by (37a) and (39). Finally, the intensities of the transmitted and diffracted waves are obtained from (38) as

$$|U_g|^2=\sum_{i=1,2,3}|u_g^{(i)}|^2+2\sum_{i\neq j}|u_g^{(i)}||u_g^{(j)}|\cos\{2\pi(\gamma_g^{(i)}-\gamma_g^{(j)})D-(\theta_g^{(i)}-\theta_g^{(j)})\}\,, \tag{40}$$

$$(g=0, h, h')$$

where $\theta_g^{(i)}$ is the phase angle of $u_g^{(i)}$, that is,

$$u_g^{(i)}=|u_g^{(i)}|\exp i\theta_g^{(i)}\,. \tag{40a}$$

(b) The case where $|V_{h'-h}|\gg|V_h|, |V_{h'}|$, and the lattice plane $h'-h$ is perpendicular to the crystal surface

We investigate first the case where $|V_{h'-h}|$ is much larger than $|V_h|$ and $|V_{h'}|$. The dispersion curve coincides in this case almost exactly with the two hyperbolae (Fig. 9). We assume further that the lattice plane $h'-h$ is perpdicular to the crystal surface. Then, since the c-plane is parallel to the lattice plane $h'-h$, the ν-normal and accordingly the three wave points on it are contained in a c-plane.

When the ν-normal passes through the central region of the A_+-hyperbola, as shown in Fig. 9, the values of $\xi_+^{(1)}$, $\xi_+^{(2)}$, and $\xi_-^{(3)}$ (for the wave points $P^{(1)}$, $P^{(2)}$, and $P^{(3)}$, respectively) are small compared with $\xi_-^{(1)}$, $\xi_-^{(2)}$, and $\xi_+^{(3)}$, so that $u_0^{(3)}$ in (39) may be negligible compared with $u_0^{(1)}$ and $u_0^{(2)}$. From (26) and (27) it can be shown that $u_+^{(3)}$, $u_-^{(3)}$, $u_h^{(3)}$, and $u_{h'}^{(3)}$ are also negligible. This means that the wave point $P^{(3)}$ can be entirely neglected.* In this case we say after Hoerni⁽²⁾ that only the two branches belonging to the A_+-hyperbola are the 'effective' branches.

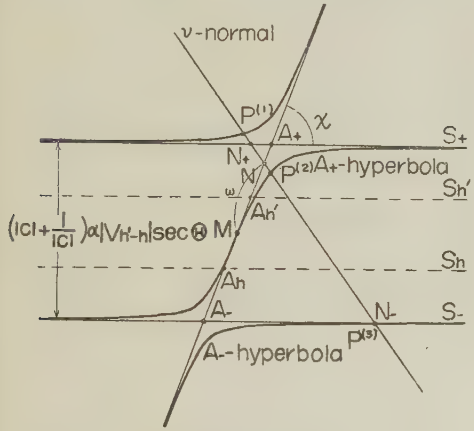

Fig. 9. Dispersion curve in the case $|V_{h'-h}| \gg |V_h|, |V_{h'}|$.

The fact that the dispersion curve can be approximated by the A_+-hyperbola implies that $\xi_+^{(1)}$ and $\xi_+^{(2)}$ are so small compared with $\xi_-^{(1)}$ and $\xi_-^{(2)}$ that the second term of (31) can be neglected. For the same reason we can neglect $u_-^{(1)}$ and $u_-^{(2)}$ considering (25) and (26). As the result, only the four amplitudes $u_0^{(1)}$, $u_0^{(2)}$, $u_+^{(1)}$, and $u_+^{(2)}$ are regarded as appreciable, and the wave function in the crystal is given by

$$\psi = \psi^{(1)} + \psi^{(2)}, \tag{41}$$

where

$$\psi^{(i)} = u_0^{(i)}\psi_0^{(i)} + u_+^{(i)}\psi_+^{(i)}. \quad (i=1,2) \tag{42}$$

The amplitudes $u_0^{(i)}$ and $u_+^{(i)}$ $(i=1,2)$ satisfy the relation

$$\left.\begin{aligned} x_0^{(i)}u_0^{(i)} + \alpha V_+^* u_+^{(i)} &= 0, \\ \alpha V_+ u_0^{(i)} + x_+^{(i)}u_+^{(i)} &= 0, \end{aligned}\right\} \tag{43}$$

which is the reduced form of (19). From (43) we have

$$x_0^{(i)} = \frac{|\alpha V_+|^2}{x_+^{(i)}}, \tag{44}$$

and

$$\frac{u_+^{(i)}}{u_0^{(i)}} = -\frac{\alpha V_+}{x_+^{(i)}} = -\frac{x_0^{(i)}}{\alpha V_+^*}. \tag{45}$$

The equations from (41) to (45) are analogous to the relations found in the ordinary problem of single reflexion with the Fourier amplitude V_+, although the excited wave ψ_+ in the present case is not a single plane wave, but a superposition of two plane waves ψ_h and $\psi_{h'}$ in the ratio $u_{h'}/u_h = c$ (Cf. (13) or (29)).

When the ν-normal passes through the central region of the A_--hyperbola, their two branches are the effective ones, and the same relations (41) to (45) hold when we replace the symbol $+$ by $-$, and the superfices $i=1, 2$ by $i=2, 3$. The excited wave ψ_- is a superposition of ψ_h and $\psi_{h'}$ in the ratio $u_{h'}/u_h = -1/c^*$ from (13) or (29).

The position of the ν-normal in a c-plane is conveniently represented by the distance $\omega = NM$ as shown in Fig. 9, where N is the intersecting point of the ν-normal with S_0, and M is the middle point of A_+A_-; A_+ and A_- are the intersecting points of S_0 with S_+ and S_- respectively. We take as the positive direction of ω the direction pointing from M to A_-. In the example of Fig. 9 ω is negative.

The amplitudes of the waves as functions of ω can be calculated using the equations (41) to (45) in an analogous way to the problem of single reflexion.¹²⁾,¹⁸⁾,¹⁹⁾ Using (27) and (40) the intensities of the waves leaving the crystal can be obtained as:

(i) In the region of ω near $\omega_+ \equiv A_+M$ (the central region of the A_+-hyperbola),

$$\left.\begin{aligned} &|U_0|^2 = 1-(|U_h|^2+|U_{h'}|^2) = 1-|U_+|^2, \\ &|U_h|^2 = \frac{1}{N^2}|U_+|^2, \qquad |U_{h'}|^2 = \frac{|c|^2}{N^2}|U_+|^2; \end{aligned}\right\} \tag{46}$$

(ii) In the region of ω near $\omega_- \equiv A_-M$ (the central region of the A_--hyperbola),

$$\left.\begin{aligned} &|U_0|^2 = 1-|U_-|^2, \\ &|U_h|^2 = \frac{|c|^2}{N^2}|U_-|^2, \qquad |U_{h'}|^2 = \frac{1}{N^2}|U_-|^2, \end{aligned}\right\} \tag{47}$$

---

* The possibility of similar cases has been discussed by Niehrs (H. Niehrs: Zeit. f. Phys. 139 (1954) 88).

where

$$|U_\pm|^2 = \frac{1}{1+W_\pm{}^2}\sin^2\left[2\pi D\alpha|V_\pm|\sqrt{1+W_\pm{}^2}/\cos\theta\right], \tag{48}$$

$$W_\pm = \frac{b(\omega-\omega_\pm)}{\alpha|V_\pm|}. \tag{48a}$$

θ is the angle between $\boldsymbol{K}_0$ and the ν-normal, which is nearly constant in the range of ω concerned. b is defined by $b=NN_\pm/NA_\pm$ (Cf. Fig. 9),* being a geometrical parameter determined by the direction of the ν-normal and the angle χ between the lines S_0 and S_+ (or S_-). $W_\pm$ corresponds to the parameter W used by Bethe.[20] (Cf. Thomson-Cochrane,[18] p. 292).

Fig. 10 shows schematically the intensities of the transmitted wave and the two diffracted waves as functions of ω, where the values in the range of ω near ω_+ is obtained from (46) and those near ω_- from (47). Rapid oscillations due to the so-called 'Pendellösung' are smoothed out; that is, we consider here only the factor $1/(1+W_\pm{}^2)$ in (48), neglecting the squared sine factor. The values in the middle range is obtained by interpolation taking account of the fact that we have obviously $|U_0|^2=1$, $|U_h|^2=0$, $|U_{h'}|^2=0$ except in the narrow ranges near $\omega=\omega_+$ and $\omega=\omega_-$.

The intensity variations as shown in Fig. 10 may be followed experimentally if the direction of the incident wave is changed keeping the ν-normal in the c-plane concerned. This corresponds to the movement of $\boldsymbol{K}_0$ keeping the angle between $\boldsymbol{K}_0$ and the lattice plane $h'-h$ constant.

In Fig. 10 we note that the intensities $|U_h|^2$ and $|U_{h'}|^2$ have double peaks, each made up of A_+ and A_--peaks located at ω_+ and ω_- respectively. From (46) and (47) we can consider that the intensities $|U_h|^2$ and $|U_{h'}|^2$ are divided components of $|U_+|^2$ or $|U_-|^2$ in the ratios $1:|c|^2$ or $|c|^2:1$, respectively. The distance between the A_+-peak and the A_--peak is given by $\left(|c|+\frac{1}{|c|}\right)\alpha|V_{h'-h}|\sec\Theta\sec\chi$, and is minimum for $|c|=1$.

If the reflexion takes place solely by the lattice plane h, $|U_h|^2$ would have only a single peak at the position $\omega=\omega_h\equiv A_hM$ as indicated by a broken line in Fig. 10 (Cf. Fig. 9). Similarly, the single reflexion h' would give a single peak of $|U_{h'}|^2$ at $\omega=\omega_{h'}\equiv A_{h'}M$.

It is to be noted in Fig. 10 that ω_+ is always negative, and ω_- is always positive for any value of $|c|$ (Cf. Fig. 4). It means that both the angles between $\boldsymbol{K}_0$ and the lattice planes h and h' are always smaller for A_+-peak than for A_--peak. In other words, the angle between $\boldsymbol{K}_h$ and the lattice plane h and also the angle between $\boldsymbol{K}_{h'}$ and the lattice plane h' are both always larger for A_+-peak than for A_--peak. This is an important criterion to distinguish A_+ and A_--peaks from each other in experiment.

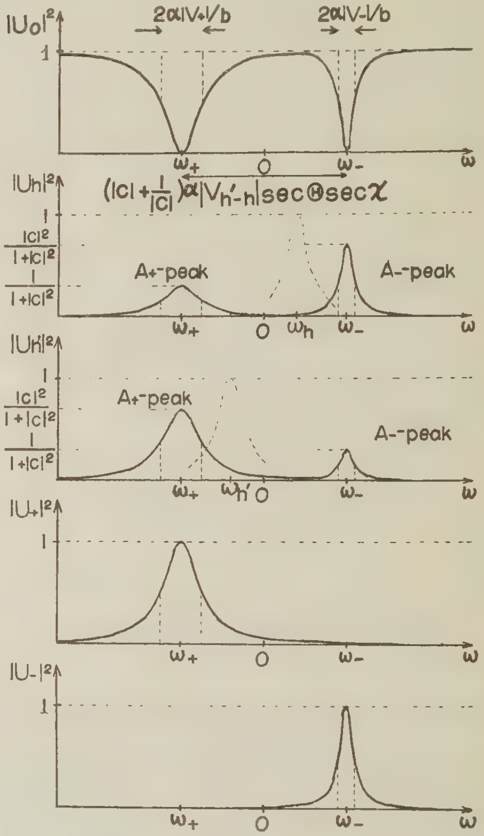

Fig. 10. Intensity curves of transmitted and diffracted waves shown with the curves of $|U_+|^2$ and $|U_-|^2$. Peaks shown by broken lines indicate diffracted intensities in the case of single reflexion.

(c) General Cases

When $|V_{h'-h}|$ is not particularly large compared with $|V_h|$ and $|V_{h'}|$, the treatment becomes more complicated, not only because the dispersion curve cannot well be approximated by the combination of the A_+ and A_--hyperbolae, but also because all three branches become effective so that the primary and reflected waves should be treated as superpositions of three waves. We do not discuss this case in further detail. It may be worth noting, however, that use of the cross sections by c-planes and of the functions ψ_+ and ψ_- is highly profitable also in this case. For instance, simple form of (31) enables us to work out a graphical solution in obtaining the wave points instead of carrying out troublesome numerical solution of third-order argebraic equations.

---

* In Fig. 9, N_- incidentally coincides with $P^{(3)}$.

When the lattice plane with the index $h'-h$ is not perpendicular to the crystal surface, the ν-normal does not lie in the c-plane. Therefore, the procedure to obtain wave points is not so simple as that described above. However, the difficulty is not so serious when the smallness of the curvature of the dispersion surface is taken into account. Let us consider the projection of the ν-normal onto the c-plane passing through the cross point of the ν-normal with the sphere Σ_0. Then, when the curvature of the dispersion surface in the direction perpendicular to the c-plane is neglected, the three cross points of the projection of the ν-normal with the dispersion curve coincide with the projections of the wave points lying on the ν-normal.* From the wave points obtained in this way, the intensities as functions of ω can be calculated by the similar procedure as before.

§ 6. Effect of the Phases of Structure Amplitudes

On the basis of the above results we investigate how the intensities of the transmitted and diffracted waves are related to the phases of structure amplitudes in Laue case.

Let us study first the relation between the quantities contained in the expression (40) and the phase angles $\varphi_g (g=h,\ h',\ h'-h)$ of the structure amplitudes. Since $\gamma_g^{(i)}$ is determined by the position of the wave point $P^{(i)}$, it depends on $|V_+|$ and $|V_-|$ through (31).

By (20) and (18) $|V_+|$ and $|V_-|$ are written as

$$\left.\begin{aligned} |V_+| &= \frac{1}{N}(|V_h|^2+|c|^2|V_{h'}|^2 \\ &\qquad +2|c||V_h||V_{h'}|\cos\Phi_{hh'})^{1/2}, \\ |V_-| &= \frac{1}{N}(|c|^2|V_h|^2+|V_{h'}|^2 \\ &\qquad -2|c||V_h||V_{h'}|\cos\Phi_{hh'})^{1/2}, \end{aligned}\right\} \tag{49}$$

where

$$\Phi_{hh'}=\varphi_h-\varphi_{h'}+\varphi_{h'-h}\,. \tag{49a}$$

It can be proved easily that $\Phi_{hh'}$ is an invariant quantity, while φ_h, $\varphi_{h'}$, and $\varphi_{h'-h}$ vary when the origin of coordinates in crystal is displaced. We see that $|V_+|$ and $|V_-|$, and hence, $\gamma_g^{(i)}$ in (40) depend on the phases of the structure amplitudes only through the absolute value $|\Phi_{hh'}|$. Similarly, we can prove from (39) and (37a) that $u_0^{(i)}$ $(i=1, 2, 3)$ depends on the absolute value $|\Phi_{hh'}|$. Since $x_+^{(i)}$ and $x_-^{(i)}$ are all real in Laue case, $u_0^{(i)}$ is real, thus $\theta_0^{(i)}$ is equal to 0 or π. Concerning the amplitudes $u_h^{(i)}$ and $u_{h'}^{(i)}$, we can prove similarly from (18), (20) and (27) that $|u_h^{(i)}|$ and $|u_{h'}^{(i)}|$ depend on $|\Phi_{hh'}|$ while $\theta_h^{(i)}$ and $\theta_{h'}^{(i)}$ depend on $\Phi_{hh'}$. Thus, it is concluded that the intensities given by (40) depend on the phases of structure amplitudes through the value of $\Phi_{hh'}$.

The result of the theory developed in the preceding sections indicates that the value of $\Phi_{hh'}$ can be determined by experiments most conveniently by observing the intensity curves as studied in § 5. These curves are obtained by varying the direction of $\boldsymbol{K}_0$ keeping the angle between $\boldsymbol{K}_0$ and the lattice plane $h'-h$ constant. Though the intensities depend on the value of $\Phi_{hh'}$ as mentioned above, it may be difficult to determine the sign of $\Phi_{hh'}$ from these curves,* because it requires detailed observation of rapid intensity oscillation due to the second term of (40). On the other hand, the absolute value $|\Phi_{hh'}|$ can be relatively easily determined from the smoothed-out-curves as those shown in Fig. 10.

It is instructive to consider again the case where $|V_{h'-h}|$ is very large compared with $|V_h|$ and $|V_{h'}|$. We see in the equations from (46) to (48a) that the intensities of waves depend only on $|V_+|$ and $|V_-|$. If the intensity curves as shown in Fig. 10 are obtained experimentally, the values of $|V_+|$ and $|V_-|$ can be found from the half-value widths of the A_+ and A_--peaks, or, when the value of $|c|$ is known, from the integrated intensities. The half-value widths $\varDelta\omega_\pm$ determined from (48a) by the condition $W_\pm{}^2=1$ are given by

---

* This approximation is generally quite satisfactory. An essentially similar approximation is included in the analytical procedure to obtain (48) in the single-reflexion problem.

* When the polarity of a non-centrosymmetric crystal is reversed, the sign of $\Phi_{hh'}$ is changed, thus, the intensities may change. This means that Friedel's law fails.[21]

$$\varDelta\omega_\pm=\frac{2}{b}\alpha|V_\pm|\,. \tag{50}$$

The integrated intensities $I_\pm$ are given by

$$\begin{aligned} I_\pm &= I_\pm{}^m\int_{-\infty}^{\infty}\frac{1}{1+W_\pm{}^2}d\omega \\ &= I_\pm{}^m\int_{-\infty}^{\infty}\frac{1}{1+W_\pm{}^2}\frac{\alpha|V_\pm|}{b}dW \\ &= I_\pm{}^m\frac{\pi\alpha|V_\pm|}{b}\,, \end{aligned} \tag{51}$$

where $I_\pm{}^m$ is the peak intensities depending on the value of $|c|$. These characteristic values are both proportional to $|V_+|$ and $|V_-|$.

When the crystal has a centre of symmetry, $\varPhi_{hh'}$ is either equal to 0 or π, accordingly $\cos\varPhi_{hh'}$ is either equal to 1 or -1. The two possibilities can be discriminated simply by comparing the widths of the A_+ and A_--peaks. Let us assume for simplicity that $|c|=1$, then

(i) if the A_+-peak is wider than the A_--peak, we have $|V_+|>|V_-|$, namely $\cos\varPhi_{hh'}=1$ from (49);

(ii) if the A_+-peak is narrower than the A_--peak, we have $|V_+|<|V_-|$, namely $\cos\varPhi_{hh'}=-1$.

When the origin of coordinates is chosen at the symmetry center, all structure amplitudes become real, being positive or negative. If $V_{h'-h}$ is positive, V_+ and V_- for the case $|c|=1$ becomes respectively equal to the sum and difference of V_h and $V_{h'}$. Hence, the case (i) tells us that V_h and $V_{h'}$ have the same sign, and the case (ii) tells V_h and $V_{h'}$ have opposite signs. This relation is reversed when $V_{h'-h}$ is negative.

Also in the case of non-centrosymmetric crystals we can find by a simple comparison of the peak widths the sign of $\cos\varPhi_{hh'}$, that is, we can find whether $|\varPhi_{hh'}|$ is larger or smaller than $\pi/2$.* The value of $|\varPhi_{hh'}|$ are determined more exactly when the ratio between $|V_+|$ and $|V_-|$ for a given value of $|c|$ is determined by measuring the half-value width or integrated intensities of the peaks.

When $|V_{h'-h}|$ is not very large compared with $|V_h|$ and $|V_{h'}|$, the two peaks in Fig. 10 approach and overlap each other. In this case, the value of $|\varPhi_{hh'}|$ may not be so easily determined as in the former cases, since a more accurate measurement of intensity variation is required to obtain the value of $|V_+|$ and $|V_-|$. Difficulties may come from the fact that the intensity variations occur usually in very small angular ranges and, moreover, often the value of $|c|$ cannot be experimentally determined with a sufficient accuracy.

For centrosymmetric crystals, however, we have only two possibilities for the value of $\varPhi_{hh'}$, namely 0 or π. Therefore, a simple qualitative observation may be sometimes sufficient to discriminate the two cases even when $|V_{h'-h}|$ is not particularly large.

Study of Simultaneous Reflexion in Electron Diffraction by Crystals

II. Experimental Confirmation

By Kyozaburo KAMBE*

Tokyo Institute of Technology, Oh-Okayama, Meguro-ku, Tokyo

(Received September 22, 1956)

The effect of the phases of structure amplitudes appearing in the simultaneous reflexion in electron diffraction as predicted by the dynamical theory has been examined experimentally in convergent-beam electron-diffraction patterns of graphite. Anomalous structures of Kossel-Möllenstedt lines at their cross points have been satisfactorily explained by the theory. Thus, it has been proved that the experimental determination of the phases of structure amplitudes is feasible by the observation of simultaneous reflexion. The phase effects have been found also at the intersecting points of Kikuchi lines.

§ 1. Introduction

In a preceding paper[1] (Part I) it has been shown theoretically that observations on the simultaneous reflexion in electron diffraction give information on the phases of structure amplitudes. When the simultaneous reflexion by the lattice planes with indices h and h' takes place, the intensities of the reflected waves depend on the value of $\Phi_{hh'}=\varphi_h-\varphi_{h'}+\varphi_{h'-h}$, where φ_h, $\varphi_{h'}$, and $\varphi_{h'-h}$ are the phase angles of Fourier coefficients V_h, $V_{h'}$, and $V_{h'-h}$ of the crystal inner potential V, respectively. Calculations developed for the case of electron diffraction by a lamellar crystal has revealed that in some cases the value of $|\Phi_{hh'}|$ may be easily found from the fine structure of reflexion peaks.

In the present paper an experimental verification of the theoretical result is described. The experiment has been performed by the so called convergent-beam method originated by Kossel and Möllenstedt[2].

§ 2. Convergent-beam Method

The fundamental scheme of the convergent-beam method is illustrated in Fig. 1. The electron beam passed through a slit is coverged on the specimen by an electron lens. The angular aperture of the beam is generally from 1/100 to 1/40 rad, and the diameter of the focus on the specimen is usually smaller than 10 μ. The wave transmitted the crystal produces a circular spot on the fluorescent screen. When a Bragg reflexion takes place, the reflected beam also produces a circular spot (the reflexion spot) on the screen. A diffraction pattern thus obtained is called Kossel-Möllenstedt pattern or briefly 'K-M pattern'.

---

* Now at Electrotechnical Laboratory, Nagata-cho, Chiyoda-ku, Tokyo.

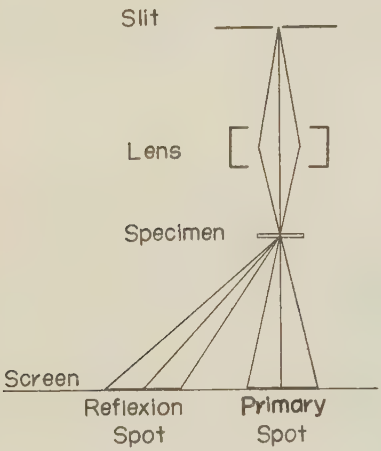

Fig. 1. Diagram of convergent-beam method.

A point in the primary spot corresponds to a certain direction of the primary wave. Similarly, a point in the reflexion spot corresponds to a certain direction of the reflected wave. The two points related by a Bragg reflexion, one in the primary spot and the other in the reflexion spot, can be easily found geometrically on the photograph by noting the relation

$$\boldsymbol{K}_{ht}=\boldsymbol{K}_{ot}+\boldsymbol{b}_{ht}\ , \qquad (1)$$

where $\boldsymbol{K}_{ot}$ and $\boldsymbol{K}_{ht}$ are the tangential components of the wave number vectors of the primary and diffracted waves, and $\boldsymbol{b}_{ht}$ the tangential component of the reciprocal lattice vector concerned.

The primary and reflected spots contain respectively extinction lines and bright lines (K-M lines) at the positions where the Bragg condition is exactly satisfied. These lines are accompanied by subsidiary maxima and minima due to the finite thickness of the crystal.

A K-M pattern is always accompanied by a number of Kikuchi lines in its diffuse background. K-M lines are similar to Kikuchi lines since the both are due to the diffraction of the wave diverging in the crystal, though in the former the wave comes from outside while in the latter the wave is produced inside the crystal by the incoherent scattering of the incident wave.

When the incident wave satisfies the Bragg condition for a certain lattice plane, one in a parallel pair of Kikuchi lines passes through the primary spot, and the other passes through the corresponding reflexion spot. Geometrically, the Kikuchi lines outside the spots are extensions of the K-M lines inside the spots.

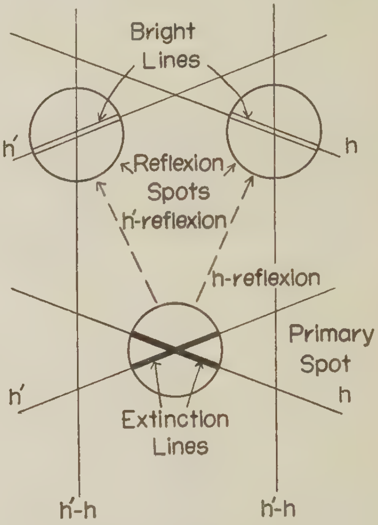

Fig. 2. Simultaneous reflexion in K-M pattern. Pairs of lines marked h, h', and $h'-h$ are Kikuchi lines.

Fig. 2 shows the case where the reflxions h and h' occur simultaneously. The pairs of Kikuchi lines for these indices pass through the primary and reflexion spots. Another pair of Kikuchi lines with the index $h'-h$ passes through the two reflexion spots, showing that the reflected waves satisfy mutually the Bragg condition for the lattice plane $h'-h$. By the coupling between the reflected waves due to this reflexion, intensity anomalies appear at the cross point of extinction lines in the primary spot and at the corresponding points on the bright lines in the reflexion spots.

The convergent-beam method is particularly suitable for the investigation of simultaneous reflexion owing to the following advantages.

1) By virture of a fine focus on the specimen, we can pick up a perfect portion of the crystal.

2) Since the angular aperture of the incident wave is finite, the intensity variation near the

condition of simultaneous reflexion can be observed at once without rotating the crystal.

3) With the aid of Kikuchi lines, the condition of simultaneous reflexion can be realized very easily by rotating the crystal so as to put an intersecting point of the Kikuchi lines, associated with the wanted reflexions, into the primary spot.

It must be noted that K-M lines and Kikuchi lines are superposed in the spots. Thus, when we want to investigate K-M lines in detail, we have to use sufficiently thin crystals for which the intensities of Kikuchi lines are reasonably weak compared with K-M lines.

§3. Experimental

We used an electron diffraction apparatus of so called 'high resolution' type. A slit 0.01∼0.1 mm in diameter was used as the point source. Using two-stage electron-microscope lenses a reduced image of about 5 μ in diameter was obtained with the beam having the angular aperture 1/100∼1/40 rad.

We have chosen graphite crystal as the sample, because 1) it has a simple crystal structure, 2) it is easily cleavable to get a thin lamellar crystal, 3) owing to small scattering power of carbon atom we can avoid undesirable dynamical effects. A disadvantage of graphite is its tendency of containing stacking faults and rhombehedral phases within the layers. However, these faults or extraordinary phases are readily detected by characteristic variations of the pattern, so that it is easy to choose crystals free from the imperfections.

It was necessary to use crystal flakes thinner than 1000 Å, to get a clear K-M pattern free from excessive incoherent scattering with the electron acceleration 40–50 kV. We used graphite crystals from Mongoria and Korea. Crystal flakes having the area about 3 mm ×3 mm were cloven with a sharp needle and a pincet. The obtained cloven flakes were in general smaller than 1 mm×1 mm. Small areas (usually smaller than 10 μ×10 μ) thinner than 1000 Å could be sometimes found at edges of the cloven flakes.

These thin crystals were always more or less curved. Therefore, with the focus of electron beam larger than 5 μ in diameter, only very limited number of specimens were sufficiently flat to give satisfactory K-M patterns. The Kikuchi pattern could be used as a convenient criterion of the flatness of the crystal. As pointed out by Uyeda, Fukano, and Ichinokawa[3)], Kikuchi lines can be observed distinctly even from very thin crystals provided the crystal is not curved. As a rule, Kikuchi patterns are more sensitively disturbed by the curving of the crystal than K-M patterns.

§4. Theoretical Predictions

Fig. 3 illustrates the primary spot in the case where the reflexions h and h' occur simultaneously. As mentioned before the position of a point in the primary spot corresponds to a direction of the incident wave. Points on the lines $h\cdots h$ and $h'\cdots h'$ represent the directions of the primary wave for which the Bragg condition is exactly satisfied. Thus, these lines correspond to the positions of the Kikuchi lines.

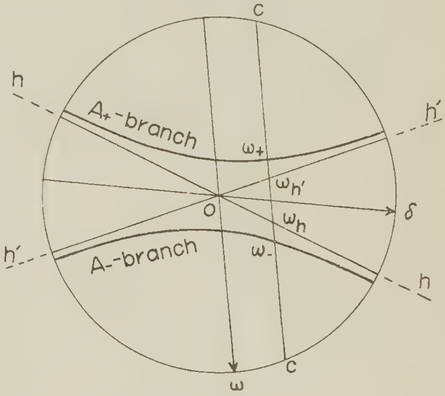

Fig. 3. The primary spot in the case of simultaneous reflexion.

In Part I the direction of the incident wave has been specified by the quantities δ (or $|c|$) and ω*. Therefore, these quantities can be used as coordinates for points in the primary spot. The origin of coordinates lies at the intersecting point of the lines $h\cdots h$ and $h'\cdots h'$. We can show easily from the definition of δ and ω in Part I that the ω-axis is parallel to the Kikuchi line with the index $h'-h$.

In Part I the intensity variation of the transmitted wave $|U_0|^2$ was calculated for a fixed value of δ (that is, for a fixed c-plane,

---

* In Part I direction of the incident wave is specified in reciprocal space by the position of the ν-normal on a c-plane, namely by the value of δ or $|c|$ (Eq. (17), Part I) and by the value of ω specifing the position of the point N (Fig. 9, Part I).

Cf. (17) in Part I). It gives the intensity distribution of the primary spot along a line $c\cdots c$ parallel to the ω-axis. Fig. 10 in Part I shows that when $|V_{h'-h}|$ is particularly large compared with $|V_h|$ and $|V_{h'}|$, we have two intensity dips at ω_+ and ω_- on the line $c\cdots c$. With the variation of δ, the line $c\cdots c$ moves in parallel. The loci of the dips make a hyperbola having $h\cdots h$ and $h'\cdots h'$ as its asymptotes. The intervertex distance between the branches of this hyperbola is proportional to $|V_{h'-h}|$.

We call the locus of ω_+ the A_+-branch, and that of ω_- the A_--branch. In accordance with the consideration in § 5 (b) in Part I, the distinction between the two branches can be easily made in the observed pattern by discriminating which branch lies between the Kikuchi-line pairs concerned, and which one lies outside. This relation is reversed in the reflexion spots.

As shown in Fig. 10 in Part I, the dips located at ω_+ and ω_- in the intensity curve for the transmitted wave $|U_0|^2$ have the half-value widths $2\alpha|V_+|/b$ and $2\alpha|V_-|/b$ respectively. The values of $|V_+|$ and $|V_-|$ which vary with the value of δ (or $|c|$) are given, according to (49) in Part I, by

$$\left.\begin{aligned} |V_+| &= \frac{1}{\sqrt{1+|c|^2}}(|V_h|^2+|c|^2|V_{h'}|^2 \\ &\qquad +2|c||V_h||V_{h'}|\cos\Phi_{hh'})^{1/2} \\ |V_-| &= \frac{1}{\sqrt{1+|c|^2}}(|c|^2|V_h|^2+|V_{h'}|^2 \\ &\qquad -2|c||V_h||V_{h'}|\cos\Phi_{hh'})^{1/2} \end{aligned}\right\} \qquad (2)$$

where $|c|$ is related to δ by (17) in Part I, namely,

$$\delta=\left(|c|-\frac{1}{|c|}\right)\alpha|V_{h'-h}| \qquad (3)$$

Accordingly, the extinction lines making a hyperbola in the primary spot show variations in their widths with the value of δ or $|c|$, as shown in Fig. 4. It should be noted that the depth of the dips do not vary in the primary spot.

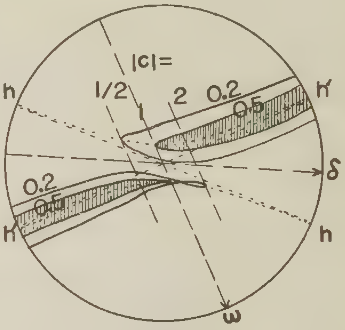
From (2) we see that the branches in the primary spot should have following features according to the value of $\cos\Phi_{hh'}$.

1) When $\cos\Phi_{hh'}>0$, the A_+-branch is wider than A_--branch (Fig(5 (a)).

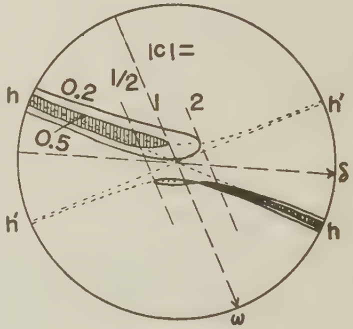
2) When $\cos\Phi_{hh'}<0$, the A_+-branch is narrower than A_--branch (Fig. 5 (b)).

3) When $\cos\Phi_{hh'}=0$, the two branches are symmetric with respect to the origin in the primary spot (Fig. 5 (c)).

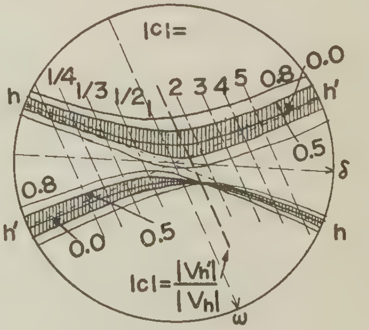
Particularly, when the crystal has a center of symmetry, $\cos\Phi_{hh'}$ is either equal to 1 or -1, so we have only the cases 1) and 2). In this case we have further:



h' Reflexion Spot

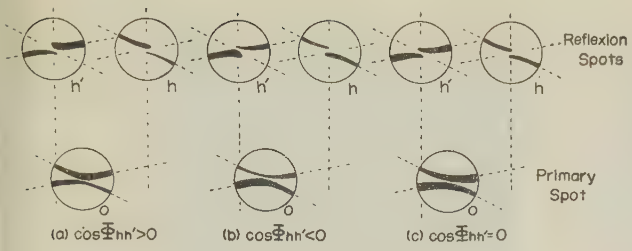


h Reflexion Spot



Primary Spot

Fig. 4. Intensity variation calculated for the case $|V_{h'-h}|\gg|V_h|,|V_{h'}|$ assuming $|V_{h'}|/|V_h|=3/2$, and $\cos\Phi_{hh'}=1$. The numbers attached to the contour indicate intensity values assuming that the intensity of the incident wave is unity. In the shadowed area the intensity is smaller than 0.5 for the primary spot, and larger than 0.5 for the reflexion spots.



(a) $\cos\Phi_{hh'}>0$ (b) $\cos\Phi_{hh'}<0$ (c) $\cos\Phi_{hh'}=0$

Fig. 5. Intensity variations predicted by the theory, showing different characters depending on the value of $\cos\Phi_{hh'}$.

1′) When $\cos\Phi_{hh'}=1$, the A_+-branch has maximum width $2\alpha\sqrt{|V_h|^2+|V_{h'}|^2}/b$ and the A_--branch has zero width at $|c|=|V_{h'}|/|V_h|$ (Fig. 4).

2′) When $\cos\Phi_{hh'}=-1$, the A_+-branch has zero width and the A_--branch has maximum width $2\alpha\sqrt{|V_h|^2+|V_{h'}|^2}/b$ at $1/|c|=|V_{h'}|/|V_h|$.

By the similar treatment it can be shown that characteristic intensity variations appear at the corresponding positions of bright lines in the reflexion spots, as illustrated in Fig. 4 and Fig. 5.

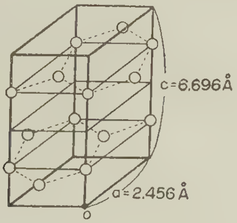


Fig. 6. Unit cell of graphite.

§ 5. Results

Graphite has a well known crystal structure, being piling up of hexagonal nets in alternating sequences $ABAB\cdots$. It belongs to a hexagonal space group $C_{6v}{}^4(C6mc)$. In order to make all the structure amplitudes real, we have chosen the origin of unit cell at a symmetry center lying halfway between the layears (Fig. 6). The unit cell contains four atoms located at

$$0\,0\,\frac{1}{4},\ 0\,0\,\frac{3}{4},\ \frac{2}{3}\,\frac{1}{3}\,\frac{1}{4},\ \frac{1}{3}\,\frac{2}{3}\,\frac{3}{4}.$$

The sings of structure amplitudes are determined by the factor

$$\sum\exp 2\pi i(hx+ky+lz)$$

The values of this factor for various combinations of reflexion indices are shown in Table I.

Table I. Values of $\sum\exp 2\pi i(hx+ky+lz)$ for hexagonal graphite.

	$h-k=3m$	$3m+1$	$3m+2$
$l=4n+0$	4	1	1
1	0	$\sqrt{3}$	$\sqrt{3}$
2	-4	-1	-1
3	0	$-\sqrt{3}$	$-\sqrt{3}$

In our experiment two sets of the *h*

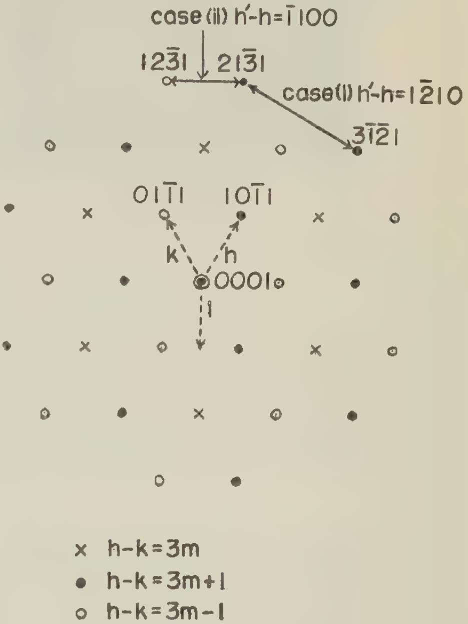

Fig. 7. The reciprocal lattice plane specified by $l=1$.

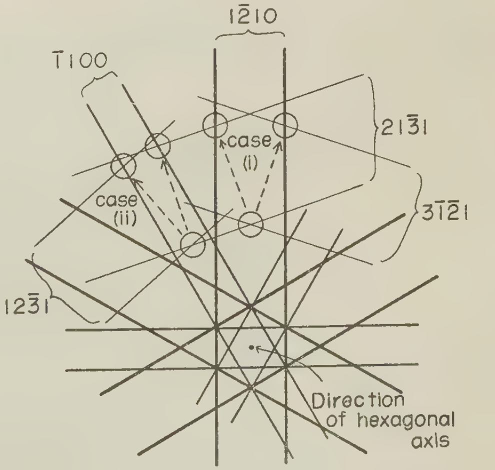

Fig. 8. Kikuchi pattern of graphite illustrating the positions of simultaneous reflexion used in the observation.

and h' reflexions were chosen from the group {211} as tabulated in Table II. Fig. 7 shows the reciprocal lattice plane specified by $l=1$ which contains the reciprocal lattice points concerned. Fig. 8 shows the Kikuchi pattern for graphite. To realize the two cases of simultaneous reflexion, the orientation of the crystal was adjusted so as to put the primary spot at the positions as shown in Fig. 8. In each case, two reflected spots appear at the positions as indicated.

We see in Table II that the value of $|V_{h'-h}|$ is large compared with $|V_h|$ and $|V_{h'}|$ in the both cases. The value of $\cos\Phi_{hh'}$ is 1 for Case (i), -1 for Case (ii). In other words, V_h and $V_{h'}$ have the same sign for (i), opposite signs for (ii), since $V_{h'-h}$ is positive for the present choice of the origin (Cf. Part I, 6). The cases (i) and (ii) correspond respectively to the cases 1′) and 2′) in the preceding section.

Table II. Two combinations of simultaneously excited reflexions used in the present observation.

	$hkil$			
Case (i)	$h=(21\bar{3}1)$	$\lvert V_h\rvert=0.63$ volt	$\varphi_h=0$	$\cos\Phi_{hh'}=1$
	$h'=(\bar{3}1\bar{2}1)$	$\lvert V_{h'}\rvert=0.63$	$\varphi_{h'}=0$	
	$h'-h=(1\bar{2}10)$	$\lvert V_{h'-h}\rvert=3.29$	$\varphi_{h'-h}=0$	
Case (ii)	$h=(21\bar{3}1)$	$\lvert V_h\rvert=0.63$	$\varphi_h=0$	$\cos\Phi_{hh'}=-1$
	$h'=(12\bar{3}1)$	$\lvert V_{h'}\rvert=0.63$	$\varphi_{h'}=\pi$	
	$h'-h=(\bar{1}100)$	$\lvert V_{h'-h}\rvert=1.47$	$\varphi_{h'-h}=0$	

Since $|\boldsymbol{b}_h|=|\boldsymbol{b}_{h'}|$ and $|V_h|=|V_{h'}|$ for the both cases, the patterns in the primary spot are symmetrical with respect to the ω-axis. When $|c|=|V_{h'}|/|V_h|=1$ ($\delta=0$), the line $c\cdots c$ in Fig. 3 passes the vertices of the hyperbola, and we have in Case (i)

$$|V_+|=\sqrt{2}\,|V_h|, \quad |V_-|=0\,,$$

so that the A_--branch vanishes at its vertex, while in Case (ii)

$$|V_+|=0\,, \quad |V_-|=\sqrt{2}\,|V_h|\,,$$

so that the A_+-branch vanishes at its vertex.

Fig. 9 shows the photographs obtained for these cases. We see that the observation verifies the theoretical predictions quite satisfactorily. At the vertices the A_+-branch has a maximum width and A_--branch vanishes in Case (i), while in Case (ii) the A_+-branch vanishes and A_--branch has a maximum width. It is seen also that the bright lines in the reflexion spots show corresponding intensity variations. Although in Case (ii) the value of $|V_{h'-h}|$ is only about twice the values of $|V_h|$ and $|V_{h'}|$, the photograph shows that this is sufficient to discriminate the value of $\cos\Phi_{hh'}$ from the observation.

§ 6. Discussion

The result obtained above shows that the phase determination is practically feasible by the present method. However, since our observation is limited to most favourable cases, it is desired that the method is applied to more general cases of phase determination in crystal analysis. As the convergent-beam method requires a very thin plate of perfect single crystal, it can be applied to very limited kind of crystals. However, also some other experimental methods can be used for the study of simultaneous reflexion; for example, observation of Kikuchi lines, and observation of extinction lines due to Bragg reflexion in electron-micrographs may be applied for this purpose.

Fig. 10 shows the Kikuchi pattern obtained from a relatively thick crystal. This corresponds to the part indicated in Fig. 8 as Case (i). The phase effect similar to the case of K-M line can be observed for the intersecting points of Kikuchi lines appearing at the positions corresponding to the reflexion spots in Fig. 9. This result can be proved theoretically by applying our method described in Part I to Kikuchi lines. Thus, the range of practical application of our method is considerably extended, since the observation of Kikuchi lines is comparatively easier than K-M lines. Particularly, we may utilize Kikuchi patterns obtained by reflexion from natural or cloven

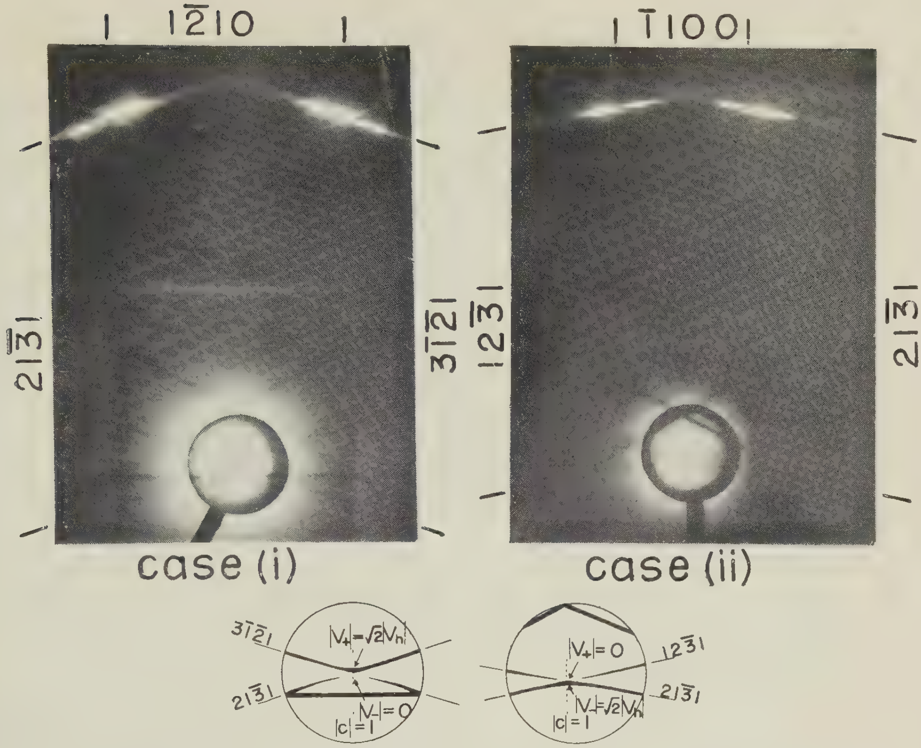

Fig. 9. Convergent-beam electron-diffraction photographs of graphite, showing the phase effect in simultaneous reflexion. (Accelerating voltage 41 kV, crystal thickness $\sim$1000 Å.) The exposure of the primary spot is diminished by covering it with a disc. Sketches illustrate the intensity variation in the primary spot.

faces of block single crystals. We have actually found examples of Kikuchi lines in reflexion patterns revealing the phase effect. A more detailed analysis of Kikuchi lines will be reported in another paper.

When we observe thin crystal plates by an electron microscope, extinction lines due to Bragg reflexion appear frequently in the image. The phase effect may appear at the cross point of two extinction lines; dark-field micrographs obtained by using reflected rays may be utilized for indexing the extinction lines[4][5].

The author expresses his sincere thanks to Prof. S. Miyake for his guidance throughout the work.

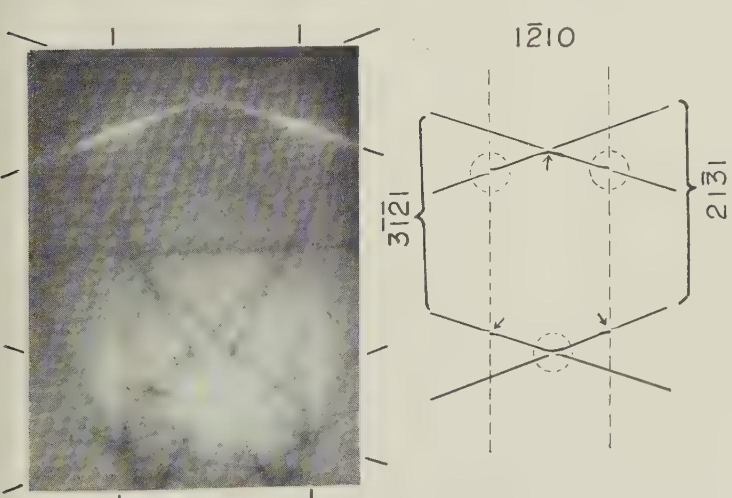

Fig. 10. Kikuchi pattern corresponding to Case (i) in Fig. 9, obtained by using a relatively thick crystal. At the cross points surrounded by circles in the sketch the same intensity variations as in the spots in Fig. 9 are observed. Also the points indicated by arrows show similar intensity variations, though white and black relation is reversed.

Intermolecular Potential between Large Molecules

By Akira ISIHARA*

Department of Physics, University of Maryland, College Park, Maryland

and Ryuzo KOYAMA

The Electrical Communication Laboratory, Musashino, Tokyo, Japan

(Received August 28, 1956)

The intermolecular potential between spherical polyatomic molecules is calculated, assuming the Lennard-Jones potential between atoms of polyatomic molecules. Owing to the distribution of atoms in polyatomic molecules the degree of infinit of potential is lowered when two polyatomic molecules approach each other. In the case of uniform distribution of atoms in polyatomic molecules, the degree is lowered by 5 orders and the minimum value of the potential is proportional to the radius of polyatomic molecule and to the square of the density of the atoms. At large intermolecular distance, the result of calculation of this case coincides with the results of Atoji and Lipscomb and of Hamaker. Calculation for a parabolic distribution of atoms is also given. The temperature and molecular weight dependence of the second virial coefficient of high polymer solutions are explained by the aid of calculated potential function.

§ 1. Introduction

In 1937, following the calculation of de Boer¹⁾, Hamaker¹⁾ calculated the potential energy between two spheres composed of particles which are uniformly distributed within each sphere, assumping Van der Waals-London forces between the particles in one sphere and those in the other. Hamaker showed that various colloidal phenomena can be explained with the aid of total potential curves, obtained by superposing these Van der Waals-London attractive forces and a repulsive force, conforming to a very simple and crude approximation. Since then, many calculation have been made, using the repulsive potential arising from electric double layer interactions¹⁾.

Recently, Atoji and Lipscomb²⁾ calculated the potential energy between polyatomic molecules composed of randomly distributed atoms, but they used a series expansion which is only applicable to molecular distances which are sufficiently large in comparison with the radius of the molecules.

In this paper, we shall first calculate the potential energy between two polyatomic molecules having spherical symmetry. The calculation is general and can be applied even if the density of the polyatomic molecules is not constant. It can be used when the distance between the polyatomic molecules is very small.

Theoretical investigations on high polymers, particularly those on high polymer solutions³⁾, make remarkable strides in recent years. However, with respect to the interaction potential between polymer molecules we do not have sufficient knowledge. Although most of important properties of polymers are determined by the molecular weight, specific properties of polymers should depend on the interaction potential between high polymer molecules.

We have shown in a previous paper⁴⁾ that the temperature and molecular weight dependence of the second virial coefficient can be interpreted if we take all the interactions between segments of polymer molecules into consideration. Particularly, our theoretical predictions about the behavior of second virial coefficient near the Flory point—the temperature at which the second virial coefficient vanishes—fit the experimental data of Krigbaum and Flory on polyisobutyrene in benzene⁵⁾ and of Krigbaum on polystyrene in cyclohexane⁶⁾.

The second virial coefficient is determined by the radial distribution function of two polymer molecules in solutions and the function is determined by the interaction potential between chain polymers. We can consider that the interaction potential is a function of the molecular weight and, as a result, the second virial coefficient become dependent on the molecular weight.

---

* On leave from Department of Physics, Faculty of Science, University of Tokyo, Japan.

Polymer molecules takes various configurations, and the potential function between two polymer molecules is a function of such configurations. However, the average value should be a function of the distance between centers of gravity of two polymer molecules and also of the degree of polymerization and the distribution of segments in polymer molecules. We are concerned here in calculating such average potential functions.

§ 2. Potential Energy between Polyatomic Molecules

We wish to calculate the potential energy between two spherical polyatomic molecules as a function of their distance, each polyatmic molecule being composed of atoms whose interaction is assumed to be known. The object of the calculation is to see the relation between the interactions of atoms and that of polyatomic molecules. Let the distance between the centers of gravity O and O′ of two polyatomic molecules be S, and consider the differential volumes $d\boldsymbol{r}$ and $d\boldsymbol{r}'$ located respectively at the distances $\boldsymbol{r}$ and $\boldsymbol{r}'$ from O and O′. If $\rho \boldsymbol{r} d\boldsymbol{r}$ or $\rho(\boldsymbol{r}')\,d\boldsymbol{r}'$ atoms are included in each differential volume, then the average potential energy between the two polyatomic molecules is given by

$$\varPhi(s)=\iint \rho(\boldsymbol{r})\varphi(s)\rho(\boldsymbol{r}')d\boldsymbol{r}d\boldsymbol{r}' , \qquad (2.1)$$

where $\varphi(s)$ is the potential between the atoms of different polyatomic molecules and s is the distance between $\boldsymbol{r}$ and $\boldsymbol{r}'$ (Fig. 1). The integration is over the volumes of two polyatomic molecules.

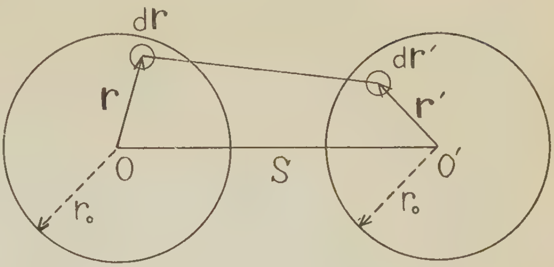

Fig. 1. The spherical polyatomic molecules at distance S.

In Eq. (1), it is assumed that deformation of polyatomic molecules does not occur even when the two polyatomic molecules approach each other closely and the potential energy between atoms is additive. Some kinds of potential function will make the value of Eq. (1) infinite for S below a certain value. In such a case, we consider that the polyatomic molecules interact there with a rigid body potential and cannot get nearer to each other. For convenience sake, we assume that the polyatomic molecules have spherical symmetry around their center of gravity and that the distribution functions $\rho(\boldsymbol{r})$ and $\rho(\boldsymbol{r}')$ depend only on the magnitude r and r' of the vector-arguments.

For the potential $\varphi(s)$, we adopt the Lennard-Jones potentials:

$$\varphi(s)=\varphi_0\{(s_0/s)^{12}-2(s_0/s)^6\} , \qquad (2.2)$$

where s_0 is the position of the minimum of $\varphi(s)$ and φ_0 is the corresponding value $\varphi(s_0)$. Let the radius of polyatomic molecules as rigid bodies be r_0, than Eq. (1) can be reformed as follows

$$\varPhi(S)=4\pi^2N^2\varphi_0(s_0/r_0)^6[(s_0/r_0)^6\psi_{12}(S')-2\psi_6(S')] ,$$
$$\psi^{12}(S')=\frac{1}{90}\frac{1}{S'}\int_{-1}^{1}\int_{-1}^{1}\frac{xy\sigma(x)\sigma(y)}{(S'+x+y)^9}dxdy ,$$
$$\psi^{6}(S')=\frac{1}{12}\frac{1}{S'}\int_{-1}^{1}\int_{-1}^{1}\frac{xy\sigma(x)\sigma(y)}{(S'+x+y)^3}dxdy ,$$
$$S'=S/r_0 , \qquad (2.3)$$

by a straight-forward calculation.

Here N represents the total number of atoms in one polyatomic molecule and the function $\sigma(x)$ is a reformed distribution function normalized to unity:

$$r^2\rho(r)\,dr=Nx^2\sigma(x)\,dx ,$$
$$\int_0^\infty 4\pi x^2\sigma(x)dx=1 ,$$
$$r=r_0x . \qquad (2.4)$$

The first and the second terms in the bracket of $\varPhi(S)$ of Eq. (2.3) come respectively from the first and the second terms of the Lennard-Jones potential and are respectively the repulsive and the attractive parts of the potential $\varPhi(S)$. The repulsive part of $\varPhi(S)$ has a factor $(s_0/r_0)^{12}$ which is very small in the case of large molecules so that the repulsive part becomes effective only when the polyatomic molecules are near to each other. At $S'=2$ or $S=2r_0$, where the polyatomic molecules will contact with each other, $\Phi(S)$ becomes infinite.

To obtain the potential function explicitly, we must know the distribution function $\rho(r)$. For this, we can think of several functional forms. If polyatomic molecules are chain like polymer molecules, and if we assume the random flight model for these polymers, we may use the results of the calculation for $\rho(r)$ of Isihara, Debye-Bueche, Benoit-Goldstein[7]. However, this adoption makes the result of the integration of Eq. (2.3) very annoying, particularly at small values of $S'-2$, also there arises the problem of how to normalize the distribution function in accordance with the rigid body radius r_0. Thus, in the following sections we shall calculate $\Phi(S)$ for much simpler forms of $\rho(r)$.

§ 3. Uniform distribution of Atoms

As the simplest example, we shall treat first the case of a uniform distribution of atoms:

$$\begin{aligned}\rho(r)&=q=\text{const.}, \quad r\leq r_0\,,\\ &=0 \qquad\quad\;\;, \quad r>r_0\,.\end{aligned}\tag{3.1}$$

In terms of the reduced distribution function:

$$\begin{aligned}\sigma(x)&=\frac{3}{4\pi}\,, \quad x\leq 1\,,\\ &=0\;\;, \quad x>1\,.\end{aligned}\tag{3.2}$$

Inserting this into Eq. (2.3), we obtain

$$\begin{aligned}\Phi(S)=&\frac{2}{3}\pi^2q^2\varphi_0 s_0{}^6\\ &\times\left[\frac{1}{15}\left(\frac{s_0}{r_0}\right)^6\left\{\frac{1}{56}\frac{1}{S'}\left(\frac{1}{(S'-2)^7}+\frac{1}{(S'+2)^7}+\frac{2}{S'^7}\right)-\right.\right.\\ &-\frac{1}{168}\frac{1}{S'}\left(\frac{1}{(S'-2)^6}-\frac{1}{(S'+2)^6}\right)+\\ &\left.+\frac{1}{1680}\left(\frac{1}{(S'-2)^5}+\frac{1}{(S'+2)^5}+\frac{1}{S'^5}\right)\right\}-\\ &\left.-\left\{\frac{1}{S'^2-4}+\frac{1}{S'^2}+\frac{1}{2}\log\frac{S'^2-4}{S'}\right\}\right].\end{aligned}\tag{3.3}$$

The first and the second terms in the braces represent respectively the repulsive and attractive parts of the potential. The latter can be easily shown to coincide with the result obtained by Hamaker.

When two polyatomic molecules are close to each others, Eq. (3.3) is approximated by the following formula:

$$\begin{aligned}\Phi(S)=&\frac{2}{3}\pi^2q^2\varphi_0 s_0{}^6\\ &\times\left[\frac{1}{15}\left(\frac{s_0}{r_0}\right)^6\frac{1}{112}\left\{\frac{1}{x^7}-\frac{5}{6}\frac{1}{x^6}+\frac{9}{20}\frac{1}{x^5}-\cdots\cdots\right\}-\right.\\ &\left.-\frac{1}{4}\left\{\frac{1}{x}+2\log x+\frac{3}{4}-\frac{39}{16}x+\cdots\right\}\right],\end{aligned}\tag{3.4}$$

where

$$x=S'-2\,.\tag{3.5}$$

From this equation, the minimum point S_0 $\Phi(S)$ can be calculated as follows:

$$x_0=60^{-1/6}\left(\frac{s_0}{r_0}\right)\left\{1+\frac{3}{14}60^{-1/6}\left(\frac{s_0}{r_0}\right)+\cdots\cdots\right\},\tag{3.6}$$

that is

$$S_0=2r_0+60^{-1/6}s_0\left\{1+\frac{3}{14}60^{-1/6}\left(\frac{s_0}{r_0}\right)+\cdots\cdots\right\}.\tag{3.7}$$

In deriving this, it was assumed that the ratio (s_0/r_0) is very small compared with 1. Accordingly, the minimum value of $\Phi(S)$ is given

$$\begin{aligned}\Phi(S_0)=&-\frac{1}{7}60^{1/6}\pi^2\varphi_0 s_0{}^5q^2r_0\\ &\times\left\{1+\frac{7}{3}60^{-1/6}\left(\frac{s_0}{r_0}\right)\log\left(\frac{s_0}{r_0}\right)-\right.\\ &\left.-0.5884\cdot 60^{-1/6}\left(\frac{s_0}{r_0}\right)+\cdots\cdots\right\}.\end{aligned}\tag{3.8}$$

From Eq. (3.8) the minimum value of the potential seems to be proportional to the radius and to the square of the density q of the atoms of the polyatomic molecule.

When the intermolecular distance S becomes much larger than the radius of the polyatomic molecule, $\Phi(S)$ can be expanded[2)] in the power series of $r_0/s_0=1/S'$:

$$\begin{aligned}\Phi(S)=N^2\varphi_0&\left[\left(\frac{r_0}{S}\right)^{12}\left\{1+\frac{132}{5}\left(\frac{r_0}{S}\right)^2+\right.\right.\\ &\left.+\frac{10296}{25}\left(\frac{r_0}{S}\right)^4+\cdots\cdots\right\}-2\left(\frac{s_0}{S}\right)^6\left\{1+\right.\\ &\left.\left.+6\left(\frac{r_0}{S}\right)^2+\frac{144}{5}\left(\frac{r_0}{S}\right)^4+\cdots\cdots\right\}\right].\end{aligned}\tag{3.9}$$

In the limit when S/r_0 is sufficiently large compared to 1, $\Phi(S)$ approaches the Lennard-Jones type function:

$$\Phi(S)\approx N^2\varphi_0\left\{\left(\frac{s_0}{S}\right)^{12}-2\left(\frac{s_0}{S}\right)^6\right\}.\tag{3.10}$$

Eq. (3.4) shows that the repulsive and the attractive parts of the potential begin respectively from the terms $(1/x)^7$ and $(1/x)$, these powers being just greater by 5 than those in the corresponding terms of the original Lennard-Jones potential. Accordingly, $\Phi(S)$ becomes infinite when S approaches $2r_0$ by 5 orders lower than the degree of infinity of the Lennard-Jones potential.

§ 4. Parabolic Distribution of Atoms

Next, we shall apply the general formula (2.3) to the case of a parabolic distribution of atoms about the center of gravity:

$$\begin{aligned}\rho(r)&=\frac{15}{8\pi}\frac{1}{r_0^3}N\left(1-\frac{r^2}{r_0^2}\right), && r\le r_0\,,\\ &=0 && ,\ r>r_0\,,\\ \sigma(x)&=\frac{15}{8\pi}(1-x^2) && ,\ x\le 1\,,\\ &=0 && ,\ x>1\,, \qquad (4.1)\end{aligned}$$

and shall compare the result with the former case. The calculation of the potenial $\Phi(S)$ in the present case is more complicated but since it is straight-forward we shall only give the result:

$$\begin{aligned}\Phi(S)=\frac{75}{32}\pi^2N^2\varphi_0(s_0/r_0)^6\Bigg[&\frac{1}{15}\left(\frac{s_0}{r_0}\right)^6\Bigg\{\frac{1}{420}\frac{1}{S'}\left(\frac{1}{(S'-2)^5}+\frac{1}{(S'+2)^5}-\frac{1}{2}\frac{1}{S'^5}\right)-\\ &-\frac{1}{280}\frac{1}{S'}\left(\frac{1}{(S'+2)^4}-\frac{1}{(S'+2)^4}\right)+\frac{1}{336}\frac{1}{S'}\left(\frac{1}{(S'-2)^3}-\frac{1}{(S'+2)^3}+\frac{2}{5}\frac{1}{S'^3}\right)-\\ &-\frac{1}{560}\frac{1}{S'}\left(\frac{1}{(S'-2)^2}-\frac{1}{(S'+2)^2}\right)+\frac{1}{1120}\frac{1}{S'}\left(\frac{1}{S'-2}+\frac{1}{S'+2}-\frac{2}{S'}\right)\Bigg\}-\\ &-\left\{\left(\frac{3}{20}S'^4-S'^2+2\right)\log\frac{S'^2-4}{S'^2}-\frac{4}{5}\frac{1}{S'}\log\frac{S'-2}{S'+2}+\frac{3}{5}S'^2-\frac{4}{15}\right\}\Bigg]. \qquad (4.2)\end{aligned}$$

If an intermolecular separation is small, it is convenient to use x, equal to $S'-2$, and to reform Eq. (4.2) as follows:

$$\begin{aligned}\Phi(S)=\frac{75}{32}\pi^2N^2\varphi^0\left(\frac{s_0}{r_0}\right)^6\Bigg[&\frac{1}{1260}\left(\frac{s_0}{r_0}\right)^6\left\{\frac{1}{x^5}-\frac{2}{x^4}+\frac{9}{4}\frac{1}{x^3}-\cdots\cdots\right\}-\\ &-\left\{\left(x+\frac{5}{2}x^2\right)\log x+\frac{4}{5}\left(\log 2-\frac{1}{2}\right)-\frac{2}{5}\left(\log 2-\frac{11}{2}\right)x+\frac{1}{5}\left(\log 2+\frac{1}{8}\right)x^2+\cdots\right\}\Bigg].\end{aligned}$$

(4.3)

When x approaches zero, the attractive part approaches a constant value $4/5\cdot(\log 2-\frac{1}{2})$. The repulsive parts has a power 7 orders higher than that of the original Lennard-Jones potential and starts at $1/x^5$. The power in the attractive part is diminished similarly.

Thus, the degree of infiniteness in the present case is lower than the uniform distribution of segments. The difference comes particularly from the distribution of atoms in the neighborhood of the polyatomic molecule. The minimum point of the potential function just calculated is given by the following equation when s_0/r_0 is very small compared to 1.

$$(s_0/r_0)^6\approx 2520x^6\left\{-\log x-\frac{2}{5}(8-\log 2)\right\}. \qquad (4.4)$$

§ 5. The Potential Curves

Fig. 2 and Fig. 3 illustrate the potential function given by Eq. (3.3) or (3.4) between polyatomic molecules with uniform distribution of atoms. As shown in Eqs. (3.3) and (3.4), the absolute value of the potential $\Phi(S)$ is depend on the molecular radius r_0 as well as on the density of atoms $q=3N/4\pi r_0^3$ even if φ_0 and s_0 are constant. For convenience, we designate that part of the potential function of Eq. (3.4) which is dependent upon the distance S by $\Psi(S)$ and express the potential function in the following form:

$$\Phi(S)=\frac{60^{1/6}}{42}\pi^2q^2\varphi_0 s_0^5 r_0\Psi(S)\,, \qquad (5.1)$$

where $\Psi(S)$ depends on s_0/r_0 as well as on S. The three curves in Fig. 2 and Fig. 3 correspond to the following values of s_0/r_0:

curve 1. $s_0/r_0=1/10$,
curve 2. $s_0/r_0=1/100$,
curve 3, $s_0/r_0=1/1000$.

Fig. 2 shows the function $\Psi(S)$ plotted against the intermolecular distance. The abscissa is the intermolecular distance divided by the molecular radius r_0. Fig. 2 is useful to see how the potential curves depend on the molecular diameters. It also shows that how the potentials are different from the rigid body potential at various molecular diameters.

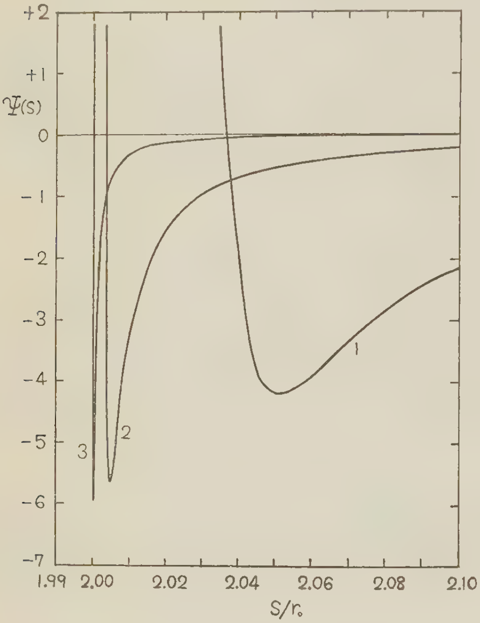

Fig. 2. Potential between polyatomic molecules composed of atoms distributed uniformly as a function of molecular distances S.

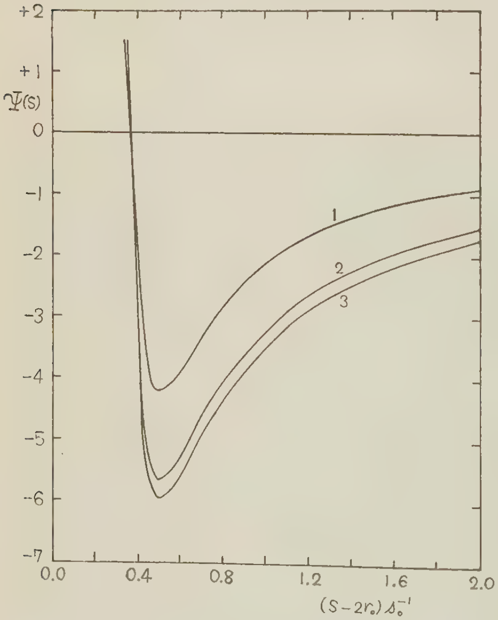

Fig. 3. Potential between polyatomic molecules composed of atoms distributed uniformly as a function of molecular separation $S-2r_0$.

Fig. 3 represents the function $\Psi(S)$ for the intermolecular separation $S-2r_0$. The unit of the abscissa is s_0, which is the minimum point of the original Lennard-Jones potential. From Fig. 3, we can infer that the minimum position of potential function of polyatomic molecules appear, as they should, at positions corresponding to the intermolecular separation of about $1/2\cdot s_0$, nearly independent of molecular sizes when the diameters of molecules become large.

When the polyatomic molecules are randomly kinked chain molecules which are spherical, and if we use the result of the random flight model, we can put

$$r_0=\lambda(Nb^2)^{1/2}, \tag{5.2}$$

where b is the length of one segment and λ is a constant independent of the degree of polymerization N.

§ 6. Application to High Polymer Molecules

The potentials we have calculated are functions of the total number of atoms in a molecule, and thus it is expected that if we use such potentials to calculate the second virial coefficient A_2, in the expansion of osmotic pressure π as a power series of concentration c:

$$\frac{\pi}{RTc}=\frac{1}{M}+A_2c+A_2c^2+\cdots, \tag{6.1}$$

π becomes a function of molecular weight. Here, R is the gas constant and T the absolute temperature. Accoding to the theories of McMillan and Mayer[8] and Kirwood and Buff[9], A_2 assume the form:

$$A_2=-\frac{2\pi N_0}{M^2}\int_0^\infty (g_2(S)-1)\,S^2\,dS, \tag{6.2}$$

where N_0 is Avogadro's number of $g_2(S)$ is the radial distribution function at infinite dilution of two polymer molecules separated by a distance S.

For the distribution function $g_2(S)$, we shall adopt the form:

$$g_2(S)=e^{-\Phi(S)/kT}, \tag{6.3}$$

where $\Phi(S)$ is an average potential given by Eq. (3.3) or Eq. (4.2). If we use Eq. (3.3) in Eq. (6.3), we arrive at the following expression for the second virial coefficient:

$$A_2=\frac{16}{3}\pi N_0 r_0^3 M^{-2}\{1+(s_0/r_0)f(-\Phi(S_0)/kT)\}, \tag{6.4}$$

where $-\Phi(S_0)$ is the potential minimum given by Eq. (3.8). For small values of x, $f(x)$ is estimated as follows:

$$f(x)=\frac{1}{2}\sqrt{\frac{\pi}{2}}\left\{6^{6/7}e^{-1}x^{1/7}-\sqrt{7}\,e^{-1/7}x\right\}. \tag{6.5}$$

Whereas for large values of x, $f(x)$ is approximately proportional to $\sqrt{x}\,e^x$.

If we neglect the possible temperature dependence of r_0 or q, the temperature variation of the second virial coefficient A_2 is given by

$$\frac{\partial A_2}{\partial(1/T)}=\frac{16}{3}\pi N_0 r_0^3 M^{-2}\cdot(-\Phi(S_0)/kT)\cdot(s_0/r_0)\cdot\times$$
$$\times f'(-\Phi(S_0)/kT)\,. \tag{6.6}$$

On the other hand, in dilute solution the partial heat of dilution is calculated as follows:

$$\Delta H_1=\frac{16}{3}\pi R N_0 V_S s_0 r_0^2 M^{-2}c^2\Phi(S_0)/k\cdot f'(-\Phi(S_0)/kT), \tag{6.7}$$

where V_S is the molar volume of solvent. The function $f(x)$ increases according to whether the argument x is small or large. Since x is small when T is large or when $-\Phi(S_0)$ is small, we see from Eqs. (6.6) and (6.7) that the temperature derivative of the second virial coefficient is positive in poor solvents where the heat of solution of negative. This is in line with experiments.

In the theory of high polymer solution, Huggins' parameter μ is often used. To explain the temperature dependence of A_2, a semi empirical temperature dependent form of μ is assumed. From our theory, μ is calculated as a function of temperature:

$$\mu=\frac{1}{2}-\frac{16}{3}\pi N_0 r_0^3 V_S \rho^2 M^{-2}$$
$$\times\{1+(s_0/r_0)\cdot f(-\Phi(S_0)/kT)\},$$
$$r_0=\lambda N^{1/2}b\,. \tag{6.8}$$

where ρ is the density of high polymer.

In the region where $f(-\Phi(S_0)/kT)$ is small A_2 is expressed by the equation:

$$A_2\approx\frac{16}{3}\pi N_0 \lambda^3 b^3 M_0^{-3/2} M^{-1/2}, \tag{6.9}$$

from which we can see the molecular weight dependence of A_2 easily. Here we introduce λ which is a proportional constant connecting the radius of polymer molecule r_0 and the end-to-end distance and is defined by Eq. (5.2). In Eq. (6.9), we have neglected the second term in the bracket of Eq. (6.4). If we insert the experiment data of Outer, Carr, and Zimm[10] into Eq. (6.9), using the Eq. (5.2), the following values for λ are obtained:

polystyrene–butanone	0.264 ,
polystyrene–dichlorethane	0.296 .

The theory of random flight predicts the value 0.408, because if we consider the radius r_0 to be the average square root distance of segments from the center of gravity, r_0 is given by $(1/6\cdot Nb^2)^{1/2}$. Both values of λ are of the same order of magnitude. This is a reasonable correspondence.

In turn, if we consider that λ is related to a volume exclusion effect which varies with the molecular weight, Eq. (6.9) can be expressed as

$$A_2=CM^{-\alpha}, \tag{6.10}$$

which is an empirical formula. Here α is a constant and assumes numerical values between about 0.2 and 0.5.

In the region where $f(-\Phi(S_0)/kT)$ is not small we can not predict easily the molecular weight dependence of A_2.

We shall now discuss the second virial coefficient near the Flory point. If only the neighborhood of the Flory point is concerned, we can deduce from Eq. (6.4) following approximate expression for the second virial coefficient:

$$A_2\approx\frac{16}{3}\pi N_0 r_0^3 M^{-2}$$
$$\times\left[1-\exp\left\{-\left(-\frac{\Phi(S_0)}{k\Theta}+\frac{1}{2}\right)\left(1-\frac{\Theta}{T}\right)\right\}\right], \tag{6.11}$$

where Θ means the Flory point. This expression shows that when $T-\Theta$ is small, A_2 versus temperature curve is a straight line which has a positive slope, determined by $r_0^3M^{-2}\left(-\frac{\Phi(S_0)}{k\Theta}+\frac{1}{2}\right)\frac{1}{\Theta}$. At larger values of $T-\Theta$, the curve bends towards the abscissa.

This is determined by the magnitude of $r_0{}^3M^{-2}\left(-\frac{\Phi(S_0)}{k\Theta}+\frac{1}{2}\right)\left(-\frac{\Phi(S_0)}{k\Theta}+\frac{5}{2}\right)\frac{1}{\Theta^2}$.

All these behaviors coincide with the data of Krigbaum⁶⁾ on polystyrene in cyclohexane and the data of Krigbaum and Flory⁵⁾ on polyisobutylene in benzen. By comparing Eq. (6.11) with these data we can determine r_0 and $\Phi(S_0)$ separately. The values we thus obtained from the data of Krigbaum⁶⁾ for polystyrene in cyclohexane systems are illustrated in Table I. In this table R means the root of the average of squre distances of segments from the center of gravity of the polymer molecule. This quantity was calculated by using the relations:

$$R=(1/6\cdot Nb^2)^{1/2},$$

$$(Nb^2/M)^{1/2}=735\times10^{-11}\ \mathrm{cm}.$$

The numerical value of the right hand side of the second equation is calculated from the data of Krigbaum, Mandelkern and Flory, and Schults¹¹⁾. r_0 is the radius of polymer molecule as a rigid sphere and is considerep to be nearly equal to R. Table I shows this is actually true. In the last column of Table I the minimum values of the potential between polymer molecules are indicated. Similar to r_0 these depend on the molecular weight. In Fig. 4 we illustrated the dependence. As can see from Fig. 4., r_0 and $-\Phi(S_0)$ are nearly proportional to $M^{0.56}$ and $M^{0.23}$ respectively. This is a very natural dependence.

Table I

M	r_0	R	$-\Phi(S_0)/k\Theta$
50,500	49 Å	67 Å	6.1
125,000	80	107	8.2
359,000	148	180	9.4
566,000	188	226	11.2

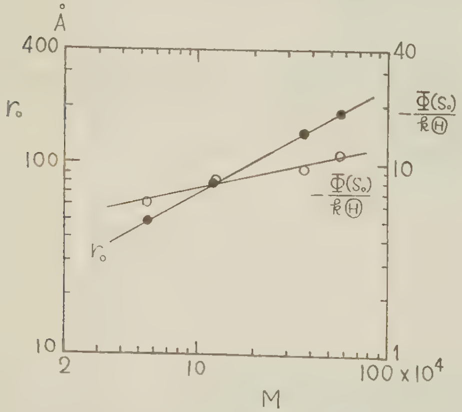

Fig. 4. Molecular radius r_0 and minimum values of intermolecular potentials $-\Phi(S_0)/k\Theta$ of polystyrene molecules in cyclohexane as a function of the molecular weight, calculated from the experimental data of Krigbaum⁶⁾.

According to the theories of Flory and Krigbaum³⁾, Grimley³⁾, and the previous one of ourselves⁴⁾, the Flory point does not depend on the molecular weight or degree of polymerization of polymers. However, from our present theory there is a possibility that the point depend on the molecular weight or degree of polymerization. The data of Krigbaum⁶⁾ show the possibility. We hope that this point will be elucidated in the near future.

So far we have only treated high polymer solutions. Overbeek and Sparnaay¹²⁾ reported that such type of attractive forces as calculated by de Boer and Hamaker¹⁾ and ourselves was found experimentally. Further applications of the potentials we have calculated will be given in a subsequent paper.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 1, JANUARY, 1957

Dependence of Quadrupole Coupling Constant on the Vibrational State in ICN Molecule

By Takeshi OKA, Hiromasa HIRAKAWA and Akira MIYAHARA*

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo, Japan

(Received September 20, 1956)

The microware spectrum of the hyperfine components of the $J=1\leftarrow 0$ and $J=2\leftarrow 1$ rotational transitions of ICN molecule has been measured and the dependence of quadrupole coupling constant on the vibrational state was found. The values of $(eqQ)_I$ for each vibrational state are as follows:

Vibrational States	$(eqQ)_I$ in Mc/sec from the frequencies of the $J=1\leftarrow 0$ transition	 from the frequencies of the $J=2\leftarrow 1$ transition
(0, 0, 0)	-2418.8 ± 0.5	-2420.1 ± 0.3
(1, 0, 0)	-2426.8 ± 0.7	-2425.1 ± 0.5
(0, 2, 0)	-2403.3 ± 0.8	-2403.1 ± 0.5

The difference in the $(eqQ)_I$ value for the (0, 2, 0) state from that for the (0, 0, 0) state, previously explained by Javan for the (0, 1, 0) state, was confirmed, thuogh the numerical values are slightly different from his. The change of $(eqQ)_I$ due to the excitation of the stretching vibration was also found and was explained in terms of the change of the double bond character of I–C bond.

§ 1. Introduction

The dependence of quadrupole coupling constant on the vibrational states of the molecule has been described by several authors.[1)–5)] Tetenbaum pointed out the change of $(eqQ)_{Br}$ of BrCN molecule when the bending viration was excited.[2)] Javan remeasured the lines of the $J=4\leftarrow 3$ rotational transition of ICN molecule and confirmed the change of $(eqQ)_I$ [5)]. He explained it taking into account the change of q, the gradient of the electric field along the nuclear axis produced by the electrons.

Though both of them did not refer to the change of the quadrupole coupling constant due to the excitation of the stretching vibration, this change seems to be possible, because the stretching vibration tends to elongate the bond and thus decreases the double bond character of I–C bond, which results in the increase of $(eqQ)_{\mathrm{I}}$. This work has been carried out with the aim of investigating these changes.

§ 2. Experiments and Results

The hyperfine components of the $J=1\leftarrow 0$ and $J=2\leftarrow 1$ rotational transitions of ICN molecule have been measured with the Stark modulation spectrometer of four meters in length. The frequencies have been obtained by extrapolating the observed frequencies at various Stark fields to those at zero field. The measured frequencies with the calculated ones are shown in Table I a and II a. For almost all lines, probable errors were less than 0.05 Mc/sec. The largest probable error amounted to 0.5 Mc/sec for the weakest lines.

I. Hyperfine components of the $J=1\rightarrow 0$ rotational transition.

Three hyperfine components due to the nuclear quadrupole moment of I^{127} were observed for each vibrational state, (0, 0, 0), (1, 0, 0), and (0, 2, 0). Since the initial state is $l=0$, (0, 1, 0) lines are not allowed. Because of the nuclear quadrupole moment of N^{14}, the lines are further split. This effect was taken into consideration in the analysis of the frequencies using the method proposed by Bardeen and Townes with -3.8 Mc/sec for $(eqQ)_{\mathrm{N}}$ of ICN molecule.⁷⁾ The lines of the excited vibrational states were so weak that the splitting due to the nitrogen quadrupole moment could not be measured. The values of $(eqQ)_{\mathrm{I}}$ and the rotational constants B derived from the measured frequencies and used in the calculation are listed in Table I b.

II. Hyperfine components of the $J=2\leftarrow 1$ rotational transition.

According to the selection rule $\Delta F=\pm1, 0,$

(0, 2, 0)	-2403.1 ± 0.5	3242.11 ± 0.05

nine hyperfine components should be observed for each vibrational state, (0, 0, 0), (1, 0, 0), (0, 2, 0), (0, 1, 0), and (1, 1, 0), where the last two allow l-doublets. Because of complexity of the Stark pattern of these l-doublets and their inadequacy for the purpose of this work, only strong lines belonging to the (0, 0, 0), (1, 0, 0), and (0, 2, 0) vibrational states have been measured. Many strong l-doublets with large Stark shift made it very difficult to measure accurately the lines which overlap with them, and some lines were abandoned for this reason. The values of $(eqQ)_{\mathrm{I}}$ and rotational constants B derived from these frequencies and used in the calculation are listed in Table II b.

§ 3. Discussions

The changes of $(eqQ)_{\mathrm{I}}$ due to the excitation of the bending vibration were 15.5 Mc/sec and 17.0 Mc/sec for the $J=1\leftarrow0$ and $J=2\leftarrow1$ transitions, respectively. Javan5) measured (0, 1, 0) lines and obtained 9.45 Mc/sec for the change, which corresponds to 18.90 Mc/sec of our case, because of the fact that the mean sequare amplitude is proportional to the vibrational quantum number. The gradient of the electric field when the bending vibration is excited is given by the formula, $q=(1-3/2\,\overline{\theta^2})q_0$5) where q_0 is the value of q for the ground vibrational state and $\overline{\theta^2}$ is the mean square amplitude of the deflection angle of I–C bond from its equilibrium direction when the bending vibration is excited. Using the above formula with the mean square amplitude calculated from the vibrational spectrum, the change of $(eqQ)_{\mathrm{I}}$ is calculated to be 12.6 Mc/sec. The rest of the change seems to be due to the fact that the valence electrons do not follow the motion of I and C nuclei.

The changes of $(eqQ)_{\mathrm{I}}$ due to the excitation of the stretching vibration are 8.0 Mc/sec and 5.0 Mc/sec for the $J=1\leftarrow0$ and $J=2\leftarrow1$ transitions, respectively. Though there is rather large discrepancy between these values, the change of $(eqQ)_{\mathrm{I}}$ is beyond the experimental error. This change may be explained by considering the change of the weight of the two resonating structures,6) $\mathrm{I{-}C{\equiv}N}$ and $\mathrm{I^+{=}C{=}N^-}$. The magnitude of q of the double bond structure is half as large as that of the single bond structure. When the stretching vibration is excited, the bond is elongated owing to the anharmonicity of the potential energy and thus the double bond character of I–C bond is decreased. This consideration explains the increase in the magnitude of $(eqQ)_{\mathrm{I}}$ in agreement with the experiment. The order of magnitude of this kind of change is estimated using Pauling's relation between the bond length and the double bond character. The change of the rotational constant B due to the excitation of the stretching vibration is assumed to be due to the proportional stretching of I–C bond and C–N bond, approximating the bond length of I–C bond in (1, 0, 0) state as $r_v=r_0\,(B_0/B_v)^{1/2}$, where r_0 is the bond length of I–C bond in the ground vibrational state and B_0 and B_v are rotational constants of the ground and excited vibrational states, respectively. Substituting the values in Table I b and II b with $r_0=1.995$ A8), it gives $r_v=1.998$ A. The double bond character x of I–C bond for ICN molecule calculated from the observed value of $(eqQ)_{\mathrm{I}}$ is 0.136). From Pauling's relation,9)

$$R=[R_1(1-x)+3R_2x]/[(1-x)+3x]\ ,$$

the variation of x due to the change of the bond length δR is calculated to be

$$\delta x=x(2x+1)\delta R/(R-R_1)\ ,$$

where R_1 is the I–C bond length when pure single bond is assumed. Substituting $x=0.13$, $R=1.995$ A, $R_1=2.10$ A, and $\delta R=r_v-r_0=0.003$ A, this formula gives the change of the double bond character due to the stretching of the I–C bond as $\delta x=-0.0047$. Though the value of 2.10 A for R_1 is not quite definite, the difference as large as 0.01 A in R_1 does not affect the first figure of δx. The gradient of the electric field is given by the formula,

$$q(x)=[-(1-s+d)(1-x)\\ -(1/2-s+d)(1+\mathcal{E})x]\,q_{510}\ ,$$ 10)

where q_{510} is the value of q for iodine atom, and s and d indicate the fraction of s and d

hybridization, respectively. Because of the positive ionization of the I atom in the $I^{+}=C=N^{-}$ structure, which pulls the electron closer to the nuleus, the factor $1+\mathcal{E}$ is multiplied to the second term. This is differentiated to give the variation of q due to the change of the double bond character x as

$$\delta q=[1/2-\mathcal{E}(1/2-s+d)]q_{510}\delta x\ .$$

For the case of I–C bond $s-d$ and $\mathcal{E}$ can safely be estimated to be 0.15 and 0.15, respectively. With these values and the above mentioned value of δx, it is shown that

$$q(1,0,0)/q(0,0,0)=1.0026$$

which is in fair agreement with the following experimental values

$$q(1,0,0)/q(0,0,0)=\begin{cases}1.0033 & (J=1\leftarrow 0)\\ 1.0021 & (J=2\leftarrow 1).\end{cases}$$

Major part of the discrepancy between the two values seems to be due to the experimental error, which arises chiefly from the weakness of the lines and the splittings due to the nuclear quadrupole moment of N^{14}. The value derived from the lines of the $J=2\leftarrow 1$ transition seems to be more reliable than that from the $J=1\leftarrow 0$ transition, because more appropriate lines could be adopted for analysis in the former case than the latter.

§ 4. Isotope Lines

The spectrum of the hyperfine components of the $J=1\leftarrow 0$ rotational transition for $IC^{13}N$ molecule in the (0, 0, 0) state was observed. The measured frequencies are shown in Table III. The hyperfine components of the $J=2\leftarrow 1$ transition of $IC^{13}N$ molecule could not be measured, being hidden by the complicated l-doubling lines of $IC^{12}N$.

Microwave Spectrum of Vinylidene Chloride

By Shōzō SEKINO* and Tetsuji NISHIKAWA**

Department of Physics, Faculty of Science,
University of Tokyo, Tokyo, Japan

(Received September 22, 1956)

The microwave spectrum of vinylindene chloride has been observed and analyzed. The molecular parameters have been determined to be $d_{CCl}=1.727$A and $\angle$Cl C C$=123°10'$ on the assumption of $d_{CC}=1.32$A, $d_{CH}=1.07$A and $\angle$H C C$=120°$. The quadrupole coupling constant along the bond direction has been found to be -78.7 Mc together with the asymmetry parameter $\eta=0.12$, for Cl^{35}. The five percent double bond character of C Cl bond estimated from the quadrupole data is consistent with the value of six percent estimated from the bond length.

§ 1. Introduction

It is known that the bond length, d_{CCl}, in carbone-chlorine compounds decreases as the electronic structure around the carbon atom tends to have more s character than sp_3 hybridization. For example, the bond length was determined to be 1.781 A in methyl chloride, whereas 1.632 A in chloroacetylene[1),2)].

These values are compared with the values of C H bond distance in methane 1.094 A and in acetylene, 1.059 A. Since the change in C Cl bond length, 0.150 A, is larger than that in C H bond, 0.035 A, some other effects besides the increase of s character in bonding electron of carbon atom have to be considered. The double-bond character of C Cl bond would take a considerable part in this change, while Duchesne[3)] presented an effect of the hybridization of chlorine atom which would change in a way as to increase the overlap integral between carbon and chlorine orbitals.

In these respects, it is interesting to examine the C Cl bond in chloroethylenes, in which the bonding electron around the carbon has sp_2 hybridization. The vinylidene chloride is such a typical molecule with a permanent dipole moment and a two-fold symmetry axis. The molecular structure was obtained by Brockway and others[4)] by an electron diffraction method. The bond length, d_{CCl}, and the bond angle, $\angle$Cl C Cl, were reported to be 1.69 ± 0.02 A and $116°\pm2°$, respectively, on the assumption of the bond length, d_{CC}, of 1.38 A. Theoretical discussion of the structure was given by Pauling, Brockway, and Beach[5)] on the line of Pauling's resonance method. However, their assumed value of C=C bond length seems to be too large compared with the recent value, ~1.32 A, in ethylene-like molecule determined by Karl and Karl[6)] and others.

The microwave investigation of this molecule can give informations of its structure and the quadrupole coupling constant of the C Cl bond which is another clue to examine the bond structure. Recently, Goldstein[7)] gave a method to estimate the double-bond structure from the asymmetry parameter of quadrupole coupling constant in a planar asymmetric molecule such as the chloroethylene.

§ 2. Experiment

The sample of vinylidene chloride was obtained from the Asahi Dow Chemical Company by courtecy of Dr. Y. Tsunoda. The boiling point is about 31°C. Though the pure one is coloreless, the sample used was colored with very little stabilizer (less than 1%) in order to prevent polimerization.

An ordinary Stark-modulation microwave spectrometer with sine-wave modulation at 120 kc superposed on a dc voltage was used. A three meter X-band absorption cell with teflon seals similar to that reported by Hardy and others[8)] was constructed. The vacuum system was composed of metals, glass, and teflon without using any other organic compound, since the sample is an active solvent.

Table I and II show the observed frequencies of nearly 90 lines in the frequency range

between 18 and 26 kMc/sec. Having two chlorine atoms in one molecule, the spectrum of vinylidene chloride shows very complicated quadrupole hyperfine structures which have been generally observed as unresolved broad lines. Therefore, rather large errors in frequencies are estimated as ±1.5 Mc/sec for very weak lines (*WW*), ±1 Mc/sec for weak lines (*W*), and ±0.5 Mc/sec for stronger lines.

§ 3. Analysis of the Observed Spectrum

Vinylidene chloride is a planar asymmetric top molecule, principal axes of which are shown in Fig. 1. The dipole moment (~1.3 D[9]) lies along b axis.

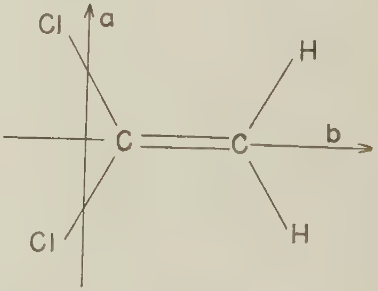

Fig. 1.

The rigid rotor model can be used in a good approximation for this molecule. The rotational energy was calculated by the method of King, Hainer, and Cross[10] using the Table of Turner, Hicks, and Reitwiener[11], and the Table of Erlandsson[12]. First, the molecular structure by Brockway and others was assumed in calculating frequencies. Comparing the calculated frequencies with the experimental data, the Q-branch lines could be assigned easily, and more accurate values of asymmetry parameter, $\kappa=\{2B-(A+C)\}/(A-C)$, as well as $(A-C)/2$, was determined. Secondly, using a relation $1/C=1/A+1/B$, $(A+C)/2$ could be estimated, so that the *R*-branch lines were assigned definitely. The assignments of lines with their calculated frequencies are shown in Table I both for $Cl_2{}^{35}C_2H_2$ and $Cl^{35}Cl^{37}C_2H_2$, while the lines of $Cl_2{}^{37}C_2H_2$ were so weak that they could not be assigned. Table III gives the rotational constants used in the calculation. The assignments of some *Q*-branch lines have been confirmed by their characteristic triplet patterns of their quadrupole hyperfine structures. The Stark effect study was also used to check the assignment of low *J* *R*-branch lines.

Table III. Rotational Constants of Vinylidene Chloride

	$Cl^{35}Cl^{35}C_2H_2$	$Cl^{35}Cl^{37}C_2H_2$
$\frac{A+C}{2}$ (Mc)	4902.9	4857.6
$\frac{A-C}{2}$ (Mc)	2563.9	2566.2
κ	−0.58178	−0.59948
A (Mc)	7466.8	7423.8
B (Mc)	3411.3	3319.2
C (Mc)	2339.0	2291.4
I_a (amu.A)	67.697	68.088
I_b (amu.A)	148.18	152.29
I_c (amu.A)	216.11	220.60
Δ (amu.A)	0.23	0.22

Calculated frequencies contain errors due to the centrifugal distorsion which are smaller than 1 Mc/sec even for $J=10$. Since the rotational constants in a vibrational state $v_1,\cdots,v_{12}$ are expressed as

$$A(v_1,\cdots,v_{12})=A_e+\sum_i \alpha_i\left(v_i+\frac{1}{2}\right)$$

$$B(v_1,\cdots,v_{12})=B_e+\sum_i \beta_i\left(v_i+\frac{1}{2}\right)$$

$$C(v_1,\cdots,v_{12})=C_e+\sum_i \gamma_i\left(v_i+\frac{1}{2}\right),$$

the equilibrium rotational constants, A_e, B_e, and C_e, can not be obtained, unless thirty six vibrational coupling constants, α_i, β_i, and γ_i are determined. Many vibrationally excited lines have been found for each rotational transition, but the complete analysis could not be done. Therefore, the calculated rotational constants in Table III include the error due to the zero-point vibration, the order of which can also be estimated from the quantum defect $\Delta=I_c-(I_a+I_b)$. The magnitude of quantum defect of vinylidene chloride is compared with those of related molecules as shown in Table IV.

§ 4. Molecular Structure

Five parameters are necessary in describing the molecular structure of vinylidene chloride. Two of them, d_{CCl} and $\angle$Cl C C can be calculated from the rotational constants A and B of $(Cl^{35})_2C_2H_2$, assuming d_{CC}, d_{CH} and $\angle$H C C. The rotational constants of $Cl^{35}Cl^{37}C_2H_2$ could also be used to determine the molecular parameters, but, actually, they give no further knowledge on account of the error due to zero-point vibration.

Because d_{CH} and $\angle$H C C would not be very different from those of ethylene values, and also because of the lightness of the hydrogen atom, it is safe to assume them equall to the ethylene values. The C C bond length of the ethylene molecule was determined to be 1.353 A from the infrared spectroscopic method by Gallaway and Barker[13]), while that of tetrachloroethylene was obtained to be 1.30 A from the electron diffraction method by Karle and Karle[6]). In any case, the values of $d_{CC}=1.38$ A assumed by Brockway and others appeared to be too large*. We have assumed the C C bond length of vinylidene chloride to be 1.32 A, and obtain the C Cl bond length of 1.727A ± 0.01A and the Cl C C bond angle of 123°10′ ± 1°30′, which are compared with the values of tetrachloroethylene, $d_{CCl}=1.72$ A and $\angle$Cl C C $=123°$. The probable errors of these values correspond to the change of assumed C C bond length by ±0.02 A.

§ 5. Quadrupole Coupling Constants

The quadrupole hyperfine structure of vinylidene chloride is very much complicated, since two chlorine atoms are in one molecule. The theory for this case was worked out by Robinson and Cornwell[14]). The perturbation energy described by the quantum numbers J and F, and a pseudoquantum number ε is written by

$$E_{\varepsilon JF}=X^{+}\lambda_{\varepsilon JF}\,, \qquad (1)$$

---

* It is also noticed that the C C bond length of 1.38A is nearly equal to that in benzene (1.39A), in which one must assume about 50 percent single bond structure in C C bond.

where

$$X^{+}=eQ\left(\frac{\partial^2 V}{\partial Z^2}\right)_{av}=\frac{eQ}{J(J+1)(2J+3)}$$
$$\times\left\{\frac{\partial^2 V}{\partial a^2}\left[J(J+1)+E(\kappa)-(\kappa+1)\frac{\partial E(\kappa)}{\partial\kappa}\right]\right.$$
$$+2\frac{\partial^2 V}{\partial b^2}\frac{\partial E(\kappa)}{\partial\kappa}+\frac{\partial^2 V}{\partial c^2}$$
$$\left.\times\left[J(J+1)-E(\kappa)+(\kappa-1)\frac{\partial E(\kappa)}{\partial\kappa}\right]\right\},$$

and Z is the axis along the direction of J. The values of $\lambda_{\varepsilon JF}$ were given in a table$^{14)}$. The coupling scheme is chiefly written by

$$\boldsymbol{I}_1+\boldsymbol{I}_2=\boldsymbol{I}\,,\quad \boldsymbol{I}+\boldsymbol{J}=\boldsymbol{F} \tag{2}$$

while a little contribution from another scheme,

$$\boldsymbol{I}_1+\boldsymbol{J}=\boldsymbol{F}_1\,,\quad \boldsymbol{I}_2+\boldsymbol{F}_1=\boldsymbol{F}\,, \tag{3}$$

have to be taken into account. $\boldsymbol{I}_1$ and $\boldsymbol{I}_2$ are the nuclear spin angular momentum vectors of two chlorine nucleus. The pseudo-quantum number, $\varepsilon=0, 1, 2, 3$, becomes equal to $\boldsymbol{I}$ when J becomes large. With the selection rules, $\Delta F=0, \pm1$ and $\Delta\varepsilon=0$, each rotational line splits into many hyperfine component lines.

Since the total wave function of vinylidene chloride is symmetric with respect to 180° rotation about the two-fold symmetry axis, b, a symmetric rotational wave function must be paired with a symmetric total spin function. The total spin function is composed of the spin function of chlorine nucleus and that of hydrogen nucleus; an odd ε line corresponds to a symmetric spin function of chlorine nucleus, whereas an even ε line corcesponds to the antisymmetric chlorine spin function. Therefore, if the rotational wave function is symmetric, the statistical weight due to proton spin is 3 for $\varepsilon=3$ and 1, and 1 for $\varepsilon=0$ and 2; the relation is revered for an antisymmetric rotational level. The lines corresponding to the transitions, $\Delta F=\pm1$ are negligibly weak and only the $\Delta F=0$ lines should be considered. The relative intensity of each $\Delta F=0$ line is approximately given by

$$(2F+1)\frac{\{F(F+1)-I(I+1)+J(J+1)\}^2}{F(F+1)}\times g_{IH} \tag{4}$$

$g_{IH}=3$ when $\varepsilon=3$, 1 for a symmetric rotational level.
when $\varepsilon=0$, 2 for an antisymmetric rotational level.
$g_{IH}=1$ for other lines.

For a Q-branch line, these component lines can be grouped into three, being observed as a triplet. The separation can be calculated from equation (1) taking the weighted means of unresolved components. These quadrupole triplets have been measured for $9_{45}\leftarrow9_{36}$, $10_{37}\leftarrow10_{28}$, and $13_{49}\leftarrow13_{310}$ lines. A typical Stark effect pattern of the triplet line is shown in Fig. 2.

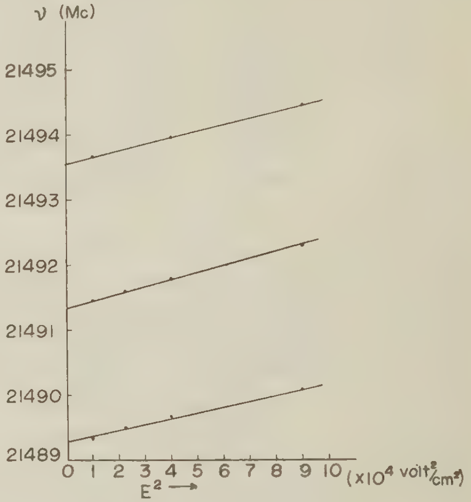

Fig. 2. Stark pattern of $10_{37}\leftarrow10_{28}$ line, showing quadrupole triplet.

From the observed separations of these triplet lines, the quadrupole coupling coefficient, $eq_{zb}Q$ (direction of C Cl bond), has been determined to be -78.7 ± 1.0 Mc/sec and the asymmetry parameter to be

$$\eta=\frac{q_{xb}-q_{yb}}{q_{zb}}=0.12\pm0.01 \text{ for Cl}^{35}.$$

§6. Discussion

The C Cl bond length and quadrupole coupling constant for various carbon-chlorine compounds are listed in Table *V*. It is noted that the bond length decreases systematically and the quadrupole coupling constant increases, as the *s* character of carbon bonding orbital increases. Following effects will be considered in addition to the change of *s* character of carbon orbital:

1) ionic structure with Cl^-,
2) double-bond character with Cl^+,
and 3) other effects concerning the charge distribution around the chlorine nucleus, such as hybridization of *s* character in the chlorine bonding orbitals.

Taking account these effects, the quadrupole coupling constant along the bond direction can approximately be written as[15]

$$eQ\approx\left[(-1+s)(1-i-k)-\left(\frac{1}{2}-s\right)(1+\xi)k\right]\times eq_{310}Q\ , \qquad (5)$$

where s, i, and k are the importance of s character in the chlorine bonding orbital, of ionic structure, and of double-bond character, respectively. ξ is a correction factor for the change in screening caused by positive ionizaton of chlorine atom, and it was estimated to be 0.15[16]. In this expression, the double-bond character with Cl^+ atom is assumed to be a p_σ bond of the same hybridized one as the single bond plus a pure p_π bond perpendicular to the bond direction.

In such an asymmetric planar molecule as vinylidene chloride, we can take the p_π bond perpendicular to the molecular plane or in the x_b direction. Then the double bond importance, k, is given by[7],

$$k=\frac{2}{3}\,\frac{\delta}{109.6(1+\xi)}\ , \qquad (6)$$

where $\delta\,(\mathrm{Mc})=eq_{yb}Q-eq_{xb}Q=-\eta eq_{zb}Q$. The importance of double-bond character has been calculated to be 5% for vinylidene chloride from the observed values. This value is compared with the double-bond character of 6% for vlnyl chloride determined by Goldstein[7]. He pointed out too, that these values appeared to be considerably smaller than the value of 18% estimated from the bond length of 1.69 A by Pauling and others[5]. However, if we take the C Cl bond length of 1.72~1.73 A (See also Appendix for vinyl chloride), the importance of double-bond character is now calculated to be 5~8% using Pauling's method. The consideration on the dipole moment also imparted the importance of about 7%[17].

On the other hand, the importance of ionic structure, i, is not uniquely determined from the observed quadrupole coupling constant until the bond hybridization is determined. It seems unfavourable, however, to suppose as Duchesne[3] that the change of s character would play considerable role in the carbon-chlorine bonds. We can rather assume that the hybridization of chlorine atom is constant for C Cl bonds in various molecules, and to be 15% for p_σ bond and 0% for p_π bond[18]. Based upon this assumption, we have obtained he ionic character from the observed $eq_{zb}Q$ to be about 15% for vinylidene chloride and vinyl chloride.

Accordingly, the importance of double-bond character and ionic structure for various carbon-chlorine compounds are shown in Table VI. In this table, the double-bond character and the ionic structure were determined in order to give the observed quadrupole coupling constant when the s character of 15% was assumed for p_σ bonds. As is known, the double-bond character of 17% for Cl C N and Cl C C H is rather small to explain the shorteness of their C Cl bond length, whereas it is too large to explain the C N or C C bond length of these molecules. This interal inconsistency needs further discussion on the nature of C Cl bond.

Table IV. Quantum Defects

Molecule	Δ(amu.A)
$C_2H_2F_2$	0.143
$C_2H_2Cl^{35}F$	0.191
$C_2H_2Cl^{37}F$	0.190
$C_2H_2Cl^{35}Cl^{35}$	0.23
$C_2H_2Cl^{35}Cl^{37}$	0.22
$C\,Cl^{35}Cl^{35}O$	0.251
$C\,Cl^{35}Cl^{37}O$	0.252
$C\,H_2O$	0.057

On the other molecules than vinylidene chloride, the above values were taken from reference 1).

Appendix: The Structure of Vinyl Chloride

The microwave spectrum of vinyl chloride

was studied by Goldstein and Bragg.[19] Goldstein[7] calculated the bond angle, $\angle$Cl C C, to be about 123° on the assumption of Brockway's value;
$d_{CC}=1.38$ A, $d_{CCl}=1.69$ A, $d_{CH}=1.08$ A and $\angle$C C H$=120°$.

We have, however, reexamined the structure on our assumption of $d_{CC}=1.34\pm0.02$ A, and the results are $d_{CCl}=1.724\pm0.015$ A and $\angle$Cl C C$=120°3'\pm30'$. This value of C Cl bond length also agrees with the C Cl bond length of vinylidene chloride and that of tetrachloroethylene. The assumed bond length d_{CC} of 1.34 A has been chosen by interpolating the values of those in ethylene, vinylidene chloride, and tetrachloroethylene.

Table VI. Double-bond character and ionic structure of various carbon-chlorine compounds.

Molecule	Importance of double-bond character (%)	Importance of ionic structure (%)
CH_3Cl*	0	20
C_2H_3Cl	7	16
$C_2H_2Cl_2$	5	15
C_2HCl*	18	0
CClN*	17	0

* See reference 1)

The quadrupole coupling constant along the bond direction, $eq_{zb}Q(Cl^{35})$, and the asymmetry parameter, η, have also been calculated to be -77.8 Mc and 0.20, respectively. These values give the importance of double-bond character of 7% and that of ionic structure of 16% as shown in Table VI.

Line Width of the Pure Quadrupole Resonance of Bromine in $NaBrO_3$

By Yoshitaka Kôi

Faculty of Technology, Tokushima University, Tokushima

(Received September 27, 1956)

Using a regenerative spectrometer the line widths of the two bromine isotopes in $NaBrO_3$ were measured at melting ice and liquid oxygen temperatures. The full width at half-maximum intensity of Br^{79} is 3.85 ± 0.1 kc and that of Br^{81} is 4.09 ± 1 kc. No observable dependence of the line width on temperature was found. From the ratio of the line widths it is concluded that the main cause of the line width in $NaBrO_3$ is the magnetic dipole interaction, and the contribution from the relaxation is of the order of 0.1 kc.

§ 1. Introduction

The pure quadrupole resonance of bromine in solid state has been investigated for a good many compounds by many workers. The positions of the resonance lines and the problems relating to the positions are their main concerns, the origin of the line width, however, is also an interesting problem. The possible causes of the line broadening are spin-lattice relaxation, magnetic dipole interaction, and field fluctuation due to the crystal strain. The electron-coupled spin-spin interaction found by Kojima and Tsukada[1] in iodine crystals will be important provided that the atom bonded covalently to bromine has a nuclear magnetic moment. However, this condition is met only in a few compounds such as Br_2. Therefore, in most compounds the above three are the possible causes. Their contributions to the observed line width are, however, not yet fully understood. Fortunately, since the two equally abundant bromine isotopes Br^{79} and Br^{81} have the same spin number 3/2 and the isotope with the larger magnetic moment has the smaller quadrupole moment, comparison of the widths of the two isotopes in one and the same chemical compound should give much information about this problem. From this point of view, measurements of the line width were made on the bromine isotopes in $NaBrO_3$ at melting ice and liquid oxygen temperature.

$NaBrO_3$ gives the sharpest resonance of all the bromine compounds. The resonant frequency of Br^{79} is about 180 Mc at 0°C, and that of Br^{81} is 150 Mc[2]. The ratio of the quadrupole couping constant of Br^{79} to that of Br^{81} is 1.2. By the way, the magnetic moment of Br^{79} and Br^{81} is 2.1058 and 2.2296 nuclear magnetons respectively; the ratio between them is 0.928.

A brief report of a regenerative spectrometer and the result of measurement made on one sample has already been reported[3]. In this article are given the details of the experimental method and the results of later measurements made on several samples with more precision. A conclusion different from the previous one was drawn from the results of later measurements.

§ 2. Regenerative Spectrometer and Experimental Procedure

The resonant frequency of bromine is in the range of 140–350 Mc, and for the detection of the resonance super-regenerative spectrometers with Lecher's lines are usually used

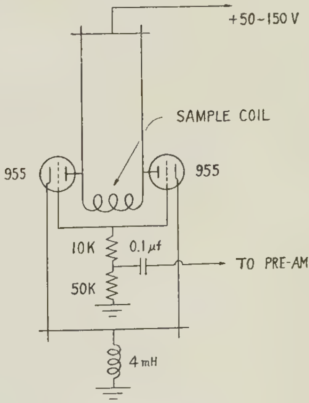

Fig. 1. Regenerative spectrometer. When a quenching voltage is applied to the top of the choke, this can be used as a super-regenerative one.

because of their simplicity and high sensitivity[4][2]. However, super-regenerative scheme seems not to be suitable for the study of line shape and line width, because the line shape depends upon the amplitude and frequency of the quenching voltage. Therefore, in order to get reliable results, it is necessary to use a regenerative spectrometer. The circuit shown in Fig. 1 has proved to be usable for this purpose.

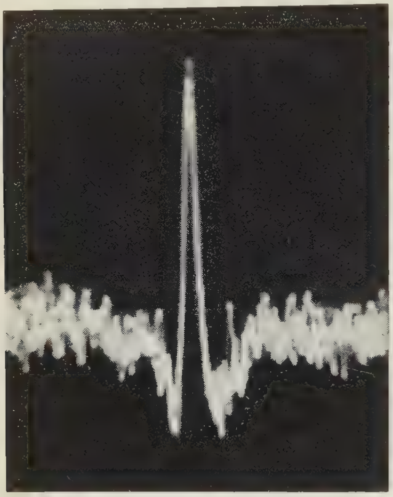

Fig. 2. Oscilloscope trace of the pure quadrupole resonance of Br^{81} in $NaBrO_3$ at melting ice temperature.

It is similar to the one used by Dehmelt[4] as a super-regenerative spectrometer, but with an important alteration that a choke is used in place of the cathode resistance. This choke is characteristic of the circuit and has the role of preventing the self-quenching oscillation. The detection principle is obvious and needs no account. Fig. 2 shows the absorption line of Br^{81} at melting ice temperature displayed on a cathode ray oscilloscope. From the oscilloscope trace, rough measurement of the line width is possible, but very precise one is impossible.

Accordingly, the derivative of the absorption line was recorded by means of conventional narrow-band and phase-sensitive detection technique, the spectrometer being frequency modulated at 210 cps.

Fig. 3 shows the schematical side view of the spectrometer and the block diagram of the whole measuring system. The frequency modulator is a metal foil attached to a $6\frac{1}{2}''$ dynamic speaker and placed near the plate Lecher's lines as shown in Fig. 3. The frequency sweeper is another metal foil placed also near the plate Lecher's lines and rotated slowly with a clock motor suitably reduced. The level of oscillation was kept sufficiently weak, though there seemed to be no tendency for the line to saturate. The spurious 210 cps voltage due to the frequency modulation was cancelled by applying a suitable voltage to the suppressor grid of the pre-amplifier from the 210 cps oscillator.

As is well known, in order to obtain the faithful derivative of the line, the modulation amplitude must be sufficiently small with respect to hte line width. However, the signal-to-noise ratio decreases with the amplitude. As a compromise between these two conside-

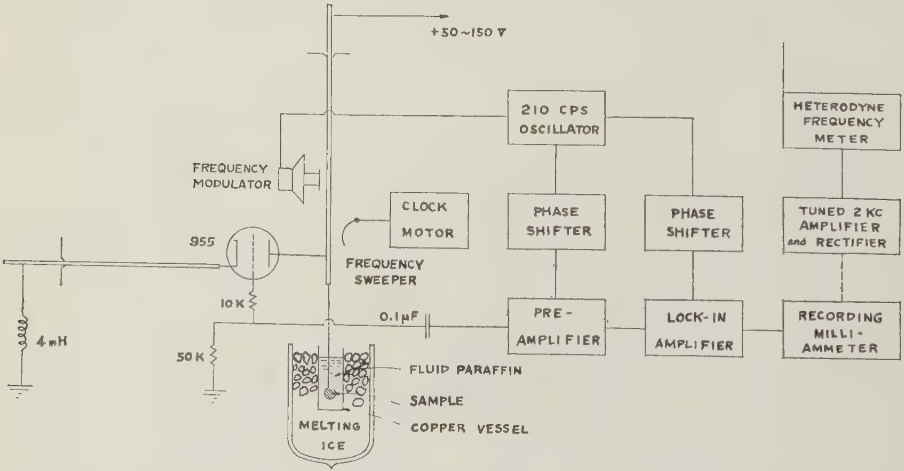

Fig. 3. The schematical side view of the spectrometer and the block diagram of the whole measuring system.

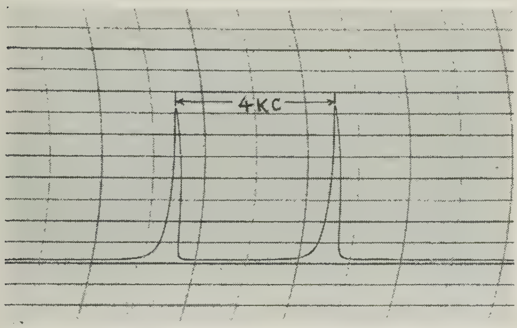
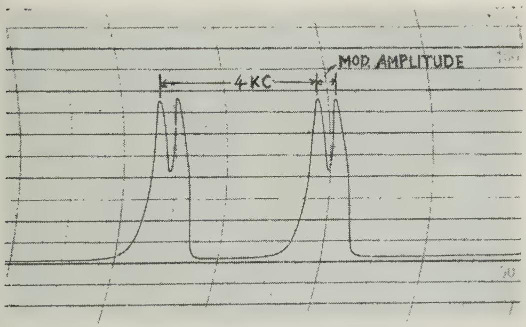
rations, amplitudes used were about one-tenth of the line width. When they were of this order of magnitude, there was no effect of modulation on the line width. They were measured by the following way.

The electromagnetic wave from the spectrometer was received with a heterodyne frequency meter, whose dial was fixed at a suitable position. Then the mean frequency of the spectrometer was swept slowly. The beat-output produced between the spectrometer and the frequency meter was amplified with a tuned 2 kc amplifier and rectified with a diod. The rectified output was recorded with the recording meter. In Fig. 4 are shown the records of the 2 kc beat. From these records the modulation amplitude and also the sweep rate of the mean frequency were able to be measured easily. The sweep rates used were 0.2–0.3 kc per second, and the times required to sweep over the absorption lines were 1–2 minutes. The time constant of the phase-sensitive detector and the associated circuit was 0.25–0.5 sec.



(a) Medulation amplitude = 0



(b) Modulation amplitude = 0.5 kc

Fig. 4. Records of the 2 kc beat.

Since the resonant frequency has a temperature coefficient of the order of 100 parts per million per degree C[5,2], even a temperature inhomogeneity of the order of 0.01°C in the sample may cause a considerable broadening of the line width. Therefore, for precise measurement of the line width, it is essential to keep the sample at a constant temperature. Accordingly, the sample was immersed in a fluid paraffin whose temperature was kept at 0°C by means of melting ice as shown in Fig. 3. For the observations at liquid oxygen temperature the sample was immersed directly in a liquid oxygen. In this case the sample coil and the plate Lecher's lines were connected through condencers in order to prevent heat conduction.

The terrestrial magnetic field also gives rise to a broadening of the line width[6]. Therefore, its horizontal and vertical components were concelled separately by two small permanent magnets placed about 35 cm apart from the sample.

The samples used were assemblages of small crystal grains prepared by means of recrystallization from aqueous solutions of $NaBrO_3$ which was purified by repeated recrystallizations. The sample No. 1 was recrystallized with slowest rate, each grain of which is transparent and about 10 mm^3 in volume. No. 3 was rather rapidly recrystallized and may well be said to be a powder. No. 2 is intermediate between No. 1 and No. 3 with respect to both the speed of recrystallization and the size of the grain.

§ 3. Results and Discussions

The results of measurements are tabulated in Table I. The experimental derivative of Br^{81} and its integration are also shown for No. 1 in Fig. 5. The line shape is symmetric and has an intermediate character between a Lorentzian and a Gaussian shape, but it is rather close to the latter. Measurements at liquid oxygen temperature were made only on the sample No. 1. No measurable dependence of the line width on temperature was found. It is seen from the Table I that there

Table I. Width at half-maximum intensity (kc).

Sample	Br^{79}	Br^{81}
No. 1	3.85±0.1	4.09±0.1
No. 2	4.80±0.2	4.85±0.2
No. 3	6.55±0.2	6.25±0.2

is a considerable change of the line width with the samples, that is, the width and the ratio of the line width of Br^{79} to that of Br^{81} increase with the speed of recrystallization. Since, however, this is obviously to be attributable to the crystal strain, only the result on the sample No. 1, which gave the sharpest resonance and can be considered to be an assemblage of perfect crystal grain, will be discussed in the following.

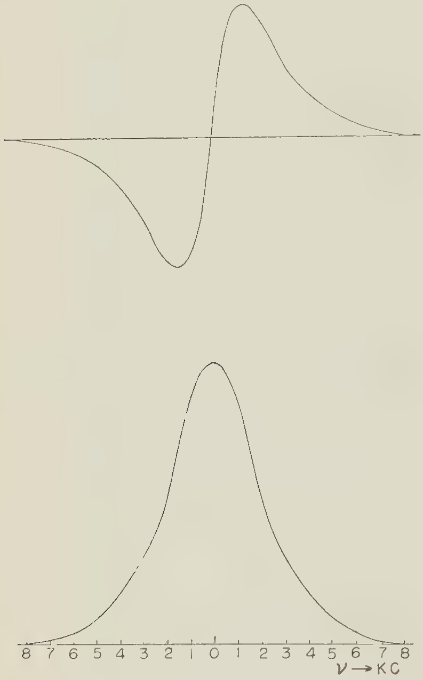


Fig. 5. Line shape of Br^{81} in $NaBrO_3$. The upper curve is the experimental derivative, and the lower is its integration.

As mentioned already, the possible mechanisms of the line broadening are the following: quadrupole spin-lattice relaxation, magnetic dipole interaction, and field fluctuation due to the crystal strain. If the first mechanism predominates, the ratio of the line widths for the isotopes Br^{79} and Br^{81} will be equal to the ratio of the squares of their quadrupole coupling constants, i.e. 1.44⁷⁾. If the second predominates, it will be equal to the ratio of their magnetic moments, i.e. 0.928, and if the third predominates, the ratio of their quadrupole coupling constants, i.e. 1.2. Of the line widths due to these mechanisms, only that due to the relaxation will depend on and decrease with temperature⁸⁾. As to the line shape, the first mechanism will give the Lorentzian shape, and the second, if there are many interacting neighbours as in the case of bromine in $NaBrO_3$, the Gaussian⁹⁾. The line shape due to the strain would depend on its nature.

Now the observed ratio is 0.94, a value which is almost equal to the ratio of the magnetic moments. Therefore, it can be concluded that the main cause of the line width of perfect $NaBrO_3$ crystal is the magnetic dipole interaction (between bromine nuclei themselves and between bromine and sodium nuclei), and the contribution from the relaxation to the line width is very small. This conclusion is in accordance with the facts that there was no observable dependence of the line width on temperature and that the line shape is rather close to the Gaussian. Abragam and Kambe¹⁰⁾ have given formulas for the contribution from the dipolar broadening to the second moment of the resonance line. Unfortunately, their formulas can not be adapted to the case of $NaBrO_3$, because there are four different directions of the electric field gradient in this substances, so that it is not possible at present to evaluate exactly the dipolar broadening. The observed values are, however, of the right order of magnitude as dipolar width.

If it is assumed somewhat arbitrarily that the width due to the strain is negligible, and those due to the dipole interaction and the relaxation are additive, the last one can be estimated to be of the order of 0.1 kc from the ratio of the line widths. Further, using the formula $\Delta\nu=1/2\pi T_1$¹¹⁾, the relaxation time T_1 of Br^{81} can be estimated to be of the order of 0.001 sec from the width due to the relaxation. Although the T_1 of Cl^{35} in $NaClO_3$, which has the same crystal structure as $NaBrO_3$, is known to be 0.4 sec¹²⁾, that of Br^{81} in $NaBrO_3$ is not yet measured. If the foregoing argument is extended to Cl^{35}, the latter is estimated to be 0.002 sec, because the quadrupole coupling constant of Br^{81} in $NaBrO_3$ is five times that of Cl^{35} in $NaClO_3$. The value is in substantial argeement with the order of magnitude estimation from the ratio of the line widths.

The author would like to express his sincere thanks to Dr. T. Kushida for valuable suggestions and kind reading of the manuscript. He also wishes to thank Messrs. A.

Tsujimura and T. Fuke for the cooperation in the earlier stage of this experiment. This work was partially supported by the Scientific Research Expenditure of the Ministry of Education.

Gloss of Machine Glazed Papers

By Jien NISHIWAKI

Department of Physics, Faculty of Science,
Tokyo Metropolitan University

(Received August 23, 1956)

The flux I_0 reflected at specular angles 45°–45° from the surface of glossy paper and the assumed value of its diffuse component I_2 defined experimentally are measured with a goniophotometer. The ratio of I_0 to I_2 is taken as a measure of gloss, and denoted by G_{NF} according to an earlier paper of E. Fukushima.[1]

For a series of machine glazed papers differing considerably in colour, the values of C_{NF} are compared with the visual gradings of 36 Japanese observers, and a linear correlation of the logarithm of G_{NF} with the visual gloss is found with a correlation coefficient +0.986 except for two papers. The method of determining the value of I_2 is also introduced and the voting distributions of the observers for the gloss of the papers are discussed.

§ 1. Introduction

If the illuminator and receptor axes of a goniophotometer are fixed with any given angle ϕ between them (this is kept 90° throughout the experiment), and the glossy surface of specimen is so rotated that its normal approaches the receptor axis from the initial position of specular reflection, the reflected flux I generally decreases rapidly first and slowly then as the angle of rotation θ increases. For many papers, the slowly decreasing part of I–θ curve has been found to be expressed approximately by $I_2 \exp(-\beta\theta^n)$, where the two constants I_2 and β depend on the sample and the other constant n on the optical geometry of goniophotometer. The value of n is equal to 2 for the photometer[2] used here which has the geometry to measure the relative brightness. A typical form of I–θ curve obtained with this photometer is shown in Figs. 1 and 2. In Fig. 1 I is plotted against θ, and in Fig. 2 $\log I$ against θ^2. From Fig. 2, I_2 can be estimated and is assumed to be the diffuse component of I_0 which is the value of I at $\theta=0$, the position of specular reflection. Thus the ratio of I_0 to I_2 may be supposed to be one kind of contrast gloss and is denoted by G_{NF}. This notation was originally adopted by E. Fukushima. In his photometer which had different geometry, above constant n was 1, whereas in the present photometer of higher resolving power and a wider available range of θ, n is 2.

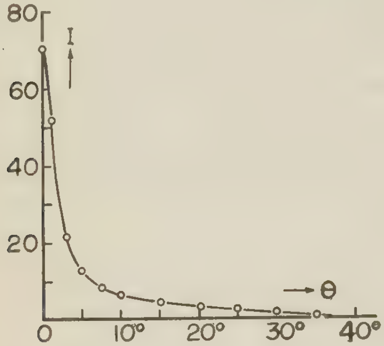

Fig. 1. A typical I–θ curve.

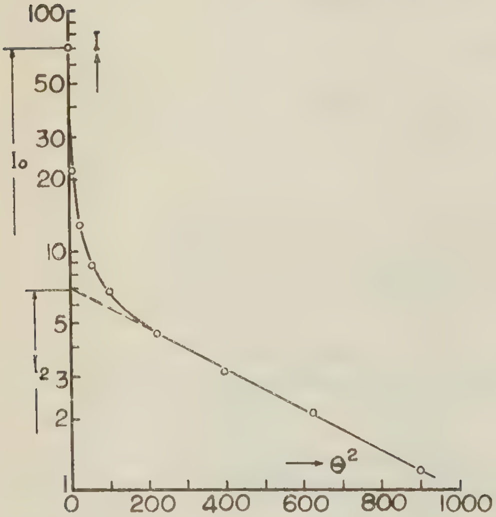

Fig. 2. log I–θ^2 curve corresponding to Fig. 1.

The author has been supplied through Professor E. Fukushima with a series of samples of machine glazed papers differing considerably in colour which he had received from Dr. V. G. W. Harrison of Printing, Packaging and Allied Trades Research Association, Leatherhead, Surrey, England.

The object of the present work is to compare the value of G_{NF} with the visual gloss for these papers. The colours of the papers evaluated by Harrison[3)] are recorded in Table I. The papers may be divided into two groups with respect to the excitation purity. Six papers A, B, D, E, L and M have the values smaller than 10%, and the others larger than 30%.

Table I. Colours of papers for C. I. E. Illuminant A evaluated by Harison[3)]. The values of chromatic coodinates are not quoted here.

Paper	Dominant wave-length (mμ)	Excitation purity (%)	Luminance factor (%)
A	490	0.4	63.0
B	508	8.7	32.3
C	587	40.5	22.3
D	603	4.1	46.7
E	589	2.0	58.8
F	588	49.1	30.2
G	591	43.5	23.6
H	590	37.2	30.2
I	595	48.3	25.7
K	589	42.2	30.0
L	499	1.2	4.2
M	430	5.7	15.5

§ 2. Experimental

With the method described above the specularly reflected flux I_0 and its diffuse component I_2 for each paper were measured. Their values in terms of scale reading and the logarithms of $G_{NF}=I_0/I_2$ are shown in Table II. The samples were backed with black matt papers througout the whole experiments.

Table II. The values of I_0, I_2 and log G_{NF}.

Paper	I_0	I_0	$\log_{10}G_{NF}$ $=\log_{10}I_0/I_2$
A	40.0	15.0	0.426
B	38.0	11.0	0.539
C	52.0	7.7	0.830
D	40.2	12.0	0.524
E	46.1	15.0	0.487
F	36.0	8.6	0.622
G	49.2	7.2	0.834
H	31.5	9.5	0.526
I	44.4	9.0	0.694
K	47.5	10.2	0.668
L	28.0	1.53	0.767
M	43.5	6.9	0.800

According to the records obtained in other experiments[2)], the value of log G_{NF} for a craped kraft paper, extremely matt, was 0.055. It was also of the same order for non-glazed ceramic surfaces or plaster surfaces. And that of a high glossy red flint paper was 1.77. The present papers had the intermediate values of 0.43 to 0.83.

In order to obtain the visual gradings for these papers, 36 Japanese observers were asked to arrange the samples visually in ascending order of gloss. The assessment of individual observer was generally carried out under uniform diffuse daylight through a winder facing south in a light room of his laboratory or home. He was also asked to be so situated that he could catch the specularly reflected light from the sample under about 45°-45° conditions of illuminating and viewing on the average.

Table III. Voting Distributions of 36 Japanese Observers.

Paper	Least Glossy					Rank						Most Glossy
	1	2	3	4	5	6	7	8	9	10	11	12
A	23	6	1	1	0	3	0	0	0	1	0	1
B	0	5	2	3	3	7	4	4	4	3	1	0
C	0	0	1	1	2	0	0	0	6	7	12	7
D	2	7	4	10	4	4	3	2	0	0	0	0
E	0	3	6	3	2	4	11	2	3	1	1	0
F	2	4	4	5	6	5	2	6	1	1	0	0
G	0	0	0	1	1	2	1	0	3	7	10	11
H	4	9	9	4	2	1	3	2	1	0	1	0
I	1	1	3	2	3	4	2	7	6	5	1	1
K	0	1	5	5	7	1	4	6	4	1	0	2
L	2	0	0	1	5	4	4	6	6	2	4	2
M	2	0	1	0	1	1	2	1	2	8	6	12

The actual voting of all the observers is summarized in Table III, where the figures relate to the number of votes for each of the possible rankings from 1 to 12. The means (μ) of these voting distributions are shown in the 2nd column of Table IV. But the forms of those distributions in Table III are not well defined. For some papers, particularly for papers E and K, they have two peaks neither of which can be ignored. This is supposed to be due to the systematic difference in the rankings given by the two groups into which the observers are divided.

The first group consists of 18 observers who had not so far participated in any similar test, and the second consists of the other 18 observers who had the experience several times in the past. The former group is denoted by Group I, and the second by Group II. The means of the voting distributions of each group are shown in the 3rd and 4th columns of Table IV.

Table IV. Means μ of voting distributions.

Paper	All observers	Group I	Group II	All Observers	
					Reduced value
A	2.3	3.1	1.5	2.1	2.3
B	6.2	7.2	5.2	exc.	—
C	9.9	9.9	9.9	8.1	9.8
D	4.1	4.9	3.4	3.6	4.2
E	5.9	7.1	4.7	exc.	—
F	5.1	4.8	5.3	4.4	5.2
G	10.2	9.6	10.8	8.4	10.2
H	3.8	3.4	4.3	3.4	3.9
I	7.1	5.9	8.3	5.8	6.9
K	6.2	5.4	7.1	5.3	6.3
L	7.6	6.8	8.4	6.2	7.4
M	9.6	10.1	9.1	7.7	9.3

For two papers B and E, the means given by Group I are considerably higher than the means given by Group II. Similar differences can also be found for papers A, D and M though they are not appreciably large. The values of excitation purity for these five papers are all smaller than the other papers except a black paper L, as shown in Table I. Thus it seems that many observers in Group I evaluate the gloss of so-called " more white " papers higher than those in Group II. The similar ambiguous effect of colour in relation to whether the observer is experienced or not has been found too in another experiment[2] where a different series of papers were graded. But this will be a subject of further study.

It is only indicated here that the exclusion of two papers B and E from the rankings of every observer was found to give fairly normal or moderate skew distributions for the rest of the papers. The means of those distributions are shown in the 5th column of Table IV. If the values of the means of the least and most glossy papers A and G are raised to those in the 2nd column and re-arrange the scale accordingly, it enables the relative positions of the other eight papers to be compared with those given by the means in the 2nd column. The reduced values for the means in the 5th column to this scale are easily calculated by the expression

$$\mu' = 2.3 + (\mu - 2.1)(10.2 - 2.3)/(8.4 - 2.1)$$

where μ represents the original value of the means for any paper. The results are shown in the last column of Table IV. Each of these values is almost equal to the corresponding one in the 2nd column. It may be then concluded that, the irregular forms of distributions in Table III originate mainly from the disagreement of the two groups for the gloss of papers B and E. Though the means for these two papers are not acceptable, the means for the other papers can be taken as the gloss value judged by all the observers, in spite of such indeterminate forms of distributions.

In Fig. 3 the values of log G_{NF} in Table II are plotted against the means of the voting distributions of all the observers in the 2nd column of Table IV. Except the doubtful points for papers B and E, all the points lie close to a straight line and the correlation coefficient is +0.986.

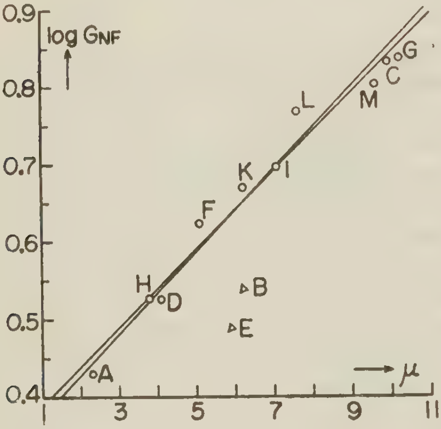

Fig. 3. Correlation between log G_{NF} & μ. (all observers)

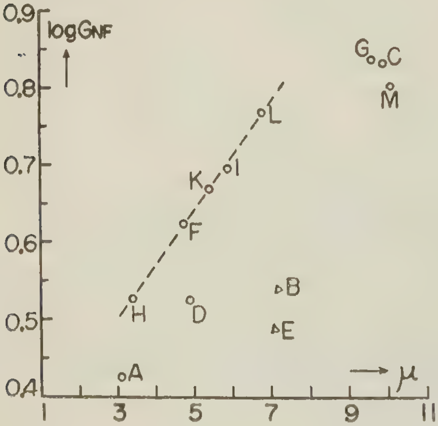

Fig. 4. Correlation between log G_{NF} & μ (Group I).

The result of plotting the values of log G_{NF} against the means given by Group I is shown in Fig. 4. The points for five papers—H, F, K, I and L—lie almost on a straight line and the points for parers B and E deviate far from this line to the higher end of the scale. If these two papers are properly down-graded, points for them will be placed more to the left and this will shift the above five points to the right. Thus the correlation will become linear. This is nearly the case in Fig. 5, where the values of log G_{NF} are shown against the means given by Group II. In this case, the correlation coefficient is +0.971 without exception.

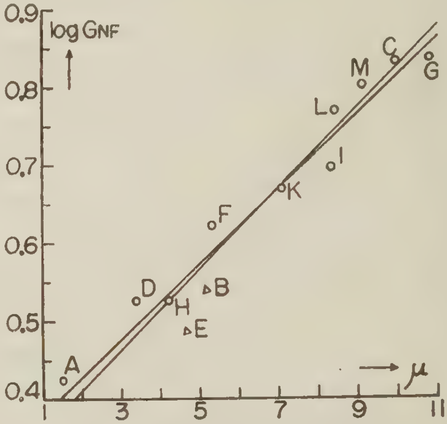

Fig. 5. Correlation between log G_{NF} & μ (Group II).

§ 3. Discussions of Disagreement with Other Visual Gradings

For the papers given above the visual gradings of 476 Swedish observers have been obtained by Steenberg[3] and many series of gradings of British observers under various viewing conditions by Harrison[3]. No good correlation of G_{NF} with any of these series of gradings could be found. This means that there is a considerable disagreedent between Swedish or British and Japanese observers. It may be due partly to the somewhat different viewing conditions and partly to the small alterations of surface or colour undergone by the samples. It must be also taken into account that the same samples have not been used for grading by all the groups of observers. The viewing conditions of Japanese observers are more or less similar to those of five British observers where the samples are illuminated at 45° with a uniformly diffused light through an opaque rectangular frame. Table V shows the rankings nearest the judgements of these five observers on the 2nd row and those nearest the values of log G_{NF} on the 3rd row. Except for the pale green paper B which might have faded appreciably, the difference between rankings for each paper is not so large.

If the rank for B on the 3rd row is raised from 5 to 8, the differences will become 1 or less except 1.5 for one paper H. The resulting rankings are shown on the 4th row of this table. The remaining minor differences will probably be attributed to the various factors mentioned above. In any case, it is likely that the illuminating and viewing conditions are the most important factors.

Table V. Rankings nearest the judgements of 5 British observers and the values of $\log G_{NF}$.

	A	B	C	D	E	F	G	H	I	K	L	M
5 British observers	1	8	11	4	3	6	12	2	7	5	$9\frac{1}{2}$	$9\frac{1}{2}$
$\log G_{NF}$	1	5	11	$3\frac{1}{2}$	2	6	12	$3\frac{1}{2}$	8	7	9	10
$\log G_{NF}$ (modified)	1	8	11	$3\frac{1}{2}$	2	5	12	$3\frac{1}{2}$	7	6	9	10

§ 4. Conclusions

The value of $\log G_{NF}$ may be supposed to be the diffuse component, expressed in logarithmic scale, of the reflected flux I_0 at given specular angles, since

$$\log G_{NF} = \log I_0/I_2$$
$$= \log I_0 - \log I_2$$

where I_2 is the diffuse component of I_0. For an extremely matt surface such as mentioned § 5, this value becomes approximately zero. Accordingly, the experimental results, though accompanied by a few doubtful exceptions, suggest that this value is practically proportional to the visual gloss estimated under the viewing conditions similar to that of the photometer with which G_{NF} is measured. But no claim is made to finalty.

The author's sincere thanks are due to Professor E. Fukushima for his advice and also to Dr. V. G. W. Harrison for his valuable suggestion as told to Prof. Fukushima.

Application of the M^2-Expansion Method to Compressible Flow past Isolated and Lattice Aerofoils

By Isao IMAI

*Institute for Fluid Dynamics and Applied Mathematics, University of Maryland, U.S.A.**

(Received September 12, 1956)

In this paper two-dimensional compressible flow past an arbitrary aerofoil in unlimited fluid or past a straight lattice of aerofoils is considered on the basis of the M^2-expansion method, which consists in expanding various quantities in powers of M^2, M being the Mach number.

The general expressions for the velocity components at any point in the field of flow are obtained, which are correct to M^4 for an isolated aerofoil and to M^2 for a wing lattice respectively. In particular, the formulae giving the velocity distribution on the surface of the aerofoil are of such a simple form that the numerical calculation for any arbitrary aerofoil or lattice of aerofoils is no longer a prohibitive work as generally believed.

As an interesting special case, the flow past a symmetrical aerofoil placed symmetrically in a channel is also considered, which was previously dealt with by Goldstein and Lighthill by means of a different method.

§ 1. Introduction

For the calculation of subsonic flow of a compressible fluid past an arbitrarily given aerofoil there are at present two methods of successive approximation, that is, the M^2-expansion method and the thin-wing-expansion method. As is well known, the former is preferable to the latter for moderately thick profiles.

After Janzen and Rayleigh's original work, a number of variants of their method have been put forward. The most famous among them is perhaps the method of Poggi16),17), which has been employed successfully by Kaplan11),12), Tomotika and Tamada20) and Tomotika and Umemoto22) for the investigation of flow past elliptic cylinders and Joukowski aerofoils. Also, Kaplan13) and Tomotika and Tamada (unpublished) have used the theory of residues to improve on the Poggi method.

On the other hand, the present author has simplified the original method of Janzen and Rayleigh by the use of complex variables4),9) and later by introducing complex velocity potential just as in the theory of incompressible flow, developing a systematic procedure of successive approximation5). Further, on the basis of this procedure the author7) has obtained general formulae which enable us to calculate the velocity distribution on the surface of any arbitrary aerofoil exact to M^4, M being the Mach number. As examples of application of the method, a circular cylinder with arbitrary circulation and a circular arc aerofoil set parallel to the uniform flow have been dealt with correctly to M^4 7). Flow past an elliptic cylinder with its major axis parallel to the undisturbed flow was also dealt with to the order M^2 by the author8), and later to M^4 by Kawaguti14) with the aid of the formulae. Also, in order to test the practicability of the method, purely numerical calculations have been carried out for flow past elliptic cylinders and Joukowski aerofoils by the author with the cooperation of Kawata10) and Sindi (unpublished) respectively.

Similar treatment based on the use of complex variables has been independently made by Goldstein and Lighthill2); their analysis is more general than ours in one respect that it covers the case of a solid body symmetrically placed in a channel as well as a single body in unlimited fluid, but it is confined to the first approximation (i.e. correct to M^2) only. Moreover, their final formulae are apparently more complicated than ours. In fact, as yet no effort seems to have been made to carry out numerical calculation based on their method.

---

* On leave of absence from the University of Tokyo.

Part I of the present paper is concerned with the refinement of the author's previous formulae concerning the velocity distribution on the surface of any arbitrary aerofoil, such that the number of necessary numerical integration involved is reduced. Moreover the formulae for the calculation of velocity components at any point in the field of flow will be explicitly given in this paper, while the procedure to be taken for such a purpose has already been given implicitly in the previous paper⁶⁾.

In part II is considered the compressible flow past an arbitrary straight lattice of aerofoils, and various formulae, exact to M^2, analogous to those for an isolated aerofoil are derived. The case of a symmetrical body symmetrically placed in a channel, which has been treated by Goldstein and Lighthill²⁾, is included as a special case. Our formulae obtained in this paper are apparently much simpler than their formulae. As an example, the case of a nearly circular cylinder placed in a channel is briefly considered, which was previously dealt with by Hasimoto³⁾.

It may be mentioned that Takami¹⁸⁾,¹⁹⁾ has recently successfully applied our formulae to two special cases of much theoretical interest: one is that of a special profile for which Cherry¹⁾ calculated the exact velocity distribution on the basis of the hodograph method, and the other is that of a family of aerofoils for which Tomotika and Tamada²¹⁾ have obtained exact solution of continuous transonic flow on the assumption of a hypothetical but very realistic pressure-density relation. Thus we may say that owing to our formulae the labour required to obtain the velocity distribution over any arbitrary aerofoil correct to M^4 is no longer prohibitive, contrary to the general opinion.

Finally, it may be of interest to remark that the results of calculation by the M^2-expansion method can be utilized as a basis for further powerful approximation. Thus, the results which could be obtained by the thin-wing-expansion method, that is the method of successive approximation starting from Prandtl-Glauert's linear theory, or by Meksyn's new procedure for treating transonic flows¹⁵⁾ are also obtainable by appropriate interpretation of the results of the M^2-expansion method. These points will be reported elsewhere.

§ 2. Fundamental Equations

Consider the steady two-dimensional irrotational flow of a compressible fluid in the (x, y) plane. Then the velocity potential Φ and the stream function Ψ can be defined by the equations:

$$u=\frac{\partial\Phi}{\partial x}=\frac{\rho_\infty}{\rho}\frac{\partial\Psi}{\partial y}\,, \tag{2.1}$$

$$v=\frac{\partial\Phi}{\partial y}=-\frac{\rho_\infty}{\rho}\frac{\partial\Psi}{\partial x}\,, \tag{2.2}$$

where (u, v) are the component velocities, ρ is the density at any point and ρ_∞ is the density in the undisturbed stream. If we introduce the complex variables z, $\bar{z}$ and F defined by

$$z=x+iy\,,\qquad \bar{z}=x-iy\,, \tag{2.3}$$

$$F=\Phi+i\Psi\,, \tag{2.4}$$

then (2.1) and (2.2) can be combined to give

$$\frac{\partial F}{\partial z}=\frac{1}{2}\left(1+\frac{\rho}{\rho_\infty}\right)(u-iv)\,, \tag{2.5}$$

$$\frac{\partial F}{\partial \bar{z}}=\left(1-\frac{\rho}{\rho_\infty}\right)\frac{\partial\Phi}{\partial\bar{z}}\,. \tag{2.6}$$

For adiabatic flow, we have

$$\frac{\rho}{\rho_\infty}=\left\{1-\frac{\gamma-1}{2}M^2\left(\frac{q^2}{U^2}-1\right)\right\}^{1/(\gamma-1)}, \tag{2.7}$$

where q is the resultant fluid velocity, U and M are the velocity and Mach number of the undisturbed flow, and γ is the ratio of specific heats.

If we suppose F to be expanded in powers of M^2,

$$F=F_0+M^2F_1+M^4F_2+\cdots\,, \tag{2.8}$$

where

$$F_N=\Phi_N+i\Psi_N\,,\quad N=0,\,1,\,2,\,\cdots\,, \tag{2.9}$$

and write

$$q^2=q_0^2+M^2q_1^2+M^4q_2^2+\cdots\,, \tag{2.10}$$

$$1-\frac{\rho}{\rho_\infty}=M^2\rho_1+M^4\rho_2+\cdots\,, \tag{2.11}$$

then

$$\left.\begin{aligned}\rho_1&=\frac{1}{2}\left(\frac{q_0^2}{U^2}-1\right),\\ \rho_2&=\frac{1}{2}\frac{q_1^2}{U^2}-\frac{2-\gamma}{8}\left(\frac{q_0^2}{U^2}-1\right)^2,\\ &\cdots\cdots\end{aligned}\right\} \tag{2.12}$$

$$q_N^2=4\left(\frac{\partial\Phi_0}{\partial z}\frac{\partial\Phi_N}{\partial\bar{z}}+\frac{\partial\Phi_1}{\partial z}\frac{\partial\Phi_{N-1}}{\partial\bar{z}}+\cdots+\frac{\partial\Phi_N}{\partial z}\frac{\partial\Phi_0}{\partial\bar{z}}\right),$$
$$N=0,\,1,\,2,\,\cdots\,. \tag{2.13}$$

Substituting these in (2.6), comparing terms of the same powers of M^2, and integrating, we find

$$F_0 = G_0(z)\ , \tag{2.14}$$

$$F_N = \int\left(\rho_1 \frac{\partial \Phi_{N-1}}{\partial \bar{z}} + \rho_2 \frac{\partial \Phi_{N-2}}{\partial \bar{z}} + \cdots + \rho_N \frac{\partial \Phi_0}{\partial \bar{z}}\right) d\bar{z} + G_N(z)\ , \tag{2.15}$$

where $G_N(z)$ are arbitrary analytic functions of z, which should be determined by appropriate boundary conditions in each particular case.

It is obvious that F_0 is the complex velocity potential for incompressible flow. Starting from F_0 we should be able to determine F_N successively by means of (2.15) together with (2.12) and (2.13).

PART I. COMPRESSIBLE FLOW PAST A SOLID BODY IN UNLIMITED FLUID

§ 3. General Expressions for the Velocity at Any Point

For a uniform flow past a solid body in unlimited fluid, the following conditions are to be satisfied:

$\partial F/\partial z$ is one-valued and continuous, (3.1)

at infinity: $z \to \infty\ , \quad \partial F/\partial z \to U e^{-i\alpha}\ ,$ (3.2)

on the boundary, $\Psi = \operatorname{Im} F = 0\ ,$ (3.3)

where α is the angle between the x-axis and the direction of the undisturbed flow. The conditions (3.1) and (3.2) are obvious from eqns. (2.5).

As is well known the zeroth approximation, which corresponds to the incompressible flow, is given by

$$F_0 = f(z) \equiv \lambda\{e^{i(\delta-\alpha)} Z + e^{-i(\delta-\alpha)} Z^{-1}\} + i\kappa \log Z\ . \tag{3.4}$$

Here it is assumed that the profile in the z-plane is conformally mapped on to a unit circle with its centre at the origin in the Z-plane by the transformation function

$$z = c_{-1} Z + c_0 + \frac{c_1}{Z} + \cdots\ , \qquad c_{-1} = \lambda e^{i\delta}\ . \tag{3.5}$$

Also, for simplicity, we have put $U=1$, and $2\pi\kappa$ is the circulation around the profile, which may be determined by Joukowski's assumption.

Now, starting from $F_0 = f(z)$ and substituting the expressions already obtained for $F_1, F_2, \cdots$ successively in (2.15), we shall find

$$F_N = H_N(z, \bar{z}) + g_N(z)\ , \qquad N = 1, 2, \cdots\ , \tag{3.6}$$

where $H_N(z, \bar{z})$ is a known function of $z, \bar{z}$ such that $\partial H_N/\partial z$ satisfies the conditions imposed on $\partial F_N/\partial z$ given by (3.1) and (3.2). Therefore

$$\frac{dg_N}{dZ} = \frac{dg_N}{dz}\frac{dz}{dZ} = \left(\frac{\partial F_N}{\partial z} - \frac{\partial H_N}{\partial z}\right)\frac{dz}{dZ}$$

is one-valued and continuous, and hence regular, outside the unit circle in the Z-plane, so that

$$g_N = i\kappa_N \log Z + a_0^{(N)} + a_1^{(N)} Z^{-1} + \cdots\ . \tag{3.7}$$

We may conveniently absorb κ_N in the zeroth approximation κ, so that κ in (3.4) becomes

$$\kappa = \kappa_0 + M^2\kappa_1 + M^4\kappa_2 + \cdots\ , \tag{3.8}$$

and then we may write (3.7) in a simpler form:

$$g_N = a_0^{(N)} + a_1^{(N)} Z^{-1} + a_2^{(N)} Z^{-2} + \cdots\ . \tag{3.9}$$

The complementary function $g_N(Z)$ can be determined by the Poisson-Schwarz formula in the following way.

For simplicity, we shall drop the suffix N in the following analysis. On the unit circle, $Z = e^{i\theta}$, which corresponds to the profile $z = z_P$ in the physical plane, let us write

$$g(e^{i\theta}) = R(\theta) + iI(\theta)\ , \tag{3.10}$$

$$H(z_P, \bar{z}_P) = P(\theta) + iQ(\theta) \equiv H(e^{i\theta})\ . \tag{3.11}$$

Then, from (2.9) and (3.6),

$$\Phi(\theta) = P(\theta) + R(\theta)\ , \qquad \Psi(\theta) = Q(\theta) + I(\theta)\ . \tag{3.12}$$

But the boundary condition (3.3) requires that $\Psi = 0$. Hence

$$I(\theta) = -Q(\theta) = -\frac{1}{2i}[H(\zeta) - \bar{H}(\bar{\zeta})]\ , \tag{3.13}$$

where $\zeta = e^{i\theta}$. By the application of the Poisson-Schwarz formula to the analytic function $g(Z)$, we have

$$\begin{aligned} g(Z) &= a_0 + \frac{1}{2\pi}\oint_C I(\theta)\frac{Z+\zeta}{Z-\zeta}\frac{d\zeta}{\zeta} \\ &= \frac{1}{\pi}\oint_C I(\theta)\frac{d\zeta}{Z-\zeta} + \text{const} \\ &= \frac{1}{2\pi i}\oint_C [H(\zeta) - \bar{H}(\zeta^{-1})]\frac{d\zeta}{\zeta - Z} + \text{const}\ , \end{aligned} \tag{3.14}$$

where the path of integration C is the unit circle $\zeta = e^{i\theta}$. In many cases where the transformation function $z = z(Z)$ is given in an explicit analytic form (e.g. elliptic cylinders and Joukowski aerofoils), the integral (3.14) may be conveniently evaluated by means of the theory of residues. It may be remarked that the constant term in (3.14) has no physical significance and so can be safely neglected.

Now that the complex velocity potential F has been found, the velocity at any point can be easily obtained. Thus we have

$$\left.\begin{aligned} u&=u_0+M^2u_1+M^4u_2+\cdots\,,\\ v&=v_0+M^2v_1+M^4v_2+\cdots\,,\end{aligned}\right\} \tag{3.15}$$

where

$$u_0-iv_0=\frac{df}{dz}\,, \tag{3.16}$$

$$\begin{aligned} u_N-iv_N=\Bigg\{&\frac{\partial H_N}{\partial Z}+\frac{\partial \overline{H}_N}{\partial Z}+\frac{1}{2\pi i}\oint_C [H_N(\zeta)\\ &-\overline{H}_N(\zeta^{-1})]\frac{d\zeta}{(\zeta-Z)^2}\Bigg\}\left(\frac{dz}{dZ}\right)^{-1}\,. \end{aligned} \tag{3.17}$$

According to the previous paper[16) the explicit form of H_N in terms of f can be given as follows:

$$H_1=\frac{1}{4}w\overline{B}-\frac{1}{4}\overline{A}\,, \tag{3.18}$$

$$\begin{aligned} H_2=&\frac{1}{16}(w\overline{w}-1)\overline{w}B+\frac{1}{32}w'\overline{B}^2\\ &+\frac{1}{16}\left\{4g_1'-i\kappa(2e^{i\alpha}w-1)\frac{Z'}{Z}\right\}\overline{B}\\ &+\frac{1}{8}w\left[\int_{z_0}^{z}\left\{4g_1'-i\kappa(e^{i\alpha}w-1)\frac{Z'}{Z}\right\}w\,dz\right]^*\\ &-\frac{1}{16}(4g_1+i\kappa\log Z\overline{Z})^*+\frac{1}{2}H_1\\ &-\frac{\gamma+1}{16}(8H_1+\overline{A}-w^2\overline{C})\,, \end{aligned} \tag{3.19}$$

with

$$w=f'=df/dz\,, \tag{3.20}$$

$$A=f+i\kappa\log\overline{Z}\,, \tag{3.21}$$

$$B=\int w^2dz+2i\kappa e^{-i\alpha}\log\overline{Z}\,, \tag{3.22}$$

$$C=\int w^3dz+3i\kappa e^{-2i\alpha}\log\overline{Z}\,. \tag{3.23}$$

Here asterisks as well as bars denote complex conjugate and dashes denote differentiation with respect to z.

§ 4. Velocity Distribution on the Surface of a Cylinder of Any Shape

The general expressions, correct to M^4, for the complex velocity potential F and for the velocity components u, v are given by (3.6), (3.14), and (3.17) together with (3.18) and (3.19). The author believes, however, that the true merit of these formulae should be found in the fact that they enable us to calculate velocity distributions over any arbitrary profile whose transformation function to a unit circle cannot be given in an explicit analytic form. In fact, the previous papers[6),7),8),14) were exclusively concerned with the velocity distribution on the surface of the obstacle.

It is well known that there exists a functional relation between the real and imaginary parts of an analytic function; thus in (3.10) we have

$$R(\theta)=I^*(\theta)+\mathrm{Re}\,(a_0)\,. \tag{4.1}$$

Here $I^*(\theta)$ is the conjugate Fourier series associated with $I(\theta)$, so that if

$$I(\theta)=a_0+\sum_{n=1}^{\infty}(a_n\cos n\theta+b_n\sin n\theta)\,, \tag{4.2}$$

then

$$I^*(\theta)=\sum_{n=1}^{\infty}(a_n\sin n\theta-b_n\cos n\theta)\,. \tag{4.3}$$

It is also known that the conjugate Fourier series can be expressed in an integral form:

$$I^*(\theta)=-\frac{1}{2\pi}\int_0^{2\pi}[I(\varphi+\theta)-I(\theta)]\cot\frac{\varphi}{2}\,d\varphi\,. \tag{4.4}$$

On account of (3.13) and (4.1), we can rewrite (3.10) and (3.12) as

$$g(e^{i\theta})=-[Q^*(\theta)+iQ(\theta)]+\text{const}\,, \tag{4.5}$$

$$\Phi(\theta)=P(\theta)-Q^*(\theta)+\text{const}\,, \tag{4.6}$$

where, by (3.11), $P(\theta)$ and $Q(\theta)$ are given as the real and imaginary parts of the known function $H(e^{i\theta})$.

From (3.4), we have, on the profile,

$$f=\Phi_0(\theta)=2\lambda\cos(\theta-\alpha+\delta)-\kappa\theta\,. \tag{4.7}$$

Also we can write

$$dz=ds\,e^{i\omega}\,, \tag{4.8}$$

where ds is the line element along the profile and ω is the angle which the line element makes with the x-axis. Substituting (4.7) and (4.8) into (3.20), (3.21), and (3.22) gives

$$w=-qe^{-i\omega}\,, \tag{4.9}$$

$$A=2\lambda\cos(\theta-\alpha+\delta)\,, \tag{4.10}$$

$$B=\int q^2e^{-i\omega}ds+2\kappa e^{-i\alpha}\theta\,, \tag{4.11}$$

where

$$q=-\frac{d\Phi_0}{d\theta}\frac{d\theta}{ds} \tag{4.12}$$

is the zeroth approximation to the velocity (incompressible fluid velocity). Inserting these in (3.18) and separating real and imaginary parts, we obtain

$$P_1 = -\frac{1}{4} q (C \cos \omega + S \sin \omega) - \frac{\lambda}{2} \cos (\theta - \alpha + \delta) , \tag{4.13}$$

$$Q_1 = -\frac{1}{4} q (S \cos \omega - C \sin \omega) , \tag{4.14}$$

where

$$C = \int q^2 \cos \omega \, ds + 2\kappa\theta \cos \alpha , \tag{4.15}$$

$$S = \int q^2 \sin \omega \, ds + 2\kappa\theta \sin \alpha . \tag{4.16}$$

These are essentially the same as the results obtained in the previous paper[6].

Purely numerical calculations based on the above formulae were carried out for the cases of elliptic cylinders[10] and symmetrical Joukowski aerofoils at zero angle of attack, obtaining quite satisfactory agreement with known analytical results.

Recently, however, it has been discovered that a modification of the formulae is possible that brings about a considerable reduction of numerical work. In the next sections such modified formulae suitable for the numerical calculation will be presented.

§ 5. Simplified Formula for the Velocity Potential along the Profile to the Order M^2

The function $H(e^{i\theta})$ defined in (3.1) can be expressed in the form

$$P(\theta) + iQ(\theta) \equiv H(e^{i\theta}) = \sum_{n=-\infty}^{\infty} C_n e^{ni\theta} . \tag{5.1}$$

Then, remembering (4.3) we have

$$P(\theta) - Q^*(\theta) = 2 \operatorname{Re} \sum_{n=0}^{\infty} C_n e^{ni\theta} + \text{const} . \qquad (5.2)^*$$

Thus, in order to obtain the velocity potential on the profile, we have only to take positive power terms in the Laurent series of $H(\zeta)$ where $\zeta = e^{i\theta}$. This is just the principle on which following modification of the expressions for the velocity potential is based. Thus we attempt to simplify the above obtained expressions for P_1 and Q_1 by adding to $H_1(Z)$ some appropriate analytic function which is regular outside the profile and so is expressible as an ascending power series in Z^{-1}.

By (3.4) and (3.5) we have

$$w = \frac{df}{dz} = e^{-i\alpha} + i\kappa \frac{1}{z} + O\left(\frac{1}{z^2}\right) , \tag{5.3}$$

and

$$\int w^2 dz = e^{-2i\alpha} z + 2i\kappa e^{-i\alpha} \log Z + \text{const} + O(z^{-1}) . \tag{5.4}$$

Consequently, on the profile, that is for $Z = e^{i\theta}$, (3.21) and (3.22) become

$$A = e^{-i\alpha} z + O(Z^{-1}) , \tag{5.5}$$

$$B = e^{-2i\alpha} z + \text{const} + O(Z^{-1}) . \tag{5.6}$$

Therefore we can express (3.18) in the form

$$\begin{aligned} 4H_1 &= w(\bar{B} - B) - (\bar{A} - A) + wB - A \\ &= -2iw \operatorname{Im} (B) + 2i \operatorname{Im} (A) \\ &\quad + \lambda e^{-i(\alpha - \delta)} (e^{-2i\alpha} - 1) Z + \boldsymbol{P}(Z^{-1}) , \end{aligned} \tag{5.7}$$

where, and hereafter, $\boldsymbol{P}(z)$ denotes a certain power series in z. As mentioned above $\boldsymbol{P}(Z^{-1})$ contributes nothing to $\Phi_1(\theta)$, so that we can simply drop it for the calculation of $\Phi_1(\theta)$. Thus substituting w, A, B from (4.9), (4.10) and (4.11) into (5.7) and separating real and imaginary parts, we get for the "modified" functions

$$P_{1m}(\theta) = -\frac{1}{2} qS \sin \omega + \lambda \sin \alpha \sin (\theta - 2\alpha + \delta) , \tag{5.8}$$

$$Q_{1m}(\theta) = -\frac{1}{2} qS \cos \omega . \tag{5.9}$$

It will be seen that the formulae (5.8) and (5.9) are more convenient than those previously given (4.13) and (4.14). Indeed, we can dispense with the numerical evaluation of C defined by (4.15); this is of particular significance in view of the fact that S can in general be calculated more accurately than C since $\sin \omega$ is usually of very small magnitude for ordinary thin aerofoils.

Further, (5.8) and (5.9) can be brought into

---

* It can be shown that

$$\sum_{n=0}^{\infty} C_n e^{ni\theta} = \frac{1}{2\pi i} \oint_C \frac{H(Z)}{Z - e^{i\theta}} dZ ,$$

where the path of integration C is a simple closed curve lying in the regularity region of the analytic function $H(Z)$ and enclosing the point $Z = e^{i\theta}$. Hence, by (4.6) and (5.2), we have

$$\Phi(\theta) = \frac{1}{\pi} \operatorname{Im} \oint_C \frac{H(Z)}{Z - e^{i\theta}} dZ ,$$

where H is given by (3.18) or (3.19). This formula is very convenient for the analytical calculation of velocity potential when the profile is given by a simple transformation function (such as the Joukowski transformation)[8),14].

more symmetric forms in the following way. For the case of vanishing angle of attack,

$$P_{1m}(\theta)=-\frac{1}{2}\,q\sin\omega\int q^2\sin\omega ds\,,$$

$$Q_{1m}(\theta)=-\frac{1}{2}\,q\cos\omega\int q^2\sin\omega ds\,.$$

These can be immediately generalized to cover the case of non-vanishing angle of attack by means of a simple geometrical consideration:

$$P_{1m}(\theta)=-\frac{1}{2}\,q\sin(\omega-\alpha)\int q^2\sin(\omega-\alpha)ds\,, \tag{5.10}$$

$$Q_{1m}(\theta)=-\frac{1}{2}\,q\cos(\omega-\alpha)\int q^2\sin(\omega-\alpha)ds\,. \tag{5.11}$$

It will be interesting to note that the circulation constant κ does not appear explicitly in these formulae; though, of course, it is involved in the expression for q.

§ 6. Simplified Formulae for the Velocity along the Profile to the Order M^4

Similar modification can be carried out for $\Phi_2(\theta)$, the second order correction to the velocity potential. Here, care must be taken of the fact that the circulation constant is usually determined by Joukowski's assumption so that $\partial\Phi/\partial\theta=0$ at the trailing edge, and hence κ is in general expressed in the form

$$\kappa=\kappa_0+M^2\kappa_1+M^4\kappa_2+\cdots\,.$$

Since, however, we have absorbed the total circulation in the zeroth approximation, q as given by (4.12) and (4.7) really contains terms dependent on κ_1, κ_2, $\cdots$. Accordingly P_{1m} and Q_{1m} given by (5.10) and (5.11) contribute a term involving κ_1 to the second approximation.

For the sake of brevity, only the final results will be given here. The velocity along the surface of an arbitrary cylinder is given by

$$q=q_0+M^2q_1+M^4q_2+\cdots\,, \tag{5.12}$$

where

$$q_0=\{2\lambda\sin(\theta-\alpha+\delta)+\kappa_0\}\frac{d\theta}{ds}\,, \tag{5.13}$$

$$q_N=\{-P_{Nm}'(\theta)+Q_{Nm}{}^{*\prime}(\theta)+\kappa_N\}\frac{d\theta}{ds}\,,\qquad N=1,\,2 \tag{5.14}$$

$$\left.\begin{aligned}P_{1m}&=-\frac{1}{2}\,Sq_0\sin(\omega-\alpha)\,,\\ Q_{1m}&=-\frac{1}{2}\,Sq_0\cos(\omega-\alpha)\,,\end{aligned}\right\} \tag{5.15}$$

$$\begin{aligned}P_{2m}+iQ_{2m}&\\ =-\frac{1}{16}&(q_0^2-1)q_0e^{i(\omega-\alpha)}(C-iS)\\ &-\frac{i}{8}\,e^{-i(\omega-\alpha)}\frac{d}{ds}(q_0e^{-i(\omega-\alpha)})CS\\ &-\frac{i}{8}\,e^{-i(\omega-\alpha)}[4(Q_1{}^{*\prime}+iQ_1{}')\\ &\qquad+\kappa_0(2q_0e^{-i(\omega-\alpha)}+1)]\frac{d\theta}{ds}S\\ &-\frac{i}{4}\,q_0e^{-i(\omega-\alpha)}\int[(4Q_1{}^{*\prime}+\kappa_0)q_0\sin(\omega-\alpha)\\ &\qquad-4Q_1{}'q_0\cos(\omega-\alpha)\\ &\qquad+\kappa_0q_0^2\sin2(\omega-\alpha)]d\theta+\frac{1}{2}P_1\\ &-(\gamma+1)\Big[\frac{i}{8}\,q_0^2e^{-2i(\omega-\alpha)}\int q_0^3\sin2(\omega-\alpha)ds\\ &\qquad+\frac{1}{2}(P_{1m}+iQ_{1m})\Big]\\ &-\frac{i}{2}\,\kappa_1e^{-i(\omega-\alpha)}\Big\{\frac{d\theta}{ds}S\\ &\qquad+2q_0\int q_0\sin(\omega-\alpha)\,d\theta\Big\}\,,\end{aligned} \tag{5.16}$$

where

$$C=\int q^2\cos(\omega-\alpha)ds+2\kappa_0\theta\,, \tag{5.17}$$

$$S=\int q_0^2\sin(\omega-\alpha)ds\,, \tag{5.18}$$

$$P_1=\frac{1}{2}P_{1m}-\frac{1}{4}Cq_0\cos(\omega-\alpha)-\frac{\lambda}{2}\cos(\theta-\alpha+\delta)\,, \tag{5.19}$$

$$Q_1=\frac{1}{2}Q_{1m}+\frac{1}{4}Cq_0\sin(\omega-\alpha)\,, \tag{5.20}$$

$$Q_1{}^*=P_1-\Phi_1\,. \tag{5.21}$$

PART II. COMPRESSIBLE FLOW PAST A LATTICE OF AEROFOILS

§ 7. Incompressible Flow past a Lattice of Aerofoils

As is well known, an arbitrary wing lattice in the z-plane can be mapped conformally on to the unit circle in the Z-plane by means of a transformation function of the form

$$z=\frac{h}{2\pi}\log\frac{(Z+a^{-1})(Z+a)}{(Z-a^{-1})(Z-a)}+C(Z)\,,\qquad 0<a<1\,, \tag{7.1}$$

where $C(Z)$ is regular outside the unit circle: $|Z|>1$, so that

$$C(Z)=C_0+C_1Z^{-1}+C_2Z^{-2}+\cdots\,; \tag{7.2}$$

$Z=-a^{-1}$, a^{-1} correspond to infinity up- and downstream respectively, and h denotes the spacing of the wing lattice.

Consider a complex velocity potential

$$f=\frac{h}{2\pi}\{U_1e^{-i\alpha_1}\log(Z+a^{-1})+U_1e^{i\alpha_1}\log(Z+a)$$
$$-U_2e^{-i\alpha_2}\log(Z-a^{-1})-U_2e^{i\alpha_2}\log(Z-a)\}\,. \tag{7.3}$$

In the z-plane it represents the incompressible flow past the above mentioned lattice of aerofoils such that the inflow and outflow angles and velocities are α_1, α_2 and U_1, U_2 respectively. This can be seen from (7.1) and (7.3) in the following way.

When $Z\to-a^{-1}$,

$$f\to\frac{h}{2\pi}U_1e^{-i\alpha_1}\log(Z+a^{-1})\sim U_1e^{-i\alpha_1}z\,,$$

and when $Z\to a^{-1}$,

$$f\to-\frac{h}{2\pi}U_2e^{-i\alpha_2}\log(Z-a^{-1})\sim U_2e^{-i\alpha_2}z\,.$$

This shows the behaviour of flow at infinity up- and downstream.

Next we consider the condition at the surface of the aerofoil, that is, on the unit circle in the Z-plane: $Z=e^{i\theta}$. Putting $Z=e^{i\theta}$ in (7.3) and taking the imaginary part, we have $\Psi_0=$ constant, provided that the condition holds:

$$U_1\cos\alpha_1=U_2\cos\alpha_2\,. \tag{7.4}$$

Thus the complex velocity potential f represents flow along the aerofoil. The condition (7.4) is readily recognized to be one of continuity of mass flow past the lattice.

§ 8. Complex Velocity Potential for the Compressible Flow past Lattice of Aerofoils

For simplicity we shall consider only a first approximation (that is correct to the order of M^2).

In the following, quantities pertaining to points at infinity up- and downstream will be indicated by suffixes 1 and 2 respectively. Thus (2.5) can be written as

$$\frac{\partial F}{\partial z}=\frac{1}{2}\left(1+\frac{\rho}{\rho_1}\right)(u-iv)\,. \tag{8.1}$$

Hence the boundary conditions at infinity are expressed as

$$\frac{\partial F}{\partial z}\sim U_1e^{-i\alpha_1}\qquad\text{as } Z\to-a^{-1}, \tag{8.2}$$

$$\frac{\partial F}{\partial z}\sim\frac{1}{2}\left(1+\frac{\rho_2}{\rho_1}\right)U_2e^{-i\alpha_2}\quad\text{as } Z\to a^{-1}\,. \tag{8.3}$$

But, from (2.7) we have

$$\frac{\rho}{\rho_1}=1-\frac{1}{2}M_1^2\left(\frac{q^2}{U_1^2}-1\right)+O(M_1^4)\,. \tag{8.4}$$

Hence (8.3) can be rewritten as

$$\frac{\partial F}{\partial z}\sim\left\{1-\frac{1}{4}M_1^2\left(\frac{U_2^2}{U_1^2}-1\right)\right\}U_2e^{-i\alpha_2}$$
$$\text{as}\quad Z\to a^{-1}\,. \tag{8.5}$$

It should be noted that U_1, U_2, α_1 and α_2 are not independent from each other but subject to the condition of continuity

$$\rho_1U_1\cos\alpha_1=\rho_2U_2\cos\alpha_2\,, \tag{8.6}$$

of which the limiting case for $M_1\to0$ has already been met with in (7.4). Accordingly, if α_1, α_2 and U_1 are fixed, U_2 will in general vary with the Mach number M_1. Therefore we put

$$U_2=U_{20}+M_1^2U_{21}+\cdots\,. \tag{8.7}$$

Substituting from (8.4) and (8.7) in (8.6) and expanding in powers of M_1^2, we obtain

$$\cos\alpha_1=U_{20}\cos\alpha_2\,, \tag{8.8}$$

$$U_{21}=\tfrac{1}{2}(U_{20}^2-1)U_{20}\,, \tag{8.9}$$

where we have put for brevity $U_1=1$. The condition (8.8) is nothing other than (7.4).

Now, (8.2) and (8.5) can also be expanded in powers of M_1^2; thus, for the zeroth approximation

$$\frac{df}{dz}\sim\begin{cases}e^{-i\alpha_1}\\ U_{20}e^{-i\alpha_2}\end{cases}\quad\text{as}\quad Z\to\begin{cases}-a^{-1}\\ a^{-1}\end{cases} \tag{8.10}$$

and for the first approximation

$$\frac{\partial F}{\partial z}\sim\begin{cases}0\\ \tfrac{1}{2}U_{21}e^{-i\alpha_2}\end{cases}\quad\text{as}\quad Z\to\begin{cases}-a^{-1}\\ a^{-1}\end{cases}. \tag{8.11}$$

The zeroth approximation f has already been given by (7.3), which can be rewritten as $(U_1=1)$

$$f=\frac{h}{2\pi}[e^{-i\alpha_1}\log(Z+a^{-1})+e^{i\alpha_1}\log(Z+a)$$
$$-U_{20}\{e^{-i\alpha_2}\log(Z-a^{-1})+e^{i\alpha_2}\log(Z-a)\}]\,. \tag{8.12}$$

The general formula (2.15) gives for $N=1$

$$F_1=\frac{1}{4}\frac{df}{dz}\int\left(\frac{d\bar{f}}{d\bar{z}}\right)^2d\bar{z}-\frac{1}{4}\bar{f}+G_1(z)\,. \tag{8.13}$$

Considering the asymptotic behaviour at infinity of f as given by (8.10), we introduce a pair of new functions defined by

$$f_1=\frac{h}{2\pi}\,[e^{i\alpha_1}\log(Z+a^{-1})+e^{-i\alpha_1}\log(Z+a)$$
$$-U_{20}\{e^{i\alpha_2}\log(Z-a^{-1})+e^{-i\alpha_2}\log(Z-a)\}]\,, \tag{8.14}$$

$$f_2=\frac{h}{2\pi}\,[e^{2i\alpha_1}\log(1+a^{-1}Z^{-1})$$
$$+e^{-2i\alpha_1}\log(1+aZ^{-1})$$
$$-U_{20}^2\{e^{2i\alpha_2}\log(1-a^{-1}Z^{-1})$$
$$+e^{-2i\alpha_2}\log(1-aZ^{-1})\}]\,. \tag{8.15}$$

Then it is readily seen that

$$\bar{f}+f_1=\text{o.v.f.}\,,\qquad \int\left(\frac{d\bar{f}}{d\bar{z}}\right)^2 d\bar{z}+f_2=\text{o.v.f.}\,,$$

where o.v.f. stands for "one-valued function."

Now (8.13) can be written as

$$F_1=H_1(Z,\bar{Z})+g_1(Z)\,, \tag{8.16}$$

where

$$H_1(Z,\bar{Z})=\frac{1}{4}\frac{df}{dz}\left\{\int\left(\frac{d\bar{f}}{d\bar{z}}\right)^2 d\bar{z}+f_2(Z)\right\}$$
$$-\frac{1}{4}\{\bar{f}(\bar{Z})+f_1(Z)\}\,, \tag{8.17}$$

and $g_1(Z)$ is a certain analytic function of Z. Now it can easily be shown that $dg_1/dZ=\partial F_1/\partial Z-\partial H_1/\partial Z$ is one-valued outside the unit circle in the Z-plane, and that

$$\frac{dg_1}{dZ}\to\begin{cases}0\\ -iU_{21}\sin\alpha_2\end{cases}\qquad\text{as}\qquad Z\to\begin{cases}-a^{-1}\\ a^{-1}\end{cases}.$$

Therefore, taking account of (7.1), we can conclude that the function

$$g=g_1-iU_{21}\sin\alpha_2\frac{h}{2\pi}\log\frac{1-a^{-1}Z^{-1}}{1-aZ^{-1}}$$

is one-valued and analytic outside the unit circle. Hence, employing the formula (3.14) and making an analysis similar to that for an isolated aerofoil, we finally arrive at

$$g_1=iU_{21}\sin\alpha_2\frac{h}{2\pi}\log\frac{1-a^{-1}Z^{-1}}{1-aZ^{-1}}$$
$$+\frac{1}{4\pi^2}\oint_{\mathrm{C}}\mathrm{Im}\left[\frac{df}{dz}\left\{\int\left(\frac{d\bar{f}}{d\bar{z}}\right)^2 d\bar{z}+f_2\right\}\right]\frac{d\zeta}{\zeta-Z}, \tag{8.18}$$

where the path of integration C is the unit circle in the Z-plane and f and f_2 are given by (8.12) and (8.15) respectively. Substitution of (8.17) and (8.18) in (8.16) yields the required first approximation to the complex velocity potential. The velocity at any point in the field of flow can then be calculated by means of (3.16) and (3.17).

§ 9. Velocity Distribution on the Aerofoil

In this case the velocity potential on the aerofoil is shown to be given by

$$\Phi_1(\theta)=P(\theta)-Q^*(\theta)$$
$$+\frac{h}{2\pi}U_{21}\sin\alpha_2\left(2\tan^{-1}\frac{a\sin\theta}{1-a\cos\theta}+\theta\right), \tag{9.1}$$

where $P_1+iQ_1=H_1(e^{i\theta},e^{-i\theta})$. But the formula can be simplified in the same way as for an isolated aerofoil. For this purpose, we introduce another new function defined as

$$f_3=\frac{h}{\pi}\left\{\cos 2\alpha_1\log\frac{1+a^{-1}Z^{-1}}{1+a^{-1}Z}\right.$$
$$-U_{20}^2\cos 2\alpha_2\log\frac{1-a^{-1}Z^{-1}}{1-a^{-1}Z}$$
$$\left.+(\cos 2\alpha_1-U_{20}^2\cos 2\alpha_2)\log Z\right\}, \tag{9.2}$$

and write (8.17) in the form

$$H_1=\frac{1}{4}w\left\{\int\bar{w}^2 d\bar{z}-\int w^2 dz+f_3\right\}$$
$$+\frac{1}{4}w\left\{f_2+\int w^2 dz-f_3\right\}-\frac{1}{4}(\bar{f}+f_1)\,, \tag{9.3}$$

with $w=df/dz$. Then the second term on the right-hand side can be shown to be regular outside the unit circle and of the form $\boldsymbol{P}(Z^{-1})$, so that it contributes nothing to $\Phi_1(\theta)$. Thus after some calculation we can find the explicit form of $\Phi_1(\theta)$.

Summarizing, the velocity distribution on the surface of the aerofoil is given by

$$q=q_0(\theta)+M_1^2q_1(\theta)+\cdots\,, \tag{9.4}$$

with

$$q_N(\theta)=-\frac{d\Phi_N}{d\theta}\frac{d\theta}{ds}\,,\qquad N=0,1,\cdots\,, \tag{9.5}$$

where

$$\Phi_0(\theta)=\frac{h}{2\pi}\left\{\sin\alpha_1(\theta-2\psi)+U_{20}\sin\alpha_2(2\varphi-\theta)\right.$$
$$\left.+\cos\alpha_1\log\frac{1+a^2+2a\cos\theta}{1+a^2-2a\cos\theta}\right\}, \tag{9.6}$$

$$\Phi_1(\theta)=-\frac{h}{4\pi}\left\{\cos\alpha_1\log\frac{1+a^2+2a\cos\theta}{1+a^2-2a\cos\theta}\right.$$
$$\left.+2U_{21}\sin\alpha_2(\theta-2\varphi)\right\}$$
$$-\frac{1}{2}T(\theta)q_0\sin\omega+\frac{1}{2}[T(\theta)q_0\cos\omega]^*\,, \tag{9.7}$$

and

$$T(\theta)=\int q_0{}^2 \sin\omega\, ds-\frac{h}{2\pi}\{\cos 2\alpha_1(2\psi-\theta)$$
$$+U_{20}^2 \cos 2\alpha_2(\theta-2\varphi)\}\,, \tag{9.8}$$

$$\varphi=\tan^{-1}\frac{\sin\theta}{\cos\theta-a}\,,\qquad \psi=\tan^{-1}\frac{\sin\theta}{\cos\theta+a}\,. \tag{9.9}$$

Here $d\theta/ds$ should be regarded as already known for the case of incompressible flow.

In this connection it may be worthwhile to remark that the correspondence between θ and s can in principle be found if the velocity distribution on the aerofoil is already known for incompressible flow either theoretically (e.g. by means of the method of singularities) or experimentally; indeed, the relation

$$\Phi_0=-\int q_0 ds$$

in conjunction with (9.6) gives the functional relation between θ and s.

Finally, it may be mentioned that the various formulae for a single aerofoil in unlimited fluid, given in Part I, can be deduced by a limiting process from those for a wing lattice, as should naturally be expected.

§ 10. Symmetrical Body Symmetrically Placed in a Channel

In this case we have to put

$$U_1=U_2=1\,,\qquad \alpha_1=\alpha_2=0\,, \tag{10.1}$$

so that by (8.7)

$$U_{20}=1\,,\qquad U_{21}=0\,. \tag{10.2}$$

Hence f, f_1, f_2 as given by (8.12), (8.14) and (8.15) reduce to one and the same function:

$$f=f_1=f_2=\frac{h}{2\pi}\log\frac{(Z+a^{-1})(Z+a)}{(Z-a^{-1})(Z-a)}\,. \tag{10.3}$$

Hence (8.17) becomes

$$H_1(Z,\overline{Z})=\frac{1}{4}\,w\left\{\int\overline{w}^2\,d\overline{z}+f\right\}-\frac{1}{4}\,(f+\overline{f})\,. \tag{10.4}$$

Also (8.18) is simplified to

$$g_1=\frac{1}{4\pi^2}\oint_C \operatorname{Im}\left[w\left\{\int\overline{w}^2\,d\overline{z}+f\right\}\right]\frac{d\zeta}{\zeta-Z}\,. \tag{10.5}$$

Next, the velocity potential along the aerofoil is given by (9.8) and (9.5) in the form

$$\Phi_1(\theta)=-\frac{h}{4\pi}\log\frac{1+a^2+2a\cos\theta}{1+a^2-2a\cos\theta}$$
$$-\frac{1}{2}\,T(\theta)q_0\sin\omega+\frac{1}{2}\,[T(\theta)q_0\cos\omega]^*\,, \tag{10.6}$$

where

$$T(\theta)=\int q_0{}^2\sin\omega\, ds+\frac{h}{\pi}\tan^{-1}\left(\frac{2a}{1-a^2}\sin\theta\right). \tag{10.7}$$

This case has been treated by Goldstein and Lighthill[2] by quite a different method obtaining more complicated expressions.

§ 11. Compressible Flow past a Nearly Circular Cylinder Symmetrically Placed in a Channel

By the use of the author's formula (2.15) ($N=1$), Hasimoto[3] investigated the compressible flow past a nearly circular cylinder which is placed symmetrically between two parallel walls. For the determination of the complementary function $G_1(z)$ he was obliged to have recourse to a more or less intuitive argument. In effect, he considered a profile in the ζ-plane which is derived from a circle of radius σ in the z-plane by means of the transformation function

$$\zeta=\frac{D}{2\pi}\log\frac{(z+1)(z-\mu^2)}{(z-1)(z+\mu^2)}+\frac{i}{2}D\,,$$
$$0<\mu<\sigma<1\,. \tag{11.1}$$

To express this in terms of our notation in the present paper, we have only to make the substitution

$$z\to\sigma Z\,,\qquad \zeta\to z\,,$$
$$D\to h\,,\quad \sigma\to a\,,\quad \sigma^{-1}\mu^2\to b\quad (0<b<a<1)\,.$$

Thus we obtain

$$z=\frac{h}{2\pi}\log\frac{(Z+a^{-1})(Z-b)}{(Z-a^{-1})(Z+b)}+\frac{i}{2}h\,, \tag{11.2}$$

which can be further put in the form of (7.1):

$$z=\frac{h}{2\pi}\log\frac{(Z+a^{-1})(Z+a)}{(Z-a^{-1})(Z-a)}+C(Z)\,, \tag{11.3}$$

if we take

$$C(Z)=\frac{i}{2}h+\frac{h}{2\pi}\log\frac{(Z-a)(Z-b)}{(Z+a)(Z+b)}\,, \tag{11.4}$$

which is clearly analytic in the region outside the unit circle: $|Z|>1$.

The first approximation to the complex velocity potential can now be obtained as

$$F_1=H_1(Z,\overline{Z})+g_1(Z)\,,$$

where H_1 and g_1 are to be calculated by (10.4) and (10.5). Such a calculation employing (10.3) is straightforward, without any special consideration about the boundary conditions. For the detail of the numerical result reference should be made to Hasimoto's original paper[3].

The author wishes to thank Mr. Hideo Takami for checking some of the results in Part I and Mr. Eiji Kasahara for helpful discussions concerning the material of Part II.

The author also wishes to express his appreciation for the hospitality of the Institute for Fluid Dynamics and Applied Mathematics.

Appendix

As an illustration of the application of the formulae obtained in this paper, let us consider the flow past a circular cylinder with circulation. For a circular cylinder of radius unity, we have

$$f=z+z^{-1}+i\kappa\log z\,, \tag{A1}$$

which, on substitution in (3.18), gives

$$\begin{aligned}H_1=&\frac{1}{4}(1+i\kappa z^{-1}-z^{-2})\Big\{\bar{z}(\kappa^2+2)\bar{z}^{-1}\\&-i\kappa\bar{z}^{-2}-\frac{1}{3}\bar{z}^{-3}-2i\kappa\log z\bar{z}\Big\}\\&-\frac{1}{4}(\bar{z}+\bar{z}^{-1}-i\kappa\log z\bar{z})\,.\end{aligned} \tag{A2}$$

On the circle we can put

$$z=\zeta\,,\qquad \bar{z}=\zeta^{-1}\,,\qquad \zeta=e^{i\theta}\,,$$

and hence

$$\begin{aligned}H_1=&\frac{1}{4}\Big\{-\zeta^{-3}+i\kappa\zeta^{-2}-(\kappa^2+2)\zeta^{-1}+i\kappa(\kappa^2+3)\\&+\Big(2\kappa^2+\frac{4}{3}\Big)\zeta-\frac{4}{3}i\kappa\zeta^2-\frac{1}{3}\zeta^3\Big\}\,,\end{aligned} \tag{A3}$$

$$\begin{aligned}H_1-\overline{H}_1=&\frac{1}{4}\Big\{-\frac{2}{3}\zeta^{-3}-\frac{1}{3}i\kappa\zeta^{-2}\\&-\Big(3\kappa^2+\frac{10}{3}\Big)\zeta^{-1}+2i\kappa(\kappa^2+3)\\&+\Big(3\kappa^2+\frac{10}{3}\Big)\zeta-\frac{1}{3}i\kappa\zeta^2+\frac{2}{3}\zeta^3\Big\}\,.\end{aligned} \tag{A4}$$

Now (3.14) gives

$$g_1=\frac{1}{2\pi i}\oint_C(H_1-\overline{H}_1)\frac{d\zeta}{\zeta-z}=\mathrm{Res}_{\zeta=0}\left[\frac{H_1-\overline{H}_1}{\zeta-z}\right],$$

since the integrand is regular in the unit circle except at $\zeta=0$. Thus, calculating the residue we find

$$g_1=\frac{1}{6z^3}+\frac{1}{12}i\kappa\frac{1}{z^2}+\Big(\frac{5}{6}+\frac{3}{4}\kappa^2\Big)\frac{1}{z}\,. \tag{A5}$$

Substituting (A2) and (A5) in $\Phi_1+i\Psi_1=F_1=H_1+g_1$, we have the first order correction to the complex velocity potential.

If only the value of the velocity potential at the surface of the cylinder is required, we can more conveniently use the formulae (4.6) and (5.2). Thus, taking the real part of the positive power terms of (A3), we immediately find

$$\Phi_1(\theta)=\Big(\kappa^2+\frac{2}{3}\Big)\cos\theta+\frac{2}{3}\kappa\sin 2\theta-\frac{1}{6}\cos 3\theta\,. \tag{A6}$$

Boundary Layer Growth on a Flat Plate with Suction or Injection

By Hidenori HASIMOTO

*Department of Physics, Faculty of Science,**
University of Tokyo

(Received September 22, 1956)

Exact solutions of the Navier-Stokes equations are obtained for the boundary layer growth on an infinite flat plate with uniform suction or injection (with velocity V normal to its plane) which is started at time $t=0$ (with velocity U along its plane), for the two cases: i) $U=$arbitrary, $V=$const and ii) $U\propto t^{\alpha}$, $V\propto t^{-1/2}$.

i) gives simple relations between the cases of suction and injection and ii) gives similar velocity profiles.

Rayleigh's problem ($U=$const) is investigated in detail, and the resulting solutions show the same qualitative natures as the corresponding steady flow solutions for an semi-infinite flat plate so far obtained.

§1. Introduction

The problem of boundary layer control has become very important in the field of aerodynamics. Among several methods[1] the application of suction is widely used in recent times, in order to prevent separation and to delay transition to turbulence, by means of which we get much larger maximum lift and reduced drag.

On the other hand, we know the possibility of using injection at the wall to cool the body in a high-temperature gas.

Many authors have made mathematical studies on these problems, especially in the case of steady flow. In this paper we want to study the problem of boundary layer growth on an infinite flat plate started at time $t=0$, with uniform suction or injection. Exact solutions of the Navier-Stokes equations of motion are derived for the case of uniform suction (and injection) which is steady or proportional to $t^{-1/2}$. They have very simple forms and may give a clear insight into the corresponding steady boundary layer problem, as Rayleigh's problem for the impulsive motion which was considered initially by Rayleigh[2] for a flat plate without suction (classical Rayleigh's problem) and has been extended to general cylinder by many authors[3,4,5]. The fundamental equations of our problem were those given by Stuart[6], but his detailed study is confined to the case of periodic motion of the plate with constant suction. In §3 we treat the case when suction or injection is constant. It is found that there are very simple relation between the cases of suction and injection. In §4 we treat the case when suction or injection varies as $t^{-1/2}$ and the velocity of the plate is proportional to t^{α}. This is the case which allows similar solutions.

Numerical calculations are made for the case of impulsive motion of the plate in §3 and §4. In the case of injection, velocity profiles have inflection points. The qualitative natures of the flow are the same as the results of the corresponding studies on the steady boundary layer, so far obtained.

§2. Fundamental Equations

Let us consider the unsteady motion of an infinite flat plate $y=0$ parallel to the x-axis, starting at time $t=0$ in a viscous incompressible fluid. Uniform normal velocity of the fluid V from the surface of the plate represents suction or injection according as $V<0$ or $V>0$. In this case the Navier-Stokes equations of motion of the fluid and a equation of continuity reduce to

$$\frac{\partial u}{\partial t}+v\frac{\partial u}{\partial y}=\nu\frac{\partial^2 u}{\partial y^2}, \tag{2.1}$$

$$\frac{\partial v}{\partial t}+v\frac{\partial v}{\partial y}=\nu\frac{\partial^2 v}{\partial y^2}-\frac{1}{\rho}\frac{\partial p}{\partial y}, \tag{2.2}$$

$$\frac{\partial v}{\partial y}=0 \tag{2.3}$$

taking into account independence of the flow field on x, where $u(y, t)$ and $v(y, t)$ are velocity components, p is the pressure, and ν is the kinematic viscosity.

---

* Now at Depertment of Aeronautics University of Kyoto.

(2.1)–(2.3) are subject to the boundary conditions

$$u(0, t)=U(t)\ , \qquad u(\infty, t)=0\ , \tag{2.4}$$

$$v(0, t)=V(t) \tag{2.5}$$

and an initial condition

$$u(y, 0)=0\ . \tag{2.6}$$

(2.3) and (2.5) show that

$$v(y, t)=V(t)\ . \tag{2.7}$$

Introducing (2.7) into (2.2) and (2.1) we get equations for p and u respectively

$$p=p_0-\rho y\frac{dV}{dt}\ , \tag{2.8}$$

$$\frac{\partial u}{\partial t}+V\frac{\partial u}{\partial y}=\nu\frac{\partial^2 u}{\partial y^2}\ . \tag{2.9}$$

where p_0 is the value of p at $y=0$, ρ is the density of the fluid.

(2.9) is an equation already given by Stuart. The exact solution of it, however, is not simple for the general functional form of $V(t)$ except the cases I) $V=V_0=$const. and II) $V=V_0t^{-1/2}$ which will be studied in detail in the following sections.

§ 3. The Case $V=V_0=$Constant

In this section we consider the case of constant suction or injection; $V=V_0$.

Multiplying (2.9) and (2.4) by $\exp(-pt)$ and integrating with respect to t from 0 to ∞, we obtain

$$\frac{d^2u^*}{dy^2}-2\kappa\frac{du^*}{dy}-\frac{p}{\nu}u^*=0 \tag{3.1}$$

subject to

$$u^*(0.\ p)=U^*(p)\ , \qquad u^*(\infty, p)=0\ , \tag{3.2}$$

for the Laplace transform of $u(y, t)$:

$$u^*(y, p)=\int_0^\infty e^{-pt}u(y, t)dt \tag{3.3}$$

where

$$\kappa=V/(2\nu)\ , \tag{3.4}$$

and we used an initial condition (2.6).

These can be solved easily and yield

$$u^*=U^*\exp\left[\kappa y-\sqrt{\kappa^2+p/\nu}\,y\right]\ . \tag{3.5}$$

We want to calculate the inverse transform of $\exp(-\sqrt{\kappa^2+p/\nu}\,y)$:

$$L^{-1}\left[e^{-\sqrt{\kappa^2+p/\nu}\,y}\right]=\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}e^{pt-\sqrt{\kappa^2+p/\nu}\,y}dp\ .$$

$$c>0\ . \tag{3.6}$$

Putting $\kappa^2+p/\nu=q/\nu$, (3.6) reduces to[7]

$$\frac{1}{2\pi i}e^{-\kappa^2\nu t}\int_{c+\nu\kappa^2-i\infty}^{c+\nu\kappa^2+i\infty}e^{-\sqrt{q/\nu}\,y+qt}+dq$$

$$=e^{-\kappa^2\nu t}L^{-1}\left[e^{-\sqrt{p/\nu}\,y}\right]$$

$$=\frac{y}{2\sqrt{\pi\nu t^3}}\exp\left[-\frac{y^2}{4\nu t}-\kappa^2\nu t\right]. \tag{3.7}$$

Making use of the convolution theorem we obtain from (3.5) and (3.7)

$$u=e^{\kappa y}\int_0^t U(t-\tau)\frac{y}{2\sqrt{\pi\nu\tau^3}}\exp\left[-\frac{y^2}{4\nu\tau}-\kappa^2\nu\tau\right]d\tau\ . \tag{3.8}$$

This has a very compact form but is inconvenient for studying the behaviour near the plate $y\sim 0$. In this case the solution $E(y, t)$ for the case of the impulsive motion ($U=1$, $U^*=1/p$) is suitable. Making use of a formula 19 in Appendix V of Carslaw and Jaeger[7] we obtain for $E(y, t)$:

$$e^{-\kappa y}E(y, t)=L^{-1}\left[p^{-1}e^{-\sqrt{\kappa^2+p/\nu}\,y}\right]$$

$$=e^{-\kappa^2\nu t}L^{-1}\left[(p-\nu\kappa^2)^{-1}e^{-\sqrt{p/\nu}\,y}\right]$$

$$=\frac{1}{2}\{e^{-|\kappa|y}\operatorname{erfc}[\eta-\sqrt{\kappa^2\nu t}]$$

$$+e^{|\kappa|y}\operatorname{erfc}[\eta+\sqrt{\kappa^2\nu t}]\}\ , \tag{3.9}$$

where

$$\eta=\frac{y}{2\sqrt{\nu t}}\ , \tag{3.10}$$

and

$$\operatorname{erfc}\xi=\frac{2}{\sqrt{\pi}}\int_\xi^\infty e^{-\xi^2}d\xi\ . \tag{3.11}$$

$E(y, t)$ can be expanded into a series form in powers of t, using a formula V–11 of 7):

$$E(y, t)=e^{\kappa y-\kappa^2\nu t}L^{-1}\left[\frac{1}{p}\sum_{n=0}^\infty\left(\frac{\nu\kappa^2}{p}\right)^n e^{-\sqrt{p/\nu}\,y}\right]$$

$$=e^{\kappa y-\kappa^2\nu t}\sum_{n=0}^\infty(4\kappa^2\nu t)^n \mathrm{i}^{2n}\operatorname{erfc}\eta\ , \tag{3.12}$$

where

$$\mathrm{i}^n\operatorname{erfc}x=\int_x^\infty \mathrm{i}^{n-1}\operatorname{erfc}\xi d\xi\ ,$$

$$\mathrm{i}^0\operatorname{erfc}x=\operatorname{erfc}x\ . \tag{3.13}$$

For general $U(t)$ we get from the convolution theorem

$$u=\int_0^t U'(t-\tau)E(y, \tau)d\tau\ . \quad U'(t)=\frac{dU}{dt}\ , \tag{3.14}$$

which is equivalent to (3.8).

The frictional drag D per unit area of the plate is given by

$$D=-\mu\left(\frac{\partial u}{\partial y}\right)_{y=0}=\int_0^t U'(t-\tau)D_E(\tau)d\tau\ , \qquad (3.15)$$

where

$$D_E(\tau)=-\mu\left(\frac{\partial E}{\partial y}\right)_{y=0}$$

$$=\mu\left[\frac{1}{\sqrt{\pi\nu t}}e^{-\kappa^2\nu t}-\kappa\ \mathrm{erfc}\,(\kappa\sqrt{\nu t})\right], \qquad (3.16)$$

and μ is the viscosity: $\mu=\rho\nu$.

Here we note very interesting relations between the values for the cases of suction and injection: If the absolute value of κ or V_0 is the some, the following formulae are found,

$$\frac{u_{\kappa>0}}{u_{\kappa<0}}=e^{2|\kappa|y}\ , \qquad (3.17)$$

$$D_{\kappa<0}-D_{\kappa>0}=2\mu|\kappa|\int_0^t U'(t-\tau)d\tau=\rho|V_0|U(t)\ . \qquad (3.18)$$

where the suffix $\kappa>0$ denotes the value for the case of $\kappa>0$ and *vice versa*. It is rather interesting that (3.18) is different from $2\rho|V_0|U$ which may be supposed simply by the naive momentum consideration.

The most interesting case is that corresponding to Rayleigh's problem $U=U_0=$constant, when u and D are given respectively by

$$\frac{u}{U_0}=E(y,\ t)\ , \qquad \frac{D}{V_0}=D_E(t)\ . \qquad (3.19)$$

Fig. 1 shows the velocity profiles $E(y,\ t)$ for some values of $\xi=\kappa\sqrt{\nu t}=V_0\sqrt{t}/(2\sqrt{\nu})$. They are not similar among themselves, and have inflection points for the case of injection $V_0>0$. If $\kappa^2\nu t$ is sufficiently large they tend to $\exp(\kappa y-|\kappa|y)=\exp\frac{1}{2\nu}(V_0-|V_0|)y$ rapidly, of which profile $u/U_0=\exp(-|V_0|y/\nu)$ for $V_0<0$ is a well known suction profile for the steady flow obtained by Meredith and Grifith1).

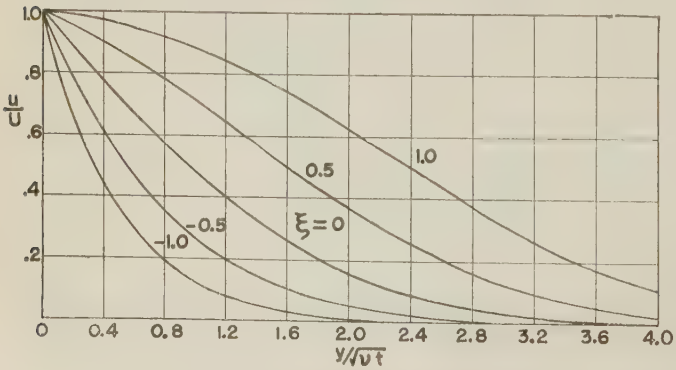

Fig. 1. The Velocity Profiles: $U=U_0$, $V=V_0$, $\xi\ \ V_0\sqrt{t}/(2\sqrt{\nu})$.

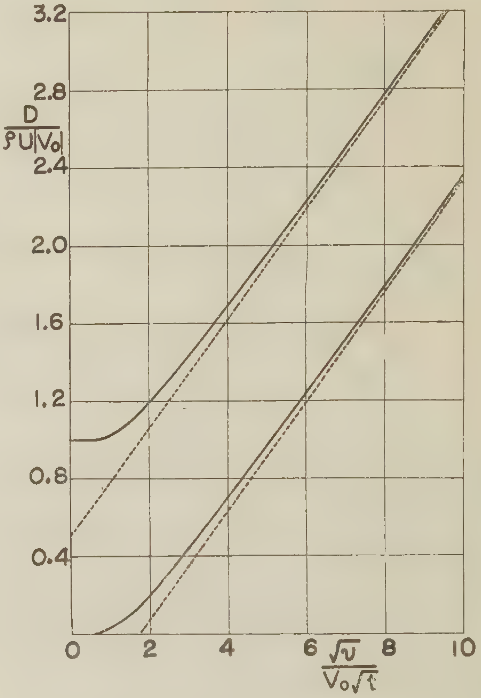

Fig. 2. Frictional Drag: $U=U_0$, $V=V_0$.

Fig. 2 shows the skin frictional drag D for the plate. If we use $|\xi|$ as an independent variable $D_E/(2\mu|\kappa|)=D/(\rho U_0|V_0|)$ is represented by two single curves:

$$\frac{D}{\rho U|V_0|}=\frac{1}{2}\left[\frac{e^{-|\xi|^2}}{\sqrt{\pi}\ |\xi|}+\mathrm{erf}\ |\xi|\mp 1\right] \qquad \xi\gtrless 0 \qquad (3.16')$$

If $\xi^2=\kappa^2\nu t$ is small D is practically identical with the classical Raylgith's value $\mu U/\sqrt{\pi\nu t}$, then it tends to 0 or $\rho U|V_0|$ according as $V_0>0$ or $V_0<0$, in the limit of $\kappa^2\nu t\to\infty$.

§ 4. The Case of Similar Profile

As the most simple case of variable V, we want to investigate the case when (2.9) gives similar solutions, which must have the following form.

$$u=U(t)G(\eta)\ , \qquad \eta=y/g(t)\ . \qquad (4.1)$$

Introducting (4.1) into (2.9) and dividing by U/g^2 we obtain

$$-[gg']\eta G'+[g^2U'/U]G+[gV]G'=\nu G'' \quad (4.2)$$

In order that (4.2) reduces to an ordinary differential equation for G the three terms in the square brackets must be equal to constants:

$$2gg'=A\,, \quad g^2U'/U=B\,, \quad gV=C\,, \quad (4.3)$$

which determine g, U and V as follows if $A \neq 0$:

$$g=\sqrt{At+k}\,,\ U\infty(At+k)^{B/A}\,,\ V=C/\sqrt{At+k}\,. \quad (4.4)$$

The case corresponding to $A=0$:

$$g=\sqrt{k}\,, \quad U\infty e^{Bt/k}\,, \quad V=C/\sqrt{k} \quad (4.5)$$

is a special case of constant V, which has been studied already in § 3 and 6). In either case (4.2) reduces to

$$G''+\frac{1}{\nu}\left[\frac{A}{2}\eta-C\right]G'-\frac{B}{\nu}G=0\,. \quad (4.6)$$

We can take in (4.4)

$$\left.\begin{aligned} U=U_0t^{\alpha}\,, \quad V=V_0t^{-1/2}\,,\\ g=2\sqrt{\nu t} \end{aligned}\right\} \quad (4.4')$$

without loss of generality (i.e. $A=4\nu$, $C=2\sqrt{\nu}V_0$, $B=4\nu\alpha$).

Then (4.6) gives for the solution $G(\eta)=G_\alpha(\eta)$

$$G_\alpha''+2(\eta-\eta_0)G_\alpha'-4\alpha G_\alpha=0\,, \quad (4.6')$$

where

$$\eta=2\frac{y}{\sqrt{\nu t}}\,, \qquad \eta_0=\frac{V_0}{\sqrt{\nu}}\,, \quad (4.7)$$

which must be solved under the boundary conditions derived from (2.4) and (2.6):

$$G_\alpha(0)=1\,, \quad G_\alpha(\infty)=0\,. \quad (4.8)$$

The solution of (4.6′) satisfying (4.8) is found to be

$$G_\alpha(\eta)=\frac{F_\alpha(\eta-\eta_0)}{F_\alpha(-\eta_0)}\,, \quad (4.9)$$

where

$$F_\alpha(\xi)=e^{-\xi^2/2}D_{-2\alpha-1}(\sqrt{2}\,\xi)\,. \quad (4.10)$$

$D_\beta(z)$ is a parabolic cylinder function which satisfies the equation

$$\frac{d^2}{dz^2}D_\beta+\left(\beta+\frac{1}{2}-\frac{1}{4}z^2\right)D_\beta=0\,. \quad (4.11)$$

When $\eta_0=0$ G_α reduces to the solution obtained by Watson[8].

Corresponding steady boundary layer on a semi-infinite flat plate has been investigated by Schlichting, Bussmann and Schaefer[1]. They have shown the existence of similar solutions for the case $U(x)\infty x^m$ and $V(x)\infty x^{(m-1)/2}$. Their x corresponds to our t.

Rayleigh's case is given by taking $\alpha=0$ ($U=U_0$). Taking into account

$$D_{-1}(x)=\sqrt{\frac{\pi}{2}}e^{x^2/4}\operatorname{erfc}\left(\frac{x}{\sqrt{2}}\right) \quad (4.12)$$

we obtain

$$\frac{u}{U_0}=\frac{\operatorname{erfc}(\eta-\eta_0)}{\operatorname{erfc}(-\eta_0)}=\frac{\operatorname{erfc}[y/(2\sqrt{\nu t})-V_0/\sqrt{\nu}\,]}{\operatorname{erfc}(-V_0/\sqrt{\nu}\,)} \quad (4.13)$$

The frictional drag D per unit area is given by

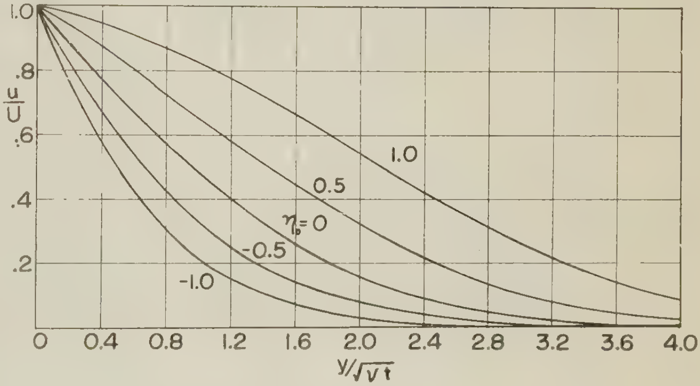

Fig. 3. The Velocity Profiles: $U=U_0$, $V=V_0t^{-1/2}$, $\eta_0=V_0/\sqrt{\nu}=V\sqrt{t}/\sqrt{\nu}$.

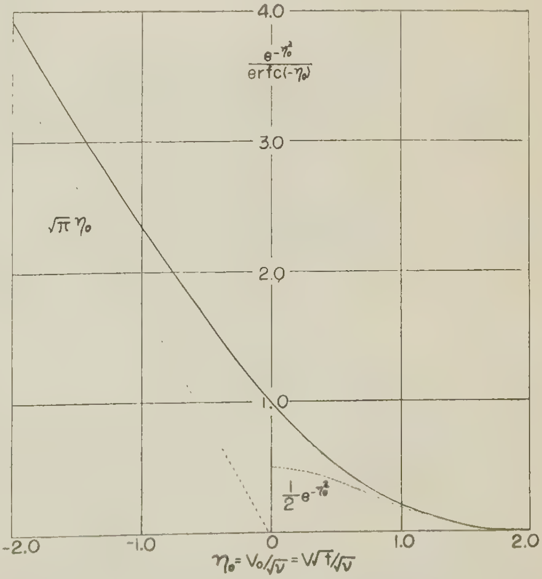

Fig. 4. $D_{\eta=\eta_0}/D_{\eta=0}$: $U=U_0$, $V=V_0t^{-1/2}$.

$$\frac{D}{\mu U_0}=\frac{1}{\sqrt{\pi\nu t}}\frac{e^{-\eta_0^2}}{\operatorname{erfc}(-\eta_0)}. \tag{4.14}$$

Fig. 3 shows the velocity profiles for some values of $\eta_0=V_0/\sqrt{\nu}$. They have inflection points at $\eta=\eta_0$, for the case of injection $V_0>0$.

Fig. 4 gives $D_{\eta=\eta_0}/D_{\eta=0}=e^{-\eta_0^2}/\operatorname{erfc}(-\eta_0)$, the factor which represents the effect of injection or suction compared with the classical Rayleigh's value $D_{\eta=0}=1/\sqrt{\pi\nu t}$. If $|\eta_0|$ is sufficiently large it is approximated by $e^{-\eta_0^2/2}$ or $\sqrt{\pi}\,|\eta_0|$ according as $V_0>0$ or $V_0<0$. These behaviours are qualitatively the same as what have been found for the corresponding steady boundary layer solution[1].

In conclusion the author expresses his cordial thanks to Professor Isao Imai for the continual guidance and encouragement throughout this work. This work was supported by the Scientific Research Fund of the Ministry of Education of Japan.

Application of the Thin-Wing-Expansion Method to the Compressible Flow past an Elliptic Cylinder, with Special Reference to its Fourth Approximation

By Yaso'o MATUNOBU

Department of Physics, Faculty of Science,
University of Tokyo

(Received September 22, 1956)

Both the complete and transonic thin-wing-expansion methods are utilized to obtain the steady irrotational flow of a compressible fluid past an elliptic cylinder. The velocity distribution over the surface is calculated up to the fourth powers in thickness ratio t. Then it is found that the fourth order perturbations include not only terms of $O(t^4)$ but also those of $O(t^4\log t)$, and that the latter group becomes negatively predominant over the former in the transonic range. In calculating the fluid velocity near the stagnation point there still remains insurmountable difficulty even for moderate subsonic flow. The resulting expressions for an elliptic cylinder prove to be transformed into those for a parabolic cylinder.

§1. Introduction and Summary

The steady irrotational flow of a compressible fluid past an elliptic cylinder at zero incidence has been studied by a number of authors by means of various methods; especially Hasimoto[1], having recourse to the (complete) thin-wing-expansion method, calculated velocity distribution over the surface exactly up to the third order of approximation. Later Imai[2,3] proposed a new method called transonic thin-wing-expansion method, showing that the velocity distribution could be obtained more easily up to the same order by the introduction of the transonic similarity hypothesis. As a continuation of these two works the fourth order of approximation will be considered in this paper.

The thin-wing-expansion method has often been proved to give a most suitable approach for such problems as chosen here. It is true, however, that the method could be successfully applied to the flow past a sharp-edged aerofoil such as Kaplan bumps[4),5)] and symmetrical circular arc aerofoils[6),7)], but it is not necessarily the case for the elliptic cylinder owing to its rounded edges which cause enormous change of the flow speed. In fact, it cannot be predicted qualitatively what happens near the stagnation point, even from the exact results including the fourth order perturbation. This fact has been corroborated by recent studies[8),9)] with regard to the flow past aparabolic cylinder with its axis parallel to the oncoming flow which can be looked upon as a magnified picture of the stagnation region of the elliptic cylinder; i.e., the small disturbance theory yields no reliable information concerning the flow pattern around such blunt-nosed bodies.

Furthermore, the resulting expressions for the velocity distribution show that the fourth order perturbation includes terms of order $t^4 \log \sqrt{1-M^2}\,t$ (t: thickness ratio, M: free stream Mach number) which did not appear in the calculation of the flow field around the sharp-edged aerofoils cited above*. Undoubtedly, these terms play such a dominant role in the high subsonic range that it becomes impossible to apply the transonic similarity approximation to the resulting expressions. It can be shown that when t is sufficiently small the fourth order perturbation as a whole proves negative even for the moderate subsonic free stream.

In the following sections calculations on the basis of the transonic thin-wing-expansion method are chiefly developed; in particular, more detailed account is given of the fourth approximation, since the analytical expressions up to the third order have already been obtained. As for the complete thin-wing-expansion method, only final results are summarized in § **6** and the basic formulae utilized are brought in the appendix in forms ready for practical use.

§ 2. Transonic Thin-Wing-Expansion Method

Suppose a uniform flow directed along x-axis blows against an aerofoil fixed in x-y plane, with velocity U and Mach number M. On the assumption that the disturbance velocities due to the presence of the obstacle are everywhere small and of the same order as the thickness ratio t, the velocity potential Φ and the stream function Ψ can be written in the forms

$$\Phi = x + \varepsilon\phi\,, \qquad \Psi = y + \varepsilon\psi\,, \tag{2.1}$$

where $\varepsilon = O(t)$ and U has been taken as unit of velocity. Further, defining the following complex quantities:

$$\begin{aligned}&\zeta = x + i\mu y, \quad \bar{\zeta} = x - i\mu y,\\ &G = \phi + i\psi/\mu, \quad \bar{G} = \phi - i\psi/\mu; \quad \mu = \sqrt{1-M^2}\end{aligned} \tag{2.2}$$

and assuming that M is nearly unity, we obtain the following equation, upon which the transonic thin-wing-expansion method is based, from the equation of motion for the two-dimensional steady irrotational flow of an inviscid fluid (cf. Ref. 4); namely,

$$\frac{\partial G}{\partial \bar{\zeta}} = \frac{\varepsilon}{16}\nu\left(\frac{\partial G}{\partial \zeta} + \frac{\partial G}{\partial \bar{\zeta}} + \frac{\partial \bar{G}}{\partial \zeta} + \frac{\partial \bar{G}}{\partial \bar{\zeta}}\right)^2, \tag{2.3}$$

where

$$\nu = 4M^2\left(1 + \frac{\gamma+1}{4}\frac{M^2}{1-M^2}\right), \tag{2.4}$$

γ being the ratio of specific heats.

On the assumption that $\beta(=\varepsilon\nu/16)$ is small, the solution of Eq. (2.3) may be expanded as

$$G = G_1 + \beta G_2 + \beta^2 G_3 + \beta^3 G_4 + \cdots\,. \tag{2.5}$$

Then G_n can be expressed in explicit forms after successive integrations, but they are omitted here since they have already appeared in Ref. 4.

The boundary conditions are

(i) $\partial G/\partial\zeta$ is one-valued and continuous throughout the flow field,

(ii) $\partial G/\partial\zeta$ vanishes at infinity,

(iii) $\mathrm{Im}\,(\zeta + \varepsilon\mu^2 G) = 0$ at the boundary surface.

§ 3. Calculations up to the Third Approximation

Now we consider the flow past an elliptic cylinder with its major axis parallel to the uniform flow. Let the ellipse be given by

---

* For symmetrical circular arc aerofoils this fact has been inferred from the results up to $O(t^3)$, whereas it is actually proved in the case of Kaplan bumps. Moreover, it is well known that such terms are required from the outset in the axially symmetrical flow past a slender body (for example, cf. Ref. 10).

$$x=a\cos\theta,\quad y=b\sin\theta;\quad b/a=t. \tag{3.1}$$

Then, by means of the transformation

$$\zeta=Z+\frac{\sigma^2}{Z};\quad \sigma^2=\frac{1-\mu t}{1+\mu t}, \tag{3.2}$$

the flow field in the ζ-plane is conformally mapped onto the region outside the unit circle $(Z=e^{i\theta})$ in the Z-plane. The boundary conditions (i) to (iii) are entirely satisfied by assuming that

$$G_1=f(\zeta)=\frac{k}{Z},\quad k=(1+\sigma^2)\frac{t}{\varepsilon\mu}. \tag{3.3}$$

The perturbation velocity potentials of higher order than the first can be obtained successively by determining the arbitrary functions $g_n(\zeta)$ corresponding to $G_n(\zeta,\bar{\zeta})$ so as to satisfy the following conditions:

(i′) $\partial G_n/\partial\zeta$ is one-valued and continuous throughout the flow field,

(ii′) $\partial G_n/\partial\zeta$ vanishes at infinity,

(iii′) $\operatorname{Im} G_n=0$ at the boundary surface $(n=2, 3, 4, \cdots)$.

Thus, we obtain

$$G_2=\frac{k^2}{\sigma^2}\left(\frac{1}{Z}+J\right)+c.c., \tag{3.4}$$

$$G_3=k^3\left\{\frac{16}{3\sigma^4}\frac{1}{Z}+\left(\frac{8+3\sigma^2}{3\sigma^4}-\frac{14}{\sigma^2}L\right)\frac{Z}{V}+\frac{8+\sigma^2}{\sigma^4}J-\frac{14}{\sigma^2}\frac{1}{V}J\right\}+c.c., \tag{3.5}$$

$$g_2=k^2\left\{2\frac{Z}{V}+\frac{1}{\sigma^2}\left(\frac{1}{Z}+J\right)\right\}, \tag{3.6}$$

$$g_3=k^3\left\{\frac{16}{3\sigma^4}\frac{1}{Z}+\frac{22+\sigma^2}{\sigma^4}J+\left(\frac{15}{\sigma^2}+\frac{8}{3\sigma^4}-\frac{14}{\sigma^2}L\right)\frac{Z}{V}-4(3-\sigma^2)\frac{Z}{V^2}+4\sigma^4\frac{Z}{V^3}-\frac{14}{\sigma^2}S\right\}, \tag{3.7}$$

where

$$\left.\begin{aligned}&J=\frac{1}{2\sigma}\log\frac{Z-\sigma}{Z+\sigma},\quad V=Z^2-\sigma^2,\\&S=\left(LZ+\frac{1}{\sigma^2}J\right)\Big/(1-\sigma^2Z^2),\end{aligned}\right\} \tag{3.8}$$

$$L=\frac{1}{2\sigma^2}\log\frac{1+\sigma^2}{1-\sigma^2}=-\frac{1}{2\sigma^2}\log\mu t, \tag{3.9}$$

and $c.c.$ denotes the complex conjugate of the preceding term. It must be noted that (3.4) and (3.5) express G_2 and G_3 at the surface and substitution $Z=e^{i\theta}$ there gives immediately the expressions for the perturbation velocity potentials $\phi_2(\theta)$ and $\phi_3(\theta)$ respectively.

§ 4. Calculation of the Fourth Approximation

In this section the practical procedure of finding the fourth order perturbation will be outlined. Calculations involved are quite analogous to, but more lengthy than, the foregoing ones.

First, substituting (3.3), (3.6), and (3.7) into the integrated form for G_4, we determine $G_4(\zeta,\bar{\zeta})$ exclusive of the arbitrary function $g_4(\zeta)$. Then, we rearrange the resulting expression appropriately with the aid of the relation $Z\bar{Z}=1$ at the surface. Further, it is necessary to choose the complementary function for each of the derived terms, i.e., the function which, in conjunction with the derived ones, satisfies the conditions (i′) to (iii′). Collecting all the sums of the derived and the complementary functions, we thus obtain G_4 at the surface. These procedures are exhibited term by term in the following scheme:

Coefficient	Derived Function	Complementary Function	Sum
$-\frac{280}{3\sigma^4}+\frac{28}{\sigma^2}L$	$\frac{Z}{V}$	$-\frac{Z}{V}$	0
$\frac{182}{\sigma^2}-36+\left(\frac{28}{\sigma^2}+84\right)L$	$\frac{Z}{V^2}$	$-\frac{Z}{V^2}$	0
$-\frac{292}{3}+52\sigma^2-16\sigma^4+56\sigma^2L$	$\frac{Z}{V^3}$	$-\frac{Z}{V^3}$	0
$88\sigma^4-32\sigma^6$	$\frac{Z}{V^4}$	$-\frac{Z}{V^4}$	0
$-48\sigma^6+32\sigma^8$	$\frac{Z}{V^5}$	$-\frac{Z}{V^5}$	0

$-\frac{28}{\sigma^2}$	$\frac{Z^3}{V}\frac{dS}{dZ}$	$-\frac{Z^3}{V}\frac{dS}{dZ}$	0
$-\frac{182}{\sigma^4}+\frac{14}{\sigma^2}$	$\frac{1}{V}\bar{J}$	$-\frac{1}{\sigma^2}J+S+L\frac{Z}{V}$	$\left(\frac{\bar{J}}{V}+L\frac{Z}{V}\right)+c.c.$
$\frac{168}{\sigma^2}+28$	$\frac{1}{V^2}\bar{J}$	$\frac{1}{\sigma^4}J+\frac{1}{\sigma^2}T+L\frac{Z}{V^2}$ $+\frac{1}{2\sigma^2}\left(\frac{1}{1-\sigma^4}-L\right)\frac{Z}{V}$	$\Big[\frac{\bar{J}}{V^2}+L\frac{Z}{V^2}+\frac{1}{2\sigma^2}$ $\times\left(\frac{1}{1-\sigma^4}-L\right)\frac{Z}{V}\Big]+c.c.$
$\frac{14}{\sigma^2}$	$\frac{1}{V^2}\bar{J}+J\frac{1}{\bar{V}^2}$	0	$\frac{1}{V^2}\bar{J}+J\frac{1}{\bar{V}^2}$
$\frac{84}{\sigma^6}+\frac{35}{2\sigma^4}-\frac{1}{2\sigma^2}-\frac{7}{\sigma^4}L$	$\bar{J}$	J	$J+\bar{J}$
$\frac{140}{3\sigma^6}+\frac{35}{2\sigma^4}-\frac{1}{2\sigma^2}-\frac{7}{\sigma^4}L$	$\frac{\bar{Z}}{\bar{V}}$	$\frac{Z}{V}$	$\frac{Z}{V}+\frac{\bar{Z}}{\bar{V}}$
$\frac{112}{3\sigma^6}$	$\frac{1}{\bar{Z}}$	$\frac{1}{Z}$	$\frac{1}{Z}+\frac{1}{\bar{Z}}$
$-\frac{182}{3\sigma^4}-\frac{14}{\sigma^2}+\frac{28}{\sigma^2}L$	$\frac{1}{V}\frac{\bar{Z}}{\bar{V}}$	$-\frac{1}{1+\sigma^2}\frac{Z}{V}$	$\frac{\sigma^2}{1-\sigma^4}\left(\frac{Z}{V}+\frac{\bar{Z}}{\bar{V}}\right)$
$-\frac{28}{3\sigma^4}-\frac{7}{\sigma^2}-1+\frac{14}{\sigma^2}L$	$\frac{\bar{Z}}{\bar{V}^2}$	$\frac{Z}{V^2}$	$\frac{Z}{V^2}+\frac{\bar{Z}}{\bar{V}^2}$
$\frac{28}{\sigma^2}$	$\bar{I}$	I	$I+\bar{I}$
$\frac{28}{\sigma^2}$	$\frac{J}{V}\frac{1}{\bar{V}}$	$-\frac{\sigma^2}{1-\sigma^4}\left(\frac{J}{V}+S+L\frac{Z}{V}\right)$	$-\frac{\sigma^2L}{1-\sigma^4}\left(\frac{Z}{V}+\frac{\bar{Z}}{\bar{V}}\right)$

where

$$T=\frac{1}{1-\sigma^2Z^2}\left\{S-\frac{2}{\sigma^2}J-LZ+\frac{1}{2}\left(\frac{1}{1-\sigma^4}-L\right)\right\}, \qquad I=\int\frac{dS}{dZ}\frac{dZ}{V}. \tag{4.1)*$$

Hence, from the first and fourth columns, we can build up G_4 at the surface; namely,

$$\begin{aligned}G_4=k^4\Big[&\frac{112}{3\sigma^6}\frac{1}{Z}+\left\{\frac{140}{3\sigma^4}+\frac{35}{2\sigma^4}-\frac{1}{2\sigma^2}+\frac{14}{1-\sigma^4}\left(\frac{6}{\sigma^4}-\frac{1}{3\sigma^2}-1\right)-\frac{273}{\sigma^4}L\right\}\frac{Z}{V}\\&+\left(\frac{84}{\sigma^6}+\frac{35}{2\sigma^4}-\frac{1}{2\sigma^2}-\frac{7}{\sigma^4}L\right)J-\left\{\frac{28}{3\sigma^4}+\frac{7}{\sigma^2}+1-\left(\frac{182}{\sigma^2}+28\right)L\right\}\frac{Z}{V^2}\\&+\left(-\frac{182}{\sigma^4}+\frac{14}{\sigma^2}\right)\frac{1}{V}\bar{J}+\left(\frac{182}{\sigma^2}+28\right)\frac{1}{V^2}\bar{J}+\frac{28}{\sigma^2}I\Big]+c.c.\end{aligned} \tag{4.2}$$

§ 5. Velocity Distribution

Let *ds* denote the line element of the profile contour measured in the positive sense. Then, from (3.1)

$$ds=(1+\sigma^2)\sin\theta\sqrt{1+t^2\cot^2\theta}\;d\theta\,. \tag{5.1}$$

Therefore, the velocity at the upper surface is given by

$$q=-\frac{d\Phi}{ds}=\frac{1}{(1+\sigma^2)\sqrt{1+t^2\cot^2\theta}}\frac{d}{d(\cos\theta)}\{\cos\theta+\mathcal{E}(\phi_1+\phi_2+\phi_3+\phi_4)\}. \tag{5.2}$$

Substituting (3.3), (3.4), (3.5), and (4.2) into (5.2) with the aid of the relation

---

* The functions T and I, as well as S given (by 3.8), can be verified to be one-valued and regular functions of Z even at the point $Z=\pm 1/\sigma$.

$$\frac{d\phi_n}{d(\cos\theta)}=\left[\frac{2}{Z-\overline{Z}}\left(Z\frac{\partial G_n}{\partial Z}-\overline{Z}\frac{\partial \overline{G}_n}{\partial \overline{Z}}\right)\right]_{Z=e^{i\theta}}, \tag{5.3}$$

we arrive at the expression for the velocity distribution over the surface:

$$q(\sigma,\,\theta)=(1+t^2\cot^2\theta)^{-1/2}[1+(t/\mu)\{1+\beta k q_2+(\beta k)^2 q_3+(\beta k)^3 q_4\}], \tag{5.4}$$

where

$$q_2=\frac{2}{\sigma^2}\left(1-\frac{1+\sigma^2}{\Theta}\right), \tag{5.5}$$

$$\begin{aligned}q_3=&\frac{32}{3\sigma^4}-\left\{\frac{64}{3\sigma^4}(1+2\sigma^2)-28\left(\frac{1}{\sigma^2}-1\right)L\right\}\frac{1}{\Theta}+4(1+\sigma^2)^2(1-\sigma^2)\\&\times\left(\frac{8+3\sigma^2}{3\sigma^4}-\frac{14}{\sigma^2}L\right)\frac{1}{\Theta^2}+\frac{28(1-\sigma^4)}{\sigma^3}\frac{\lambda}{\Theta^2}+\frac{14}{\sigma^5}\left\{\frac{1+\sigma^4}{\Theta}-\frac{(1-\sigma^4)^2}{\Theta^2}\right\}\tau,\end{aligned} \tag{5.6}$$

$$\begin{aligned}q_4=&\frac{224}{3\sigma^6}-2\left\{\frac{112}{\sigma^6}+\frac{1330}{3\sigma^4}+\frac{14}{\sigma^2}+\frac{14}{1+\sigma^2}\left(\frac{6}{\sigma^4}-\frac{10}{3\sigma^2}-1\right)-14\left(\frac{33}{\sigma^4}-\frac{19}{\sigma^2}\right)L\right\}\frac{1}{\Theta}\\&+2(1+\sigma^2)\left\{\frac{112}{\sigma^6}+\frac{1148}{3\sigma^4}-\frac{464}{3\sigma^2}-46+4\sigma^2-28\left(\frac{52}{\sigma^4}-\frac{21}{\sigma^2}-6+3\sigma^2\right)L\right\}\frac{1}{\Theta^2}\\&-\frac{8}{\sigma^2}(1+\sigma^2)^3(1-\sigma^2)^2\left\{\frac{28}{3\sigma^4}+\frac{7}{\sigma^2}+1-\left(\frac{182}{\sigma^2}+28\right)L\right\}\frac{1}{\Theta^3}+\frac{28}{\sigma}\left\{\left(\frac{39}{\sigma^4}+\frac{3}{\sigma^2}-15+\sigma^2\right)\frac{1}{\Theta^2}\right.\\&\left.-2\left(\frac{13}{\sigma^4}+\frac{2}{\sigma^2}\right)(1-\sigma^4)^2\frac{1}{\Theta^3}\right\}\lambda+\frac{14}{\sigma}\left\{\left(\frac{39}{\sigma^6}+\frac{3}{\sigma^4}+\frac{15}{\sigma^2}-1\right)\frac{1}{\Theta}\right.\\&\left.-(1-\sigma^4)\left(\frac{65}{\sigma^6}+\frac{7}{\sigma^4}+\frac{11}{\sigma^2}+5\right)\frac{1}{\Theta^2}+\left(\frac{26}{\sigma^6}+\frac{4}{\sigma^4}\right)(1-\sigma^4)^3\frac{1}{\Theta^3}\right\}\tau,\end{aligned} \tag{5.7}$$

where

$$\beta k=\frac{1+\sigma^2}{16}\frac{\nu t}{\mu},$$

$$\left.\begin{aligned}&\Theta=1-2\sigma^2\cos 2\theta+\sigma^4,\quad \lambda=\cos\theta\log\frac{1+2\sigma\cos\theta+\sigma^2}{1-2\sigma\cos\theta+\sigma^2},\\&\tau=\frac{1}{\sin\theta}\tan^{-1}\frac{2\sigma\sin\theta}{1-\sigma^2}.\end{aligned}\right\} \tag{5.8}$$

Substitution $\theta=\pi/2$ in the above expressions leads to

$$\begin{aligned}q\left(\sigma,\,\frac{\pi}{2}\right)=1+\frac{t}{\mu}\Bigg[&1+\frac{1}{8}\frac{\nu t}{\mu}+\frac{1}{64}\left(\frac{\nu t}{\mu}\right)^2\left\{\frac{14}{\sigma^3}\tan^{-1}\sigma-7\left(\frac{1}{\sigma^2}-1\right)L-\frac{7}{\sigma^2}+\frac{5}{3}\right\}\\&-\frac{1}{1024}\left(\frac{\nu t}{\mu}\right)^3\left\{\frac{49}{\sigma^4}+\frac{658}{3\sigma^2}+\frac{43}{3}+7\left(\frac{19}{\sigma^4}+\frac{40}{\sigma^2}-29-2\sigma^2\right)L\right.\\&\left.-\frac{14}{\sigma}\left(\frac{1}{\sigma^2}+3\right)\left(\frac{13}{\sigma^2}+1\right)\tan^{-1}\sigma\right\}\Bigg].\end{aligned} \tag{5.9}$$

Further, it is permissible to put $\sigma^2=1$, or $\mu t=0$, in these results, because from the beginning the terms multiplied by factors $(\overline{\zeta}-\zeta)^n$ have been neglected, $\overline{\zeta}-\zeta$ being of $O(\mu t)$ at the boundary surface (cf. Ref. 4). Thus, from (5.5), (5.6), and (5.7),

$$\left.\begin{aligned}&q_2=2-\frac{1}{\sin^2\theta},\quad q_3=\frac{32}{3}-\frac{16}{\sin^2\theta}+\frac{7\pi}{2\sin^3\theta},\\&q_4\to\frac{224}{3}-\frac{581}{2\sin^2\theta}+\frac{98\pi}{\sin^3\theta}+\frac{149}{2\sin^4\theta}+\frac{98}{\sin^4\theta}\cos\theta\log\cot\frac{\theta}{2}\\&\quad+\left(\frac{98}{\sin^4\theta}-\frac{49}{\sin^2\theta}\right)\log\mu t,\end{aligned}\right\} \tag{5.10}$$

and from (5.9),

$$q\left(1,\ \frac{\pi}{2}\right)=1+\frac{t}{\mu}\left[1+\frac{1}{8}\frac{\nu t}{\mu}+\frac{1}{64}\left(\frac{\nu t}{\mu}\right)^2\left(\frac{7}{2}\pi-\frac{16}{3}\right)-\frac{1}{1024}\left(\frac{\nu t}{\mu}\right)^3\left(\frac{848}{3}-196\pi+98\log\frac{1}{\mu t}\right)\right]. \tag{5.11}$$

These expressions are nothing other than the results based upon the transonic similarity law extended by Imai. It should be noticed, however, that q_4 has logarithmic singularity for $\sigma=\pm 1$, and consequently (5.10) and (5.11) seem to be inconsistent with the results expected from the transonic similarity law.

§ 6. Results due to the Complete Thin-Wing-Expansion Method

The exact treatment of the two-dimensional compressible flow by means of the complete thin-wing-expansion method is, in general, much more tedious than by means of the transonic thin-wing-expansion method. For comparison, however, it is worth while to reinvestigate the the same problem by the complete method. In this section, instead of following the course of the calculation, only the results corresponding to equations (5.9), (5.10), and (5.11) will be given in the following (see Appendix II):

Velocity at the mid-chord point ($\theta=\pi/2$)——

$$\begin{aligned}Q\left(\frac{\pi}{2}\right)=1&+\frac{t}{\mu}+\frac{t^2}{\mu^2}D+2\frac{t^3}{\mu^3}\left[B'+\left(C'+\frac{D^2}{2}\right)\left\{\frac{2}{\sigma^3}\tan^{-1}\sigma-\frac{1}{\sigma^2}-\left(\frac{1}{\sigma^2}-1\right)L\right\}\right]\\&-\frac{t^4}{\mu^4}\Bigg[\frac{1}{\sigma^4}\left(\frac{K_1}{2}+3K_2\right)+\frac{1}{\sigma^2}(K_1+14K_2)+(3K_1-2K_3+2K_4-D^3)\\&+\left\{\frac{1}{\sigma^4}\left(9K_2-\frac{K_1}{2}\right)+\frac{1}{\sigma^2}(K_1+18K_2)-\left(15K_2-\frac{7}{2}K_1\right)-2\sigma^2K_1\right\}L\\&-\frac{2}{\sigma}\tan^{-1}\sigma\left\{\frac{6}{\sigma^4}K_2+\frac{1}{\sigma^2}(K_1+18K_2)+3K_1\right\}\\&-\frac{1}{2}M^2\kappa\left(C'+\frac{1}{2}D^2\right)\Bigg\{\left(\frac{7}{8\sigma^6}-\frac{1}{3\sigma^4}-\frac{11}{24\sigma^2}-\frac{2}{3}\right)+(1-\sigma^2)\Bigg(\frac{13}{8\sigma^6}+\frac{13}{8\sigma^4}\\&+\frac{11}{8\sigma^2}-\frac{5}{8}\Bigg)L-(1-\sigma^2)\left(\frac{5}{2\sigma^6}+\frac{3}{\sigma^4}+\frac{5}{2\sigma^2}\right)\frac{\tan^{-1}\sigma}{\sigma}\Bigg\}\Bigg].\end{aligned} \tag{6.1}$$

Full expression expanded in powers of t——

$$\begin{aligned}Q_t(\theta)=1&+\frac{t}{\mu}+t^2\left\{2\frac{D}{\mu^2}\left(1-\frac{1}{2\sin^2\theta}\right)-\frac{1}{2}\cot^2\theta\right\}+t^3\Bigg[\frac{4}{\mu^3}\Bigg\{2B'\left(1-\frac{3}{4\sin^2\theta}\right)\\&-D^2\cot^2\theta+2\left(C'+\frac{D^2}{2}\right)\left(-\frac{1}{4\sin^2\theta}+\frac{\pi}{8\sin^3\theta}\right)\Bigg\}-\frac{1}{\mu}\left(\frac{1}{2}+2D\right)\cot^2\theta\Bigg]\\&+t^4\Bigg[\frac{1}{\mu^4}\Bigg\{16K_3-\left(\frac{7}{2}K_1+25K_2+16K_3+4K_4\right)\frac{1}{\sin^2\theta}+(-K_1+8K_2+2K_3\\&+2K_4+D^3)\frac{1}{\sin^4\theta}+(K_1+6K_2)\left(\frac{2\pi}{\sin^3\theta}+\frac{2\cos\theta}{\sin^4\theta}\log\cot\frac{\theta}{2}\right)\\&+\frac{7}{24}M^2\kappa\left(C'+\frac{1}{2}D^2\right)\left(\frac{1}{\sin^2\theta}-\frac{2}{\sin^4\theta}\right)\Bigg\}+\frac{4}{\mu^2}\Bigg\{-4B'\cot^2\theta\left(1-\frac{1}{4\sin^2\theta}\right)\\&-D^2\cot^2\theta\left(2-\frac{1}{\sin^2\theta}\right)+\left(C'+\frac{D^2}{2}\right)\Bigg(-\frac{1}{\sin^2\theta}-\frac{1}{2\sin^4\theta}+\frac{3\pi}{4\sin^3\theta}\\&+\frac{\cos\theta}{\sin^4\theta}\log\cot\frac{\theta}{2}\Bigg)+\frac{D}{2}\left(\frac{3}{2}-M^2\right)\left(\frac{1}{2\sin^2\theta}-1\right)\cot^2\theta\\&+\frac{1}{3}M^2\kappa D\left(1-\frac{1}{4\sin^2\theta}\right)\cot^2\theta\Bigg\}+\frac{3}{8}\cot^4\theta\Bigg]\\&+t^4\log\mu t\left\{\frac{1}{\mu^4}(\mathrm{K}_1+6K_2)+\frac{2}{\mu^2}\left(C'+\frac{D^2}{2}\right)\right\}\left(\frac{2}{\sin^4\theta}-\frac{1}{\sin^2\theta}\right),\end{aligned} \tag{6.2}$$

whence, putting $\theta=\pi/2$, we have

$$Q_t\left(\frac{\pi}{2}\right)=1+\frac{t}{\mu}+\frac{t^2}{\mu^2}D+2\frac{t^3}{\mu^3}\left\{B'+\left(C'+\frac{D^2}{2}\right)\left(\frac{\pi}{2}-1\right)\right\}$$
$$-\frac{t^4}{\mu^4}\left[\left\{K_1+6K_2+2\mu^2\left(C'+\frac{D^2}{2}\right)\right\}\log\frac{1}{\mu t}-6\mu^2\left(C'+\frac{D^2}{2}\right)\left(\frac{\pi}{2}-1\right)\right.$$
$$\left.-\left(2\pi-\frac{9}{2}\right)K_1-(12\pi-17)K_2-2K_3+2K_4-D^3+\frac{7}{24}M^2\kappa\left(C'+\frac{D^2}{2}\right)\right], \tag{6.3}$$

where

$$\left.\begin{aligned}&K_1=D\left(C'+\frac{D^2}{2}\right), \quad K_2=\frac{1}{3}F'+\frac{1}{2}B'D+\frac{1}{2}C'D-\frac{1}{4}D^3,\\&K_3=\frac{1}{4}E'+\frac{5}{2}B'D+\frac{1}{2}D^3, \quad K_4=3B'D+D^3.\end{aligned}\right\} \tag{6.4}$$

The other constants B', C', D, E', F', and κ involved in the above expressions are given in Appendix I. Table V lists these values in the case of high subsonic air flow ($\gamma=1.4$).

If only the highest powers of $1/\mu$ are retained in each of the third and the fourth order perturbations, equations (6.1), (6.2), and (6.3) are respectively in accord with equations (5.9), (5.10), and (5.11), as was discussed for the flow past a Kaplan bump (cf. Ref. 4). The full expression in terms of σ, which corresponds to (5.4), is shown in Appendix II. It should be mentioned that (II-1) proves to be transformed into the expression for the velocity distribution of a parabolic cylinder by suitable limiting process[8].

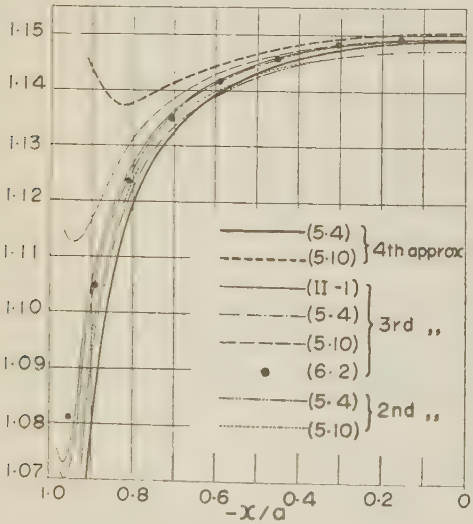

Fig. 1. The chordwise velocity distribution for an elliptic cylinder of thickness ratio 0.1, when free stream Mach number $M=0.7$.

§7. Numerical Discussions

Numerical calculations are now made for the velocity distributions (5.4) and (5.10); in particular, the results for $M=0.7$ and 0.8 with $t=0.1$ are shown in Fig. 1 and 2 respectively, and the corresponding values in Table I. In order to assess the accuracy of the transonic thin-wing-expansion method and of the derivable similarity approximation, the third approximations that were calculated from equations (II-1) and (6.2) by Hasimoto are also plotted in these figures. Then it is found that the exact equation (5.4) obtained from equation (2.3) yields satisfactory results over

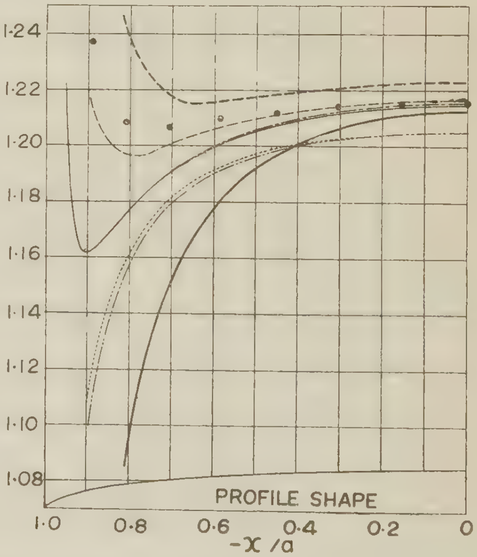

Fig. 2. The chordwise velocity distribution for an elliptic cylinder of thickness ratio 0.1, when free stream Mach number $M=0.8$.

proximation this deviation becomes more conspicuous, and the fourth order perturbation proves negative for equation (5.4), but positive for equation (5.10).

The situation can be more clarified if we examine the velocity at the mid-chord point as a function of the free stream Mach number. Fig. 3 and Table II give this relation for $t=0.1$; then it can be concluded that the results due to the transonic thin-wing-expansion method well approximate those due to the complete thin-wing-expansion method provided that the expressions in terms of σ are used, and that the results obtained as a series expansion of t seem inadequate in the fourth approximation owing to too large a value of t. In addition Fig. 4 and Table III show the variation of the mid-chord velocity $Q_t(\pi/2)$ calculated by means of Table IV for $t=0.05$; the fourth approximation now appears below the third approximation.

At any rate, neither of our results enables us to obtain the flow velocity near the stagnation point, since the series expansion based upon the assumption of small perturbation

Appendix I

Formulae of the Complete Thin-Wing-Expansion Method

The complete thin-wing-expansion method has already been formulated up to the third approximation by Imai in collaboration with Ôyama[11]. The expressions discribed in §6, however, have been derived from slightly different formulation in that solutions can be obtained in an expansion series in powers of $\bar{\zeta}-\zeta$. In the following the formulae including the fourth order correction will be given in a form ready for general application.

Now the $G_n(\zeta, \bar{\zeta})$ are differently defined as (cf. §2)

$$\left.\begin{aligned} \Phi &= x+\phi_1+\phi_2+\cdots, \\ \Psi &= y+\psi_1+\psi_2+\cdots, \\ G_n &= \phi_n+i\psi_n/\mu, \end{aligned}\right\} \qquad \text{(I-1)}$$

where the suffixes n denote the order of magnitude ε^n, ε being a constant of $O(t)$. Then it follows that

$$G_1=f(\zeta)\,, \tag{I-2}$$

$$G_2=\frac{M^2}{4}\left\{\kappa(\bar\zeta-\zeta)f'^2+(1+\kappa)\left(2f'\bar f+\int\bar f'^2d\bar\zeta\right)\right\}+g_2(\zeta)\,, \tag{I-3}$$

$$\begin{aligned}G_3=&\frac{M^4}{8}\kappa^2(\bar\zeta-\zeta)^2f'^2f''+(\bar\zeta-\zeta)\left\{A'f'^3+\frac{M^2}{2}\kappa f'g_2'+\frac{M^2}{12}\kappa D(6f'f''\bar f\right.\\&\left.-3f'\bar f'^2-2\bar f'^3)\right\}+3B'f'^2\bar f+\frac{D^2}{2}(2ff'\bar f'+f''\bar f^2+f\bar f'^2)+C'f'\int\bar f'^2d\bar\zeta\\&+B'\int\bar f'^3d\bar\zeta+D\left(f'\bar g_2+g_2'\bar f+\int\bar f'\bar g_2'\,d\bar\zeta\right)+g_3(\zeta)\,,\end{aligned} \tag{I-4}$$

$$\begin{aligned}G_4=&\frac{M^6}{48}\kappa^3(\bar\zeta-\zeta)^3(f'^3f'')'+(\bar\zeta-\zeta)^2\left[\frac{M^4}{8}\kappa^2D\{(f'^2f'')'\bar f-f'f''\bar f'^2+f'\bar f'^2\bar f''+\bar f'^3\bar f''\}\right.\\&\left.+\frac{3}{2}M^2\kappa A'f'^3f''+\frac{M^4}{8}\kappa^2(f'^2g_2')'\right]+(\bar\zeta-\zeta)\left[H'f'^4+3A'f'^2g_2'+\frac{M^2}{4}\kappa(g_2'^2+2f'g_3')\right.\\&+3(DA'+M^2\kappa B')f'^2f''\bar f+\frac{M^2}{2}\kappa D\{(f'g_2')'\bar f+f'f''\bar g_2-\frac{1}{2}g_2'\bar f'^2-f'\bar f'\bar g_2'-\bar f'^2\bar g_2'\}\\&+\frac{M^2}{4}\kappa D^2\{(ff'^2)'\bar f'+(f'f'')'\bar f^2-2ff'\bar f'\bar f''-f''\bar f\bar f'^2-2f\bar f'^2\bar f''\}+\frac{M^2}{2}\kappa C'f'f''\int\bar f'^2d\bar\zeta\\&\left.-\frac{M^2}{8}\kappa(6B'-D^2)f'^2\bar f'^2-\left(DA'+\frac{M^2}{3}\kappa C'\right)f'\bar f'^3-\frac{3}{8}(2DA'+M^2\kappa B')\bar f'^4\right]\\&+(E'f'^3+6B'f'g_2'+Dg_3')\bar f+D\left\{3B'ff'^2+C'f'\int f'^2d\zeta+D(fg_2)'\right\}\bar f'+\frac{D^3}{2}f^2f'\bar f''\\&+D\left(6B'f'f''+\frac{D}{2}g_2''\right)\bar f^2+(F'f'^2+C'g_2')\int\bar f'^2d\bar\zeta+D^3(ff')'\bar f\bar f'+(3B'f'^2+Dg_2')\bar g_2\\&+D\left\{(3B'+C')ff'+\frac{C'}{2}\int f'^2d\zeta+\frac{D}{2}g_2\right\}\bar f'^2+D^2(ff'\bar g_2'+f''\bar f\bar g_2+f\bar f'\bar g_2')\\&+\frac{D^3}{2}\left(f^2\bar f'\bar f''+\frac{1}{3}f'''\bar f^3+f\bar f\bar f'^2\right)+C'Df''\bar f\int\bar f'^2d\bar\zeta+\frac{2}{3}F'f'\int\bar f'^3d\bar\zeta\\&-2C'f'\int\bar f'\bar g_2'd\bar\zeta+3B'Df\bar f'^3+\frac{1}{8}(2E'-D^3)\int\bar f'^4d\bar\zeta+3B'\int\bar f'^2\bar g_2'd\bar\zeta\\&+D\left(f'\bar g_3+\frac{1}{2}\int\bar g_2'^2d\bar\zeta+\int\bar f'\bar g_3'd\bar\zeta\right)+g_4(\zeta)\,.\end{aligned} \tag{I-5}$$

where

$$\left.\begin{aligned}&\kappa=\frac{\gamma+1}{4}\frac{M^2}{\mu^2}\,, && D=\frac{M^2}{2}(1+\kappa)=\frac{\nu}{8}\,;\\&A'=A+\frac{M^4}{8}\kappa(2+\kappa)\,, && A=-\frac{M^6}{96\mu^2}(1+\gamma)(3-2\gamma)\,;\\&B'=B+\frac{M^4}{24}(1+\kappa)(3+5\kappa)\,, && B=\frac{M^4}{96\mu^2}\{6(\gamma-1)-(2\gamma-1)(3-\gamma)M^2\}\,;\\&C'=C+\frac{M^4}{8}(5+10\kappa+6\kappa^2)\,, && C=\frac{M^2}{32\mu^2}\{8-8(3-\gamma)M^2+(13-9\gamma+2\gamma^2)M^4\}\,;\\&E'=E+3DA+\frac{M^2}{2}(10+7\kappa)B+M^2\kappa C+\frac{M^6}{48}(18+89\kappa+118\kappa^2+50\kappa^3)\,,\\&E=-\frac{M^6}{192\mu^2}(2-\gamma)\{16\gamma-(3+13\gamma-6\gamma^2)M^2\}\,;\end{aligned}\right\} \tag{I-6*}$$

---

* The unprimed constants A, B, C, and D were used as such in Ref. 11.

$$\left.\begin{aligned}
F' &= F+\frac{3}{4}M^2\kappa A+\frac{3}{4}M^2(7+10\kappa)B+\frac{M^2}{4}(9+8\kappa)C+\frac{M^6}{32}(39+130\kappa+157\kappa^2+65\kappa^3)\,,\\
F &= -\frac{3M^4}{128\mu^2}(2-\gamma)\{8-8(2-\gamma)M^2+(7-7\gamma+2\gamma^2)M^4\};\\
H' &= H+\frac{5}{4}M^2A+\frac{5}{4}M^2\kappa B+\frac{M^6\kappa}{192}(53+61\kappa+23\kappa^2)\,,\\
H &= -\frac{M^8}{256\mu^2}(2-\gamma)(1+\gamma)(2\gamma-1)\,;
\end{aligned}\right|$$

(f' and g_n' denote differentation with respect to ζ, and over-bars complex conjugate).

The arbitrary analytic functions f and g_n should be determined in compliance with the conditions that $\partial G/\partial\zeta$ be one-valued and regular in the flow field and that at the boundary surface $\mathrm{Im}\,(\mu^2 G+\zeta)=0$.

It is noticed that if we substitute 10/3, 12, 2, 200/3, and 130 for B', C', D, E', and F' respectively in the above expressions, we obtain the basic formula for the transonic thin-wing-expansion method (cf. Ref. 4).

Phenomenological Theory of the Molecular Absorption and Dispersion of Sound in Fluids and the Relation between the Relaxation Time of the Internal Energy and the Relaxation Time of the Internal Specific Heat*

By Otohiko NOMOTO

Kobayasi Institute of Physical Research,
Kokubunzi Tokyo

(Received March 7, 1956; Received in
amended from on September 3, 1956)

Molecular absorption and dispersion formulas applicable for both liquids and gases have been derived in a phenomenological manner. It was pointed out that the relaxation time of the molecular internal energy τ must be distinguished from the relaxation time of the internal specific heat β and the relation between these two quantities was discussed in detail. The relaxation time τ has the advantage of making the dispersion formula simpler and directly comparable with the dispersion formulas in other cases, such as the relaxation of shear viscosity. The relaxation time β on the other hand, is more closely related with the collision excitation probability of the molecules than τ.

§1. Introduction

Theoretical treatment of the phenomenon of the molecular absorption and dispersion of sound has been performed by Herzfeld and Rice¹⁾, Kneser²⁾, Bourgin³⁾ and many others. (cf. the books and monographs of Bergmann⁴⁾, Vigoureux⁵⁾, Richardson⁶⁾, Kudrijawzew⁷⁾, Hiedemann⁸⁾ and Nomoto⁹⁾, and the review articles of Kneser¹⁰⁾, Markham, Beyer and Lindsay¹¹⁾, Karim and Rosenhead¹²⁾, Petralia¹³⁾, Dubois¹⁴⁾, Sette¹⁵⁾ and Richardson¹⁶⁾ for detailed references.)

In the first place, we intend to perform a simple, phenomenological derivation of the absorption and dispersion formulas applicable for both gases and liquids. The method is similar to the one used by the present author¹⁷⁾ for deriving the absorption and dispersion formulas in gases (§2, 3). Also the second approximation formulas are derived (§6).

Secondly, we intend to clarify the relation between the relaxation time of the internal energy τ to be introduced in our derivation and the relaxation time of the internal specific heat β, more commonly used for describing the relaxation phenomenon in gases (§4). Recently, the apparent relaxation time β is being distinguished from the relaxation time β_1 of the lowest normal mode vibration for organic vapours (cf. Fogg, Hanks, Lambert²⁶⁾; Fogg and Lambert²⁷⁾). If the mechanism of vibrational activation is for the mode of lowest frequency to be activated directly with relaxation time β_1, and for the energy to spread very rapidly to the other modes, the whole dispersion phenomenon takes place with a single, apparent relaxation time $\beta=\beta_1(C_s/C_1)$, where C_s means the total vibrational specific heat, and C_1 the vibrational specific heat due to the lowest normal mode.

In these circumstances, however, the difference between β and τ cannot be also disregarded, and we have to consider the meanings of β and τ more closely. It becomes all the more important, because both β and τ are being used in liquids, and sometimes indiscriminately. The difference in magnitude of these two relaxation times is trivial as long as the simple gases are concerned. It becomes, however, of importance for gases and vapours consisting of more complex molecules, or for gases at high temperatures.

First we will consider of the present status of the research in this field and the relation of our theory to the existing ones briefly. Markham, Beyer and Lindsay¹¹⁾ have made an excellent analysis of the existing theories on acoustic relaxation phenomena and classified them into four groups: (a) the method of *kinetic theory* originating from the work of Jeans in 1904 and including the papers of Bourgin2) and Saxton, (b) the method of *irreversible thermodynamics* originating from the work of Herzfeld and Rice1) and including the works of Henry18), Eucken and Becker19), Hoff Lu20), Mandelstam and Leontovich, Damköhler21), Meixner22) and Eckart's unpublished lecture, (c) the method of *statistical thermodynamics* including the works of Kneser2),10), Markham, and Landau and Teller, this method also being applied to the systems in chemical equilibrium by Einstein, Luck, Kneser and Gauler, Hall, Ghosh and liebermann, and (d) the *phenomenological approach* as performed by Frenkel and Obrastzov. The equivalence of these various approaches is not always demonstrated, although many papers assume that the methods are essentially equivalent. For gases, however, it is known that the formulation based on statistical thermodynamics gives the same result as the one based on irreversible thermodynamics. Also the kinetic theory approach and the phenomenological approach leads to the same acoustical behaviour (cf. Markham, Beyer and Lindsay11)).

---

* The text in Japanese of this paper will be published in "Bulletin of the Kobayasi Institute of Physical Research".

A considerable number of theories on these subjects are summarized in Table I, classified into groups and indicating the main scopes or contents. The table is not complete, of course. Many of the earlier papers have been omitted and some of the more recent ones must have been missed. Also the classification may not be quite adequate in some cases; especially it seems difficult to classify some of the papers on reaction kinetics into one of these four groups because they use both the relaxation equation (=equation of irreversibility) and the reaction equation at the same time. In this case they have been included in group (I)–(c)–(ii), although they are also related to the group (I)–(b)–(ii). Other theories of rather general nature were classified as (II), while the above four groups (a), (b), (c) and (d) were classified as (I). Some papers of the group (I)–(a), those on translational dispersion, are strictly speaking not the relaxation theories, although they give dispersion and absorption of sound. They deal with the transport phenomena. These theories, however, are closely related with the relaxation theories. This may be said also of the hydrodynamical theory of translational dispersion included in group (I)–(d).

It is of course beyond the scope of this paper to discuss these points in any detail. It may suffice here to notice that our theory belongs to the method of the irreversible thermodynamics together with the previous ones17),24), although the thermodynamics enters into our relaxation equation not explicitly. This is also the case in many of the theories of this group, while there are also attempts to establish the relaxation theory on irreversible thermodynamics (Damköhler21), Meixner22), Eckart, etc.). Another attempt of more direct nature, to calculate the sound absorption directly from the amount of irreversible entropy production, have been described elsewhere25).

The present theory is a phenomenological one. In this form, however, it enables a more close comparison with the results of the phenomenological approach (group (I)–(d)) as well as with those of the method of statistical thermodynamics.

As the present paper is more closely related with the theory of Herzfeld and Rice1) and that of Henry18), we will begin with the comparison with these theories. Herzfeld and Rice derived the molecular absorption and dispersion formulas for the first time by the method of irreversible thermodynamics.

For an irreversible process the entropy increases with time, even for an isolated system, and we require a statement of its increase, the equation of irreversibility (named after Markham, Beyer and Lindsay11)). In general, however, this equation needs not contain the entropy explictly. The equation of irreversibility in Herzfeld-Rice's theory is

$$\frac{dT}{dt}=-\frac{1}{\tau_H}(T-T_i)\,, \tag{1.1}$$

where T_i means the temperature of the internal degrees of freedom of the molecules (=internal temperature) and T that of the external degrees of freedom (=external temperature), and τ_H (=τ, in Herzfeld's notation) the relaxation time. As the change in external temperature and that in internal temperature are related with

$$dE=C_{v\infty}dT=-C_i dT_i=-dE_i \tag{1.2}$$

in an adiabatic system, where $C_{v\infty}$ means the

molar specific heat at constant volume at sufficiently high frequency (=for instantaneous change), and C_i the molar specific heat of the internal system (=internal degrees of freedom)

$$\frac{dT_i}{dt}=-\frac{C_{v\infty}}{C_i\tau_H}(T_i-T)=-\frac{1}{\tau_{H'}}(T_i-T)\,. \tag{1.3}$$

We will show later that the relaxation time in this latter case $\tau_{H'}$ is equal to β, the relaxation time of the internal specific heat (cf. § 5).

After De Groot[23], the equation of irreversibility of the type (1.1) or (1.2) corresponds to the expression

$$\frac{dE_i}{dt}=L\frac{T-T_i}{T_m^2}\,, \tag{1.4}$$

representing the proportionality of the "flow" dE_i/dt to the "force" $T-T_i$, where $L=C_iT_m^2/\tau_{H'}$, and T_m means the equilibrium temperature. This conclusion is to be obtained from the fact that the entropy production in this case is

$$\frac{dS}{dt}=\frac{1}{T}\frac{dE}{dt}+\frac{1}{T_1}\frac{dE_i}{dt}=\frac{dE}{dt}\frac{T_i-T}{T_m^2}\,. \tag{1.5}$$

Henry used the relaxation equation (equation of irreversibility)

$$\frac{d(E_x-E_0)}{dt}=\frac{1}{\beta}(E_T-E_0)\,, \tag{1.6}$$

where E_T means the total equiribrium energy, E_0 the total energy without vibration (or rotation) and E_x the actual energy of system at time t. This is equivalent to our equation (3.2) if β means the relaxation time of the vibrational energy. Henry, however, thinks this to be equal to the "*mean life of energy quantum*" of Kneser[2], and so he confuses the "relaxation time of the vibrational energy" with "rilaxation time of the vibrational specific heat." Thus he solves the relaxation equation (1.6) by assuming

$$T=T_0+T_1e^{i\omega t} \tag{1.7a}$$

and

$$E_T=E_0+C_xT_1e^{i\omega t}\,, \tag{1.7b}$$

and gives

$$E_x=E_0+\frac{C_xT_1}{1+i\omega\beta}e^{i\omega t}\,. \tag{1.8}$$

And he *regards* the specific heat as

$$C_v'=C_a+\frac{C_x}{1+i\omega\beta}\,, \tag{1.9}$$

where C_a means the molar specific heat (at constant volume) of the external system. This, however, is not correct, because we have to regard T defined by (1.7a) as the equilibrium temperature when the quantity C_x is the equilibrium value of the intermal specific heat, and because the actual temperature becomes no longer T when the internal energy of the molecules undergoes a change as given by (1.8).

In liquids, the circumstance is more complicated than in gases. In a paper by Hoff Lu[20], the equation of irreversibility takes the form:

$$\frac{d(s-s_\infty)}{dt}=\frac{1}{\tau}(s_0-s)\,, \tag{1.10}$$

where s_0 means the static value of the compression ($=-\Delta v/v$, v=volume), s_∞ the instantaneous compression, and s the compression at any instant. The assumption is made that the equation holds true for liquids and gases. In general, however, the relation (1.10) depends on the thermodynamic path selected.

Equations of this form, however, is also used in group (I)–(d) theories, which is obtainable from the Navier-Stokes equation and the Maxwell's equation of stress relaxation. The group (I)–(d) theories, however, contains assumptions on the relation between the thermodynamic and the hydrodynamic pressure. Attempts to explain the phenomenological theories of bulk viscosity and elastic relaxation (I)–(d) from thermodynamic standpoint are being performed (I)–(b)–(iii), especially by Sugita, Takizawa and Meixner (cf. Table I for references).

The equation of irreversibility in Herzfeld-Rice's theory is somewhat more closely related to the thermodynamics than that in the present paper. Our relaxation equation is more phenomenological than that of Herzfeld. Herzfeld uses energy relation in sound wave together with the relaxation equation. In the present treatment, the energy relation is not employed. It is replaced by the instantaneous variation of pressure accompanying the density change in the sound wave to be superposed on the relaxational pressure qariation due to the equation of irreversibility (cf. (3.11)). Our relaxation equation (3.2), however, is equivalent to that of Herzfeld, as is to be shown in § 5.

§2. General Theory of the Absorption of Sound*

We will treat of the case when there is no classical mechanism of sound absorption as viscosity, heat conduction and heat radiation. Then the equation of sound propagation is given by

$$\frac{\partial^2}{\partial t^2}(\varDelta\rho)=\nabla^2(\varDelta p)\,, \tag{2.1}$$

where $\varDelta p$ means the excess pressure and $\varDelta\rho$ the excess density. When there is sound absorption, there is produced in general a phase shift between the pressure wave and the density wave. A plane wave of sound propagating in x-direction, therefore, can be written as

$$\left.\begin{aligned}\varDelta p&=\varDelta p_0\exp i\left\{\omega t-\left(\frac{\omega}{V}-i\alpha\right)x+\psi\right\},\\ \varDelta\rho&=\varDelta\rho_0\exp i\left\{\omega t-\left(\frac{\omega}{V}-i\alpha\right)x\right\}\end{aligned}\right\} \tag{2.2}$$

where $\omega\,(=2\pi\nu;\ \nu=\text{frequency})$ means the circular frequency, V the sound velocity and α the absorption coefficient (amplitude absorption coefficient per unit length). Substituting (2.2) into (2.1) we get

$$\frac{\varDelta p_0}{\varDelta\rho_0}e^{i\psi}=\frac{V^2}{\left(1-i\dfrac{\alpha V}{\omega}\right)^2}\,. \tag{2.3}$$

This gives

$$\exp\left(-\frac{1}{2}i\psi\right)=\sqrt{\frac{\varDelta p_0}{\varDelta\rho_0}}\,\frac{1}{V}\left(1-i\frac{\alpha V}{\omega}\right),$$

and by equating the real and imaginary parts on both sides of the equation we have

$$V=\sqrt{\frac{\varDelta p_0}{\varDelta\rho_0}}\sec\frac{\psi}{2}=\sqrt{\frac{\varDelta p_0}{\varDelta\rho_0}\left(1+\frac{\alpha^2V^2}{\omega^2}\right)} \tag{2.4}$$

and

$$\alpha=\frac{\omega}{V}\tan\frac{\psi}{2}=\frac{2\pi}{\lambda}\tan\frac{\psi}{2}\,, \tag{2.5}$$

where λ means the wavelength. These become, approximately

$$V=\sqrt{\frac{\varDelta p_0}{\varDelta\rho_0}} \tag{2.6}$$

and

$$\alpha=\frac{\pi}{\lambda}\tan\psi\,. \tag{2.7}$$

If we define the complex velocity $\boldsymbol{V}$ by

$$\boldsymbol{V}=\sqrt{\frac{\varDelta p}{\varDelta\rho}}=\sqrt{\frac{\varDelta p_0}{\varDelta\rho_0}e^{i\psi}} \tag{2.8}$$

we have from (2.3) the relation

$$\boldsymbol{V}^2=\frac{V^2}{1+(\alpha^2V^2/\omega^2)^2}\left[\left(1-\frac{\alpha^2V^2}{\omega^2}\right)+2i\frac{\alpha V}{\omega}\right],$$

and the velocity and absorption are given by

$$V^2=\frac{(1+\alpha^2V^2/\omega^2)^2}{1-\alpha^2V^2/\omega^2}\Re(\boldsymbol{V}^2)=\sec\psi\cdot\sec^2\frac{\psi}{2}\Re(\boldsymbol{V}^2) \tag{2.9}$$

and

$$\begin{aligned}\alpha&=\frac{1}{2}\frac{\omega}{V}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\left(1-\frac{\alpha^2V^2}{\omega^2}\right)\\&=\frac{1}{2}\frac{\omega}{V}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\left(1-\tan^2\frac{\psi}{2}\right)\end{aligned} \tag{2.10}$$

respectively. Here $\Re(\boldsymbol{V}^2)$ and $\Im(\boldsymbol{V}^2)$ represent the real and imaginary parts of $\boldsymbol{V}^2$ respectively. In approximations up to the order of $(\alpha V/\omega)^2$ we have for the sound velocity (in second approximation)

$$V^2=\left\{1+3\frac{\alpha^2V^2}{\omega^2}\right\}\Re(\boldsymbol{V}^2)=\left\{1+\frac{3}{4}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\right\}\Re(\boldsymbol{V}^2), \tag{2.11}$$

and for the absorption coefficient (in third approximation)

$$\alpha=\frac{1}{2}\frac{\omega}{V}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\left\{1-\frac{1}{4}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\right\}. \tag{2.12}$$

The zero order approximation formula for sound velocity is

$$V^2=\Re(\boldsymbol{V}^2) \tag{2.13}$$

and the first order approximation formula for sound absorption

$$\alpha=\frac{1}{2}\frac{\omega}{V}\frac{\Im(\boldsymbol{V}^2)}{\Re(\boldsymbol{V}^2)}\,. \tag{2.14}$$

§3. Relaxation Phenomenon of the Internal Energy

When a gas or liquid contained in a vessel is instantaneously compressed, the volume experiences a sudden decrease (cf. Fig. 1, (a)) energy E_i of the internal degrees of freedoms of the molecules, however, does not change at this moment, but slowly approaches the new equilibrium value $E_i+\varDelta E_i^0$ with a relaxation time τ, after ending of the instantaneous compression (cf. Fig. 1 (b)). The value at time t is given by

---

* The treatment here presented is essentially the same as described in a former paper Nomoto[24]), §3), except the use of the complex velocity. The procedure for obtaining dispersion and absorption formulas, and especially the second approximation formulas, becomes more simple by this method.

$$\Delta E_i = \Delta E_i^0 (1 - e^{-t/\tau}) \,. \tag{3.1}$$

The external work of compression is transformed into the translational energy of the molecules at first and then into the rotational and vibrational energies of the molecules with respective relaxation times. Here we consider the case when one of the internal energies (vibrational or rotational) fail to accompany the sudden volume change, and we assume single relaxation time for simplicity's sake. (Rotational energy is known to establish equilibrium with the translational energy more rapidly than the vibrational energy, and it is the problem of time-scale of the experiment whether the rotational energy can be regarded as external energy of the molecules or not.)

The translational energy, on the other hand, increases by an amount ΔE_t^∞ in a sudden compression. This is somewhat too large as compared with the increment ΔE_t^0 corresponding to the equilibrium state, because the external work of compression is not shared to the internal degrees of freedom as yet. The increment of the translational energy approaches the new equilibrium value according to the exponential law

$$\begin{aligned} \Delta E_t &= \Delta E_t^\infty + (\Delta E_t^0 - \Delta E_t^\infty)(1 - e^{-t/\tau}) \\ &= \Delta E_t^0 + (\Delta E_t^\infty - \Delta E_t^0) e^{-t/\tau} \end{aligned} \tag{3.2}$$

with the same relaxation time τ as in (3.1) (cf. Fig. 1 (c)). The pressure, however, is a quantity proportional to the translational energy of the molecules. For example, we have in case of gases the relation

$$p = \frac{2}{3} \frac{E_t}{v} \tag{3.3}$$

where v means the molar volume. So the pressure change after an instantaneous compression is given by

$$\begin{aligned} \Delta p &= \Delta p^\infty + (\Delta p^0 - \Delta p^\infty)(1 - e^{-t/\tau}) \\ &= \Delta p^0 + (\Delta p^\infty - \Delta p^0) e^{-t/\tau} \,, \end{aligned} \tag{3.4}$$

where Δp^∞ and Δp^0 mean the instantaneous and the equilibrium increment of pressure respectively.

Differentiating this equation with time, we obtain the rate of change of pressure after an instantaneous volume change:

$$\begin{aligned} \frac{\partial(\Delta p)}{\partial t} &= -\frac{1}{\tau} (\Delta p^\infty - \Delta p^0) e^{-t/\tau} \\ &= -\frac{1}{\tau} (\Delta p - \Delta p^0) \,. \end{aligned} \tag{3.5}$$

Assuming a sinusoidal change of density at a fixed point in space, traversed by a sound beam

$$\rho = \rho_0 + \Delta\rho = \rho_0 + \Delta\rho_0 e^{i\omega t} \,, \tag{3.6}$$

the pressure will be given by

$$p^0 = p_0 + \Delta p^0 = p_0 + \Delta p_0{}^0 e^{i\omega t} \,, \tag{3.7}$$

if the change is sufficiently slow so that the pressure and density are in equilibrium, and by

$$p^\infty = p_0 + \Delta p^\infty = p_0 + \Delta p_0{}^\infty e^{i\omega t} \,, \tag{3.8}$$

if the change is sufficiently fast. The actual pressure

$$p = p_0 + \Delta p \,, \tag{3.9}$$

however, is generally different from these two extreme values. So the excess pressure Δp always tends to approach the equilibrium value

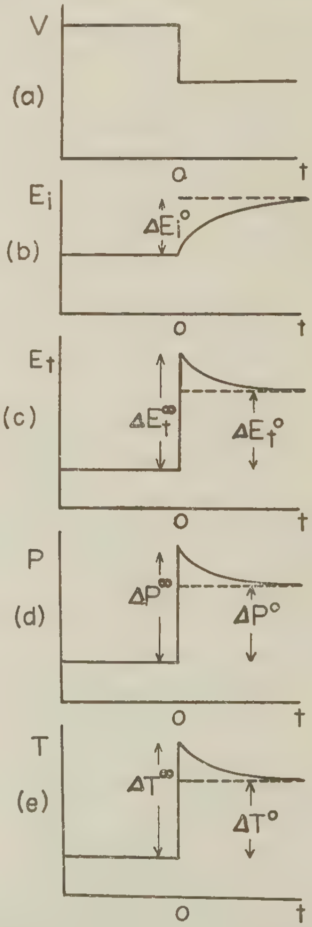

Fig. 1. The time variation of (a) volume, (b) internal energy of the molecules, (c) translational energy of the molecules, (d) pressure, and (e) temperature after an instantaneous compression.

Δp^0 after (3.5). At the same time the pressure experiences an instantaneous change accompanying the sinusoidal change of density in the sound wave (cf. (3.6)), this change being given by

$$\frac{\partial(\Delta p)}{\partial(\Delta \rho)}\cdot\frac{\partial(\Delta \rho)}{\partial t}=\left(\frac{\partial p}{\partial \rho}\right)_\infty\cdot i\omega\cdot\Delta\rho_0 e^{i\omega t}\,. \qquad (3.10)$$

The total rate of change of pressure at a fixed point in a sound beam, therefore, is given by

$$\begin{aligned}\frac{d(\Delta p)}{dt}&=\frac{\partial(\Delta p)}{\partial t}+\frac{\partial(\Delta p)}{\partial(\Delta \rho)}\cdot\frac{\partial(\Delta \rho)}{\partial t}\\&=-\frac{1}{\tau}(\Delta p-\Delta p^0)+\left(\frac{\partial p}{\partial \rho}\right)_\infty\cdot i\omega\cdot\Delta\rho_0\cdot e^{i\omega t}\,.\end{aligned} \qquad (3.11)$$

Substituting further the relation

$$\Delta p^0=\left(\frac{\partial p}{\partial \rho}\right)_0\Delta\rho=\left(\frac{\partial p}{\partial \rho}\right)_0\cdot\Delta\rho_0\cdot e^{i\omega t} \qquad (3.12)$$

in (3.11), we have

$$\begin{aligned}\frac{d(\Delta p)}{dt}=-\frac{1}{\tau}\Delta p+\Bigg\{&\frac{1}{\tau}\left(\frac{\partial p}{\partial \rho}\right)_0\\&+i\omega\left(\frac{\partial p}{\partial \rho}\right)_\infty\Bigg\}\Delta\rho\cdot e^{i\omega t}\,.\end{aligned} \qquad (3.13)$$

As we have $d(\Delta p)/dt=i\omega\cdot\Delta p$ in a sound wave, we have as the solution of (3.13)

$$\Delta p=\frac{\left(\frac{\partial p}{\partial \rho}\right)_0+i\omega\tau\left(\frac{\partial p}{\partial \rho}\right)_\infty}{1+i\omega\tau}\cdot\Delta\rho_0\cdot e^{i\omega t} \qquad (3.14)$$

or

$$\Delta p=\frac{\left\{\left(\frac{\partial p}{\partial \rho}\right)_0+\omega^2\tau^2\left(\frac{\partial p}{\partial \rho}\right)_\infty\right\}+i\omega\tau\left\{\left(\frac{\partial p}{\partial \rho}\right)_\infty-\left(\frac{\partial p}{\partial \rho}\right)_0\right\}}{1+\omega^2\tau^2}\times\Delta\rho_0 e^{i\omega t}\,. \qquad (3.15)$$

If we write this as

$$\Delta p=\Delta p_0^\omega\cdot e^{i\omega t+\psi}=\Delta p_0^\omega(\cos\psi+i\sin\psi)e^{i\omega t}\,, \qquad (3.16)$$

according to (2.2), we have the relations:

$$\Delta p_0^\omega=\frac{\left(\frac{\partial p}{\partial \rho}\right)_0+\omega^2\tau^2\left(\frac{\partial p}{\partial \rho}\right)_\infty}{1+\omega^2\tau^2}\Delta\rho_0\sec\psi \qquad (3.17)$$

and

$$\tan\psi=\frac{\omega\tau\left\{\left(\frac{\partial p}{\partial \rho}\right)_\infty-\left(\frac{\partial p}{\partial \rho}\right)_0\right\}}{\left(\frac{\partial p}{\partial \rho}\right)_0+\omega^2\tau^2\left(\frac{\partial p}{\partial \rho}\right)_\infty}\,. \qquad (3.18)$$

So the complex velocity (cf. (2.8)) is given by

$$V^2=\frac{\left(\frac{\partial p}{\partial \rho}\right)_0+\omega^2\tau^2\left(\frac{\partial p}{\partial \rho}\right)_\infty}{1+\omega^2\tau^2}(1+i\tan\psi)\,, \qquad (3.19)$$

and we have as the approximate expression of sound velocity by (2.13)

$$V^2=\mathfrak{R}(V^2)=\frac{V_0^2+\omega^2\tau^2V_\infty^2}{1+\omega^2\tau^2}\,, \qquad (3.20)$$

where

$$V_0=\sqrt{\left(\frac{\partial p}{\partial \rho}\right)_0}=\sqrt{\left(\frac{\partial p}{\partial \rho}\right)_T\frac{C_{p0}}{C_{v0}}} \qquad (3.21)$$

and

$$V_\infty=\sqrt{\left(\frac{\partial p}{\partial \rho}\right)_\infty}=\sqrt{\left(\frac{\partial p}{\partial \rho}\right)_T\frac{C_{p\infty}}{C_{v\infty}}} \qquad (3.22)$$

mean the sound velocity at sufficiently low frequency and at sufficiently high frequency respectively. In these relations, C_{p0} and $C_{p\infty}$ mean the molar specific heats at constant pressure at sufficiently low frequency and at sufficiently high frequency respectively, and C_{v0} and $C_{v\infty}$ the molar specific heats at constant volume at the respective frequencies. The absorption coefficient per wavelength becomes by (2.7) and (3.18) as

$$\alpha_\lambda=\alpha\lambda=\pi\tan\psi=\pi\frac{(V_\infty^2-V_0^2)\omega\tau}{V_0^2+V_\infty^2\omega^2\tau^2}\,. \qquad (3.23)$$

The dispersion formula (3.20) and the absorption formula (3.23) can be expressed also in terms of the specific heats by substituting (3.21) and (3.22) and using the symbols

$$D=C_{p0}-C_{v0}=C_{p\infty}-C_{v\infty} \qquad (3.24)$$

and

$$C_i=C_{v0}-C_{v\infty}(=C_{p0}-C_{p\infty})\,, \qquad (3.25)$$

where C_i means the static value of the internal specific heat (per mole) exhibiting thermal relaxation. We have the dispersion formula

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+D\frac{C_{v\infty}+C_{v0}\omega^2\tau^2}{C_{v0}C_{v\infty}(1+\omega^2\tau^2)}\right] \qquad (3.26)$$

or,

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+\frac{D}{C_{v0}}+\frac{DC_i\omega^2\tau^2}{C_{v0}C_{v\infty}(1+\omega^2\tau^2)}\right] \qquad (3.26a)$$

and the absorption formula

$$\alpha_\lambda=\alpha\lambda=\pi\frac{DC_i\omega\tau}{C_{p0}C_{v\infty}+C_{v0}C_{p\infty}\omega^2\tau^2}\,. \qquad (3.27)$$

The relations (3.26) and (3.27) are general formulas applicable both for gases and liquids. The dispersion formula (3.26) can be also written as

$$V^2=V_0^2\left[1+\frac{DC_i\omega^2\tau^2}{C_{p0}C_{v\infty}(1+\omega^2\tau^2)}\right] \qquad (3.28)$$

by employing (3.21). The form of (3.20), i.e.,

$$V^2=V_0{}^2+(V_\infty{}^2-V_0{}^2)\frac{\omega^2\tau^2}{1+\omega^2\tau^2} \tag{3.29}$$

is also often used for liquids. This simple formula, naturally, is also valid in case of gases, though hitherto not in use. This formula (3.29) has further the advantage that in this form it coincides with the relaxation formula in other cases, as for example, in case of the relaxation of shear viscosity (group (I)-(d) theories).

§ 4. Relation between the Two Relaxation Times τ and β

Although the formula (3.29) with relaxation time τ is sometimes employed for liquids, the formulas of general use in gases (Kneser's dispersion and absorption formulas) employ another relaxation time β, also called the "*period of adjustment* (*Einstelldauer*)" of the internal energy. τ was introduced in our previous paper[17] and first denoted by β'. It was called the "relaxation time of the internal energy" by Hubbard, while β was called the "relaxation time of the internal specific heat." Kneser's formulas are to be obtained from our result by employing a relaxation time β given by

$$\beta=\tau\frac{C_{v0}}{C_{v\infty}}=\tau\frac{C_{v\infty}+C_i}{C_{v\infty}} \tag{4.1}$$

in place of τ, i.e., by substituting

$$\tau=\beta\frac{C_{v\infty}}{C_{v0}} \tag{4.2}$$

in our equations. For example, the dispersion formula (3.26) transforms into

$$V^2=\left(\frac{\partial p}{\partial\rho}\right)_T\left[1+D\frac{C_{v0}+C_{v\infty}\omega^2\beta^2}{C_{v0}{}^2+C_{v\infty}{}^2\omega^2\beta^2}\right] \tag{4.3}$$

by this substitution, and the absorption formula (3.27) becomes

$$\alpha_\lambda=\pi\frac{DC_i\omega\beta}{C_{p0}C_{v0}+C_{p\infty}C_{v\infty}\omega^2\beta^2}\,. \tag{4.4}$$

As we have further

$$D=R \tag{4.5}$$

(R=universal gas constant) and

$$\left(\frac{\partial p}{\partial\rho}\right)_T=\frac{p_0}{\rho_0} \tag{4.6}$$

for an ideal gas, (4.3) and (4.4) becomes in this case as

$$V^2=\frac{p_0}{\rho_0}\left[1+R\frac{C_{v0}+C_{v\infty}\omega^2\beta^2}{C_{v0}{}^2+C_{v\infty}{}^2\omega^2\beta^2}\right] \tag{4.7}$$

and

$$\alpha_\lambda=\pi\frac{RC_i\omega\beta}{C_{p0}C_{v0}+C_{p\infty}C_{v\infty}\omega^2\beta^2} \tag{4.8}$$

in accordance with Kneser's formulas.

Kneser's formulas are to be obtained most simply by assuming a relaxation phenomenon of internal specific heat C_i with relaxation time β and formally putting

$$C_i(\omega)=\frac{C_i}{1+\omega\beta} \tag{4.9}$$

in the expression of the sound velocity (cf. Eucken-Becker[19])

$$V^2=\left(\frac{\partial p}{\partial\rho}\right)_T\frac{C_p}{C_v}=\left(\frac{\partial p}{\partial\rho}\right)_T\left[1+\frac{D}{C_{v\infty}+C_i(\omega)}\right]. \tag{4.10}$$

The sound velocity becomes complex in this case, the real part giving the approximate sound velocity and the imaginary part the effect of absorption. Thus we have

$$\begin{aligned}V^2&=\left(\frac{\partial p}{\partial\rho}\right)_T\left[1+\frac{D}{C_{v\infty}+C_i/(1+i\omega\beta)}\right]\\&=\left(\frac{\partial p}{\partial\rho}\right)_T\left[1+\frac{D(C_{v0}+C_{v\infty}\omega^2\beta^2)+iDCi\omega\beta}{C_{v0}{}^2+C_{v\infty}{}^2\omega^2\beta^2}\right].\end{aligned} \tag{4.11}$$

This immediately gives the dispersion formula (4.3) by (2.13) and the absorption formula (4.4) by (2.14).

The fact that the formulas (4.3) and (4.4) are obtained from (3.28) and (3.27) by the substitution of (4.2) means that the internal specific heat shows a relaxation phenomenon with a relaxation time β and that this relaxation time is related with the relaxation time of internal energy τ by (4.2). This is to be shown more directly from (3.14). By substituting

$$\begin{aligned}\Delta p&=\left(\frac{\partial p}{\partial\rho}\right)\Delta\rho=\left(\frac{\partial p}{\partial\rho}\right)_T\frac{C_p}{C_v}\Delta\rho\\&=\gamma\left(\frac{\partial p}{\partial\rho}\right)_T\Delta\rho_0e^{i\omega t}\end{aligned} \tag{4.12}$$

and

$$\left.\begin{aligned}\left(\frac{\partial p}{\partial\rho}\right)_0&=\frac{C_{p0}}{C_{v0}}\left(\frac{\partial p}{\partial\rho}\right)_T=\gamma_0\left(\frac{\partial p}{\partial\rho}\right)_T,\\\left(\frac{\partial p}{\partial\rho}\right)_\infty&=\frac{C_{p\infty}}{C_{v\infty}}\left(\frac{\partial p}{\partial\rho}\right)_T=\gamma_\infty\left(\frac{\partial p}{\partial\rho}\right)_T\end{aligned}\right\} \tag{4.13}$$

in (3.14), we have the relation

$$\gamma=\frac{\gamma_0+\gamma_\infty\cdot i\omega\tau}{1+i\omega\tau}\,. \tag{4.14}$$

And by putting

$$\gamma = 1 + \frac{D}{C_{v\infty}+C_i(\omega)} \tag{4.15}$$

in this equation, we have

$$\frac{1}{C_{v\infty}+C_i(\omega)} = \frac{1}{C_{v0}} \frac{C_{v\infty}+C_{v0}\cdot i\omega\tau}{C_{v\infty}(1+i\omega\tau)} ,$$

or,

$$C_i(\omega) = \frac{C_{v\infty}C_i}{C_{v\infty}+C_{v0}\cdot i\omega\tau} , \tag{4.16}$$

a relation, which coincides with (4.9) by (4.2).

It is, however, desirable to deduce the relation between the two relaxation times more directly from the relation

$$C_i = \frac{\Delta E_i}{\Delta T} . \tag{4.17}$$

For this purpose, we have first to consider the meaning of the temperature T in a sound wave. The directly observable quantities in this case are V and α; first we deduce $\partial p/\partial \rho$ from these quantities, then γ, and finally C_i. The temperature T in (4.17) means therefore, the temperature to be deduce from the pressure p, i.e., the temperature as indicated in the translational energy of the molecules. This is called the external temperature, i.e., the temperature of the external degrees of freedoms of the molecules. As E_i is not in equilibrium with E_t in this case, the temperature of the internal degrees of freedom (T_i) is naturally different from T and the internal specific heat (under infinitesimal amplitude) must be constant if we use the internal temperature as the temperature.

First we will consider of the instantaneous static compression as indicated in Fig. 1. Here the time dependence of the internal energy of the molecules E_i follows (3.1) and is represented in Fig. 1 (b). Now the temperature T of the external degrees of freedom is a quantity proportional to the translational energy E_t of the molecules, the proportionality factor being

$$\frac{\Delta E_t}{\Delta T} = 3R \tag{4.18}$$

by the law of equipartition of energy. So the time dependence of ΔT must be the same as that of ΔE_t (cf. Fig. 1 (e)) and is to be given by an equation analogous to (3.2), i.e., by

$$\begin{aligned}\Delta T &= \Delta T^\infty + (\Delta T^0 - \Delta T^\infty)(1-e^{-t/\tau}) \\ &= \Delta T^0 + (\Delta T^\infty - \Delta T^0)e^{-t/\tau} .\end{aligned} \tag{4.19}$$

Thus the time dependence of the internal specific heat after an instantaneous compression is given by

$$C_i = \frac{\Delta E_i}{\Delta T} = \frac{\Delta E_{i0}(1-e^{-t/\tau})}{\Delta T^0 + (\Delta T^\infty - \Delta T^0)e^{-t/\tau}} . \tag{4.20}$$

Denoting the static value of the internal molar specific heat by $C_i{}^0$, we have

$$C_i{}^0 = \frac{\Delta E_i{}^0}{\Delta T^0} \tag{4.21}$$

and we have by the law of conservation of energy the relation

$$C_v{}^\infty \Delta T^\infty = C_{v0}\Delta T^0 . \tag{4.22}$$

Substituting (4.21), (4.22) and (3.25) in (4.20) we have

$$C_i(t) = \frac{C_i{}^0 C_{v\infty}(1-e^{-t/\tau})}{C_{v\infty}+C_i e^{-t/\tau}} . \tag{4.23}$$

This gives by differentiation the relation

$$\frac{\partial C_i(t)}{\partial t} = \frac{1}{\tau} \frac{C_{v\infty}+C_i(t)}{C_{v0}} \{C_i{}^0 - C_i(t)\} . \tag{4.24}$$

The relations (4.23) and (4.24) are of course to be deduced more simply from (3.4) and (3.5). By substituting (4.12) and (4.13) in these relations, (3.4) gives

$$\gamma = \gamma^0 + (\gamma^\infty - \gamma^0)e^{-t/\tau} \tag{4.25}$$

and we have from (3.5)

$$\frac{\partial \gamma}{\partial t} = -\frac{1}{\tau}(\gamma - \gamma_0) . \tag{4.26}$$

As

$$\gamma = \frac{C_p}{C_v} = 1 + \frac{D}{C_{v\infty}+C_i(t)} , \tag{4.27}$$

in this case, we have (4.23) from (4.25) and (4.24) from (4.27).

At any rate, it is to be seen from (4.23) and (4.24) that the time change of C_i after an instantaneous static compression does not correspond to a simple exponential approach to the equilibrium value with a single relaxation time. Thus by writing (4.24) as

$$\frac{\partial C_i}{\partial t} = -\frac{1}{\beta'}(C_i - C_i{}^0) \tag{4.28}$$

we find that the apparent relaxation time

$$\beta' = \tau \frac{C_{v0}}{C_{v\infty}+C_i(t)} \tag{4.29}$$

changes with time from

$$\left.\begin{aligned} &\beta' = \tau\frac{C_{v0}}{C_{v\infty}} = \beta \quad \text{at} \quad t=0 \\ &\text{to} \\ &\beta' = \tau \qquad\qquad \text{at} \quad t=\infty . \end{aligned}\right\} \tag{4.30}$$

The reason of the discrepancy of this result from the case of sound wave is due to the fact that in the sound wave $\varDelta T$ has also a component which instantaneously accompanies the density change. $\varDelta E_i$, on the other hand, has no such component.

Now we will consider the case of a sound wave. (4.17) is also valid in this case. $\varDelta E_i$ satisfies the differential equation

$$\frac{\partial(\varDelta E_i)}{\partial t}=\frac{1}{\tau}(\varDelta E_i{}^9-\varDelta E_i) \tag{4.31}$$

by (3.1), after an instantaneous volume change. The time variation of $\varDelta E_i$ becomes

$$\frac{d(\varDelta E_i)}{\partial t}=\frac{\partial(\varDelta E_i)}{\partial t}+\frac{\partial(\varDelta E_i)}{\partial(\varDelta\rho)}\frac{d(\varDelta\rho)}{dt}$$

at a fixed point in a sound wave. As $\varDelta E_i$ does not change in phase with the density change, as above mentioned, we have

$$\left(\frac{\partial(\varDelta E_i)}{\partial(\varDelta\rho)}\right)_\infty=0\,. \tag{4.23}$$

So we have

$$\frac{d(\varDelta E_i)}{dt}=\frac{\partial(\varDelta E_i)}{\partial t}$$

and accordingly

$$\frac{d(\varDelta E_i)}{\partial t}=\frac{1}{\tau}(\varDelta E_i{}^0-\varDelta E_i) \tag{4.33}$$

at a fixed point in a sound wave. If $\varDelta E_i$ and $\varDelta E_i{}^0$ make sinusoidal changes with circular frequency ω, we have as the solution of (4.33)

$$\varDelta E_i=\frac{\varDelta E_i{}^0}{1+i\omega\tau}\,. \tag{4.34}$$

Now the quantity $\varDelta T$ in the denominator of (4.17) satisfies

$$\frac{\partial(\varDelta T)}{\partial t}=-\frac{1}{\tau}(\varDelta T-\varDelta T^0) \tag{4.35}$$

by (4.19) after an instantaneous static volume change. In a sound wave we have

$$\frac{d(\varDelta T)}{dt}=\frac{\partial(\varDelta T)}{\partial t}+\left(\frac{\partial(\varDelta T)}{\partial(\varDelta\rho)}\right)_\infty\frac{d(\varDelta\rho)}{dt}\,. \tag{4.36}$$

If we think, for simplicity's sake, the ideal gas, we have for sufficiently rapid adiabatic changes

$$T=c\rho^{\gamma_\infty-1}\,;\qquad c=\text{const.} \tag{4.37}$$

This gives

$$\left(\frac{\partial(\varDelta T)}{\partial(\varDelta\rho)}\right)_\infty=\left(\frac{\partial T}{\partial\rho}\right)_\infty=\frac{T}{\rho}(\gamma_\infty-1)=\frac{T}{\rho}\frac{R}{C_{v\infty}}\,. \tag{4.38*}$$

On the other hand, we have for sufficiently slow adiabatic change of an ideal gas

$$T=c'\rho^{\gamma_0-1}\,;\qquad c'=\text{const.} \tag{4.39}$$

This gives

$$\left(\frac{\partial T}{\partial\rho}\right)_0=\frac{T}{\rho}(\gamma_0-1)=\frac{TR}{\rho C_{v0}} \tag{4.40}$$

and we have from this

$$\varDelta T^0=\left(\frac{\partial T}{\partial\rho}\right)_0\varDelta\rho=\frac{TR}{\rho C_{v0}}\varDelta\rho\,. \tag{4.41}$$

Substituting (4.35), (4.38) and (4.41) into (4.36) we have as the differential equation

$$\frac{d(\varDelta T)}{dt}=-\frac{1}{\tau}\left(\varDelta T-\frac{TR}{\rho C_{v0}}\varDelta\rho\right)+\frac{TR}{\rho C_{v\infty}}\frac{d(\varDelta\rho)}{dt}\,. \tag{4.42}$$

Assuming sinusoidal changes with circular frequency ω for $\varDelta T$ and $\varDelta\rho$, we obtain as the solution of (4.42)

$$\varDelta T=\frac{TR(C_{v\infty}+C_{v0}i\omega\tau)}{\rho C_{v0}C_{v\infty}(1+i\omega\tau)}\varDelta\rho\,, \tag{4.43}$$

or, expressed in terms of $\varDelta T^0$ by (4.1),

$$\varDelta T=\varDelta T^0\frac{(C_{v\infty}+C_{v0}\cdot i\omega\tau)}{C_{v\infty}(1+i\omega\tau)}\,. \tag{4.44}$$

Substituting (4.34) and (4.44) into (4.17) we have

$$C_i=\frac{\varDelta E_i}{\varDelta T}=\frac{\varDelta E_i{}^0}{\varDelta T^0}\frac{C_{v\infty}}{C_{v\infty}+C_{v0}\cdot i\omega\tau}\,, \tag{4.45}$$

or,

$$C_i=\frac{C_i{}^0}{1+i\omega\beta}\,, \tag{4.46}$$

where

$$\beta=\tau\frac{C_{v0}}{C_{v\infty}}\,. \tag{4.47}$$

These are the required relations (4.9) and (4.1).

Non-phenomenological deductions of the relationship between β and τ has been given in a previous paper[17)].

§ 5. Relation of τ and β with the Relaxation Times of Herzfeld and Rice's Theory

The relaxation equations of Herzfeld and Rice, (1.1) and (1.3), have the form of Newton's law of cooling, the rate of temperature change being proportional to the temperature difference. The relaxation equation of pressure

---

[*] In general, we have for any fluid (liquid or gas), $\left(\frac{\partial(\varDelta T)}{\partial(\varDelta\rho)}\right)_\infty=\frac{C_{p0}-C_{v0}}{\alpha\rho C_{v\infty}}$, where α means the expansion coefficient, (cf. Nomoto (25), eq. (3.16)). Eq. (4.44) holds true also in this case.

used in the present theory, (3.5), on the other hand, is based on the phenomenological relaxation equations of energy (3.1) and (3.2). These equations, however, leads to the Herzfeld's relaxation equations. As the Herzfeld's relaxation equations are thermodynamically founded by De Groot, the phenomenological equations here employed also gain the thermodynamical supports. At the same time, the relation between the relaxation times τ_H' $(=C_i\tau/C_{v\infty}$ by Herzfeld's notation) and τ and β can be obtained.

As the increment of the internal temperature $\varDelta T_i$ is proportional to the increment of the molecular internal energy $\varDelta E_i$ by

$$\varDelta E_i = C_i \varDelta T_i\ , \tag{5.1}$$

the time change of T_i after an instantaneous compression of Fig. 1 is similar to that of E_i and is given by

$$\varDelta T_i = \varDelta T_i^0 (1-e^{-t/\tau})\ , \tag{5.2}$$

(cf. (3.1)), where $\varDelta T_i^0$ is the value of $\varDelta T_i$ corresponding to the new equilibrium state, while the external temperature is given by (4.19), i.e.,

$$\varDelta T = \varDelta T^\infty - (\varDelta T^\infty - \varDelta T^0)(1-e^{-t/\tau})\ . \tag{5.3}$$

As the energy obtained by the internal system $C_i\varDelta T_i^0$ till the equilibrium is established, is equal to the energy lost by the external system $C_{v\infty}(\varDelta T^\infty - \varDelta T^0)$, we have

$$\varDelta T - \varDelta T^0 = (C_i/C_{v\infty})\varDelta T_i^0\ . \tag{5.4}$$

Accordingly, (5.3) becomes as

$$\varDelta T = \varDelta T^\infty - \varDelta T_i^0 (C_i/C_{v\infty})(1-e^{-t/\tau})\ . \tag{5.5}$$

Then we have from (5.5) and (5.2)

$$\varDelta T - \varDelta T_i = \varDelta T^\infty - \varDelta T_i^0 (C_{v0}/C_{v\infty})(1-e^{-t/\tau})\ . \tag{5.6}$$

Differentiating (5.5) with respect to time, we have

$$\frac{\partial(\varDelta T)}{\partial t} = -\frac{1}{\tau}\varDelta T_i^0 (C_i/C_{v\infty})e^{-t/\tau}\ . \tag{5.7}$$

As the equilibrium temperature is common for the internal system and the external system, we have

$$\varDelta T_i^0 = \varDelta T^0\ , \tag{5.8}$$

and (5.7) becomes

$$\partial(\varDelta T)/\partial t = -(1/\tau)(C_i/C_{v\infty})\varDelta T^0 e^{-t/\tau}\ . \tag{5.9}$$

Moreover, there is the energy relation

$$C_{v\infty}\varDelta T^\infty = C_{v0}\varDelta T^0\ . \tag{5.10}$$

So we have from (5.6) by substituting (5.8) and (5.10)

$$\varDelta T - \varDelta T_i = (C_{v0}/C_{v\infty})\varDelta T^0 e^{-t/\tau}\ . \tag{5.11}$$

Substituting this into (5.9) we have

$$\frac{\partial(\varDelta T)}{\partial t} = -\frac{1}{\tau}\frac{C_i}{C_{v0}}(\varDelta T - \varDelta T_i)\ , \tag{5.12}$$

which corresponds to Herzfeld's relaxation equation (1.1). So we see that the relaxation time τ_H in (1.1) is related to τ and β by

$$\tau_H = \tau\frac{C_{v0}}{C_i} = \beta\frac{C_{v\infty}}{C_i}\ . \tag{5.13}$$

Similarly, we obtain from (5.2)

$$\frac{\partial(\varDelta T_i)}{\partial t} = \frac{1}{\tau}\frac{C_{v\infty}}{C_{v0}}(\varDelta T - \varDelta T_i)\ . \tag{5.14}$$

This corresponds to Herzfeld's equation (1.3), and we have accordingly the relation*

$$\tau_{H'} = \tau\frac{C_{v0}}{C_{v\infty}} = \beta\ . \tag{5.15}$$

It is known that Kneser's "period of adjustment of vibrational energy" β has the meaning of the "mean lifetime of the energy quantum" and related to the "collision probability of desactivation" f_{10} by

$$\beta = 1/(2\kappa N f_{10})\ , \tag{5.16}$$

where κ means the number of collisions taking place per each second if the molecular density is one per cm³, and N the number of molecules per cm³. It seems at first strange that the relaxation time of the internal specific heat β is more closely related to the collision probability than does the relaxation time of the internal energy τ. The Herzfeld's equation (1.3), however, explains this together with the relation (5.15). It means that the internal energy increases only at the expense of the external energy, and that the relaxation time for this process is β, instead of τ.

---

* It was erroneously stated in one[24] of our previous papers: "τ is the relaxation time to follow the change of thermal equilibrium at constant volume, i.e., after ending of an instantaneous volume change, whereas β is the relaxation time to follow the *change of thermal equilibrium* in a sinusoidal volume change, i.e., accompanying a sinusoidal change of the equilibrium state in a sound wave."

We have to correct this as follows: "τ is the relaxation time *of the internal energy* to follow the change of thermal equilibrium at constant volume, while β is the relaxation time to follow the *difference of temperature between the external and the internal degrees of freedom* in a sinusoidal volume change." (Cf. Nomoto[25], Fig. 3 as regards the relation between the various temperatures $\varDelta T$, $\varDelta T_i$ and the equilibrium value $\varDelta T^\circ (=\varDelta T_i^\circ)$).

Thus we see that the relaxation time of the internal specific heat β is physically a more significant quantity than the relaxation time of the internal energy τ.

§ 6. Second Approximation Formulas

More precisely, the sound velocity is given by (2.11). By correcting the zero approximation velocity equation (3.26) by this equation, employing the absorption value of (3.27), we have

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+\frac{D}{C_{v0}}+\frac{DC_i\omega^2\tau^2}{C_{v0}C_{v\infty}(1+\omega^2\tau^2)}\right]\cdot\left[1+\frac{3}{4}\frac{D^2C_i^2\omega^2\tau^2}{(C_{p0}C_{v\infty}+C_{v0}C_{p\infty}\omega^2\tau^2)}\right].$$

And by retaining terms up to $(DC_i/C_{p0}C_{v\infty})^2$, we have the second approximation velocity formula

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+D\frac{C_{v\infty}+C_{v0}\omega^2\tau^2}{C_{v0}C_{v\infty}(1+\omega^2\tau^2)}+\frac{3}{4}\frac{C_{p0}D^2C_i^2\omega^2\tau^2}{C_{v0}(C_{p0}C_{v\infty}+C_{v0}C_{p\infty}\omega^2\tau^2)^2}\right], \qquad (6.1)$$

or,

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+\frac{D}{C_{v0}}+\frac{DC_i\omega^2\tau^2}{C_{v0}C_{v\infty}(1+\omega^2\tau^2)}+\frac{3}{4}\frac{C_{p0}D^2C_i^2\omega^2\tau^2}{C_{v0}(C_{p0}C_{v\infty}+C_{v0}C_{p\infty}\omega^2\tau^2)^2}\right]. \qquad (6.2)$$

This may also be written as

$$V^2=V_0^2+(V_\infty^2-V_0)\frac{\omega^2\tau^2}{1+\omega^2\tau^2}+\frac{3}{4}\frac{(V_\infty^2-V_0^2)^2V_0^2\omega^2\tau^2}{(V_0^2+V_\infty^2\omega^2\tau^2)^2}. \qquad (6.3)$$

In terms of the relaxation time β, we have by (4.2) in place of (6.1) the expression

$$V^2=\left(\frac{\partial p}{\partial \rho}\right)_T\left[1+D\frac{C_{v0}+C_{v\infty}\omega^2\beta^2}{C_{v0}^2+C_{v\infty}^2\omega^2\beta^2}+\frac{3}{4}\frac{C_{p0}D^2C_i\omega^2\beta^2}{C_{v0}(C_{v0}C_{p0}+C_{v\infty}C_{p\infty}C^2\beta^2)^2}\right]. \qquad (6.4)$$

The second approximation absorption formula is obtained from (2.12) as

$$\alpha_\lambda=\pi\frac{DC_i\omega\tau}{C_{p0}C_{v\infty}+C_{v0}\omega_{p\infty}\omega^2\tau^2}\times\left[1-\frac{1}{4}\frac{D^2C_i^2\omega^2\tau^2}{(C_{p0}C_{v\infty}+C_{v0}C_{p\infty}\omega^2\tau^2)^2}\right], \qquad (6.5)$$

or, in terms of the relaxation time β, as

$$\alpha_\lambda=\pi\frac{DC_i\omega\beta}{C_{p0}C_{v0}+C_{p\infty}C_{v\infty}\omega^2\beta^2}\times\left[1-\frac{1}{4}\frac{D^2C_i^2\omega^2\beta^2}{(C_{p0}C_{v0}+C_{p\infty}C_{v\infty}\omega^2\beta^2)^2}\right]. \qquad (6.6)$$

The second approximation dispersion formulas (6.2) and (6.3) nearly coincides with the previously obtained ones (Nomoto[16], eq. (3.21) and (3.22)) in case of an ideal gas, up to a minor difference in the second order term in $\omega^2\tau^2$ (or $\omega^2\beta^2$) coming from the difference in methods of expansion. The second approximation formulas become indispensable in obtaining the dispersion formula for non-ideal gas or in calculating deviations of velocity for any real equation of state from an ideal gas. No such formulas applicable to both gases and liquids have been obtained before.

Electrical Properties of GeTe

By Yoshiro Moriguchi and Yutaka Koga
Kurume University

(Received October 20, 1956)

The electrical properties of the compounds, SnSe[1], GeSe[2] and SnTe[3], whose component elements belonging to the IV and VI groups of the periodic table have recently been reported. According to these reports, the first two compounds behave like an ordinary semiconductor, while, on the contrary the last shows rather a semi-metallic property. The measurements for GeTe, whose component elements also belong to the same groups as above, have been performed to compare with them.

The samples of the stoichiometric composition were made from Ge (from Eagle Picher Co., a few Ω cm) and Te (from Nihon Kogyo KK., 99.998%) by heating up to the melting point in an evacuated silica tube, and some of them were made into single crystals by zone-melting. The measured Hall coefficient R, resistivity ρ and thermoelectric power Q of the typical samples are shown in Fig. 1, and the Hall mobility R/ρ in Fig. 2. The signs of the Hall coefficient and thermoelectric power are positive through the whole temperature range.

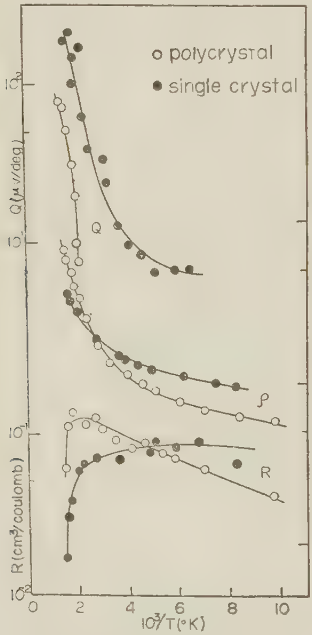

Fig. 1. The Hall coefficient R, resistivity ρ and thermoelectric power Q.

As shown in Fig. 1, the resistivity is comparatively small and its temperature coefficient is positive. In addition, the carrier concentrations obtained from the Hall coefficient have large value of about $10^{20}\sim10^{21}$ per cm³. It is to be noticed that these characteristics seem to be scarcely influenced by zone-refining. The large value of the carrier concentration and the positive temperature coefficient of the resistivity in the whole temperature range indicate that the ordinary theory for semiconductors, both homopolar and ionic, may be not able to be assumed for GeTe. These behaviours closely resemble those of SnTe, except that the Hall coefficient of GeTe decreases suddenly in high temperature range. The fact that the value of the carrier concentration is very large and do not decrease by zone-refining seems to suggest that the source of the charge carriers may be neither impurity atoms, nor the excess of one of the components as are usual in many ordinary semiconductors.

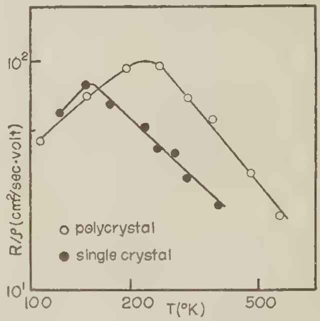

Fig. 2. The Hall mobility R/ρ.

The Hall coefficient and resistivity of GeTe are rather semi-metallic as mentioned above, but we have no preparations for the explanation of such electrical properties of GeTe at present.

We wish to express our gratitudes to Prof. Atuyosi Okazaki, Assist. Prof. Toshihiro Okada and the members of their laboratory for their kind guidances and for placing research facilities at our disposal.

Electronic Structure of a Moving Exciton in Alkali Halides

By Toshinosuke MUTO and Sei-ichi OYAMA
Institute of Science and Technology, University of Tokyo

(Received November 2, 1956)

The solutions of Wannier-Slater equation, which have been actually obtained in the previous work¹⁾, can be made use of as one-electron orbitals in our new approach of a moving exciton problem. As is well-known, the theoretical treatment of a moving exciton is considered to become essentially many electron problem in which the configuration interaction plays decisive role. As for the one-electron orbitals from which determinantal functions can be constructed, the solutions of Wannier-Slater equation corresponding to the conduction continuum and the localized exciton states just below the mentioned continuum have been used for one-electron orbitals of the excited states. The normal state of valence electrons is supposed to be approximately represented by that of the band theory since the majority of valence electrons of the crystal is expected to be in the continuum region of the energy states and a few of them is considered to be brought into the localized states below the valence continuum.

As for the electron configuration, we shall confine ourselves to the configurations with one electron excited to the ground state of a localized exciton state below the conduction continuum from any one level of the valence band. Different configurations will be specified by different hole state of the valence band and different location of the localized exciton state. The other possible configurations in which an electron is raised into the excited states of a localized exciton or to the conduction continuum, and two or more electrons are raised into the similar excited states, will be entirely disregarded for the sake of simplicity*.

Then, we can set up the determinantal functions corresponding to each electron configuration mentioned above, a suitable linear combination of which is shown to be expressed by the determinantal functions constructed directly from the corresponding Wannier functions and a wave function of a localized exciton at, say $\vec{R}_l$. The latter determinantal function, specified by the location $\vec{R}_l$ of a localized exciton and by a hole in the n-th branch of the valence band, shall be denoted by $\Psi^{(s)}(\vec{R}_l;n)$ in which $s=1$ and 3 correspond to a singlet and triplet configuration, respectively. Since the valence band of the chlorides is seen to become the Cl 3p band, it has been shown to split into three branches ($n=1, 2, 3$) according to the method of tight-binding approximation by Bethe²⁾.

The correct linear combination of the above determinantal functions and the corresponding secular equation can be worked out along the usual method of procedure.

Then, we have, for the wave function of a moving exciton in the j-th branch of the exciton band.

$$\Psi_j^{(s)}=\sum_{\vec{R}_l}e^{i\vec{K}\vec{R}_l}\sum_{n=1}^{3}A_{j,n}^{(s)}\Psi^{(s)}(\vec{R}_l;n)$$

and, for the secular equation from which $A_{j,n}^{(s)}$ and the corresponding energy E_j of the exciton band are solved,

$$\sum_{n'=1}^{3}\Big\{\sum_{\vec{R}_l\neq\vec{R}_l'}e^{i\vec{K}(\vec{R}_l-\vec{R}'_l)}(\vec{R}'_l;n'',s|H|\vec{R}_l;n',s)$$
$$+(\vec{R}'_l;n'',s|H|\vec{R}'_l;n'',s)-E\delta_{n'',n'}\Big\}A_{j,n'}^{(s)}=0,$$

in which $\vec{K}$ denotes a wave number vector in the reciprocal lattice of the crystal and

$$(\vec{R}_l';n'',s|H|\vec{R}_l;n',s)$$
$$=\int\Psi^{(s)*}(\vec{R}_l';n'')H\Psi^{(s)}(\vec{R}_l;n')\,dV,$$
$$H=-\frac{h^2}{2m}\sum_{i=1}^{N}\Delta_i+\sum_{i=1}^{N}V_0(\vec{r}_i)+\sum_{i<j}^{N}e^2/r_{ij}.$$

The propagation of our localized exciton through the lattice can be observed in the first summation factor of the wave function mentioned above. Since the secular determinant will become of a cubic as mentioned above, we have, for the lowest exciton band, at least three branches, i.e., $E=E_j(\vec{K})$, $j=1, 2, 3$ as far as the spin-orbit coupling is neglected. The spin-orbit coupling which can mix triplet and singlet states of the exciton band and higher order configuration interaction can give rise to still more multiplet structure of the exciton band, the corresponding secular equation being set up in a straightforward way.

The details of the mentioned calculation together with the numerial evaluation of the energy values of the exciton multiplet shall be reported in this journal in near future.

Asymptotic Behaviour of the Laminar Compressible Boundary Layer over a Circular Cylinder with Uniform Suction*

By Michiru YASUHARA

Institute of Science and Technology, University of Tokyo

(Received August 15, 1956)

The Solution of the incompressible boundary layer equations for the flow over a circular cylinder with uniform suction has already been presented by Wuest¹⁾ and Lew²⁾ in a simple closed form. This note treats the compressible case. If the cylinderical coordinates (x, r) is chosen, and the asymptotic state in which all quantities are independent of x is considered, the boundary layer equations become

$$\rho v \frac{du}{dr} = \frac{1}{r}\frac{d}{dr}\left(\mu r \frac{du}{dr}\right), \tag{1}$$

$$C_p \rho v \frac{dT}{dr} = \frac{1}{r}\frac{d}{dr}\left(\frac{C_p \mu}{P_r} r \frac{dT}{dr}\right) + \mu\left(\frac{du}{dr}\right)^2, \tag{2}$$

where (u, v) are the velocity components and P, ρ, T, μ, C_p, and P_r show the pressure, the density, the temperature, the coefficient of viscosity, the specific heat at constant pressure, and the Prandtl number respectively, and further suffix ∞ and w express quantities at infinity and on the cylinder. Eqs. (1) and (2) can be integrated as follows.

$$\frac{T}{T_\infty} = 1 - \left(1 - \frac{u}{u_\infty}\right)^{P_r}\left(1 - \frac{T_w}{T_\infty} + \frac{\gamma-1}{2}M_\infty^2\right) - \frac{(\gamma-1)P_r}{2(2-P_r)}M_\infty^2\left\{\left(1-\frac{u}{u_\infty}\right)^2 - \frac{2}{P_r}\left(1-\frac{u}{u_\infty}\right)^{P_r}\right\}, \tag{3}$$

$$\rho_w v_w \varepsilon \log \frac{r}{\varepsilon} = -\int_0^u \frac{\mu}{(u_\infty - u)}du, \tag{4}$$

where ε is the radius of the cylinder. μ is a function of temperature as given by Sutherland, and is known as a function of u from (3). If μ is approximated by a linear function of the temperature used by Chapman and Rubesin³⁾, (4) is integrated as follows.

$$\frac{\rho_\infty V r}{C\mu_\infty} = \left\{R_{e\varepsilon} \Big/ \left(1 - \frac{u}{u_\infty}\right)^{T_w/T_\infty R_{e\varepsilon}}\right\} \times \exp\left[\frac{T_w}{T_\infty R_{e\varepsilon}}\left[\frac{(\gamma-1)P_r}{4(2-P_r)}M_\infty^2\left\{\left(1-\frac{u}{u_\infty}\right)^2 - 1\right\} + \frac{1}{P_r}\left\{1 - \frac{T_w}{T_\infty} - \frac{(\gamma-1)M_\infty^2}{2(2-P_r)}\right\}\left\{\left(1-\frac{u}{u_\infty}\right)^{P_r} - 1\right\}\right]\right], \tag{5}$$

where C is the Chapman-Rubesin constant, and

$$V \equiv -v_\omega, \qquad R_{e\varepsilon} \equiv \frac{\rho_\infty V \varepsilon}{C\mu_\infty}, \tag{6}$$

The shear stress on the cylinder τ_w and the temperature gradient on the cylinder are given by

$$\tau_w = \left(\mu \frac{du}{dr}\right)_w = \rho_w u_\infty V, \tag{7}$$

$$\left\{\frac{d(T/T_\infty)}{d(\rho_\infty V r / C\mu_\infty)}\right\}_w = P_r\left(\frac{T_\infty}{T_w}\right)^2\left(1 - \frac{T_w}{T_\infty} + \frac{\gamma-1}{2}M_\infty^2\right), \tag{8}$$

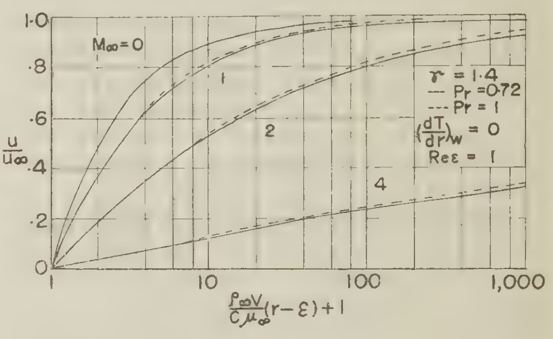

Fig. 1

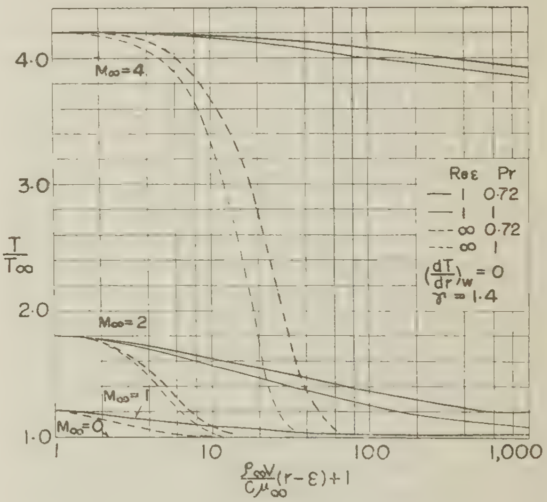

Fig. 2

Fig. 1 and Fig. 2 are several numerical examples which show qualitative natures of the flow.

Last, it should be noticed that, the condition to keep the displacement thickness finite is expressed as follows.

$$R_{e\varepsilon} > 2\frac{T_w}{T_\infty} \tag{9}$$

Carrier Concentration Changes in p-Si Induced by Heat Treatment

By Yasuo MATUKURA
Electrotechnical Laboratory, Tokyo, Japan

(Received August 14, 1956)

C. S. Fuller et al[1] has reported the changes in the resistivity of Si induced by heat treatment. We have observed the changes of carrier concentration in p-Si caused by heating at temperatures between 400° and 1000°C.

A p-Si single crystal of resistivity about 18 Ω cm was grown from the melt by the pulling technique. The room temperature-resistivity and Hall coefficient of bridge shaped specimens with Ni plated electrodes were measured before and after the heat treatment. After removing the Ni plating, the specimen were cleaned in HNO_3 and HF, then heated in H_2, air, or vacuum. The variation of the number of thermally induced electrons and holes with the temperature of treatment is shown in Fig. 1. Here the specimens were heated for 50 minutes in purified H_2 gas and quenched. The effect of the rate of cooling is shown in Table I, where specimens were heated in H_2 gas for 50 minutes. The slowest cooling (the last column) from 700°C gives an increase in electron content, which may be expected from the fact that the specimen is cooled through the region of 400° to 600°C at slow cooling rate. On the other hand, thermally induced carriers seem to influenced by the ambient gas. The heat treatment at 500°C in vacuum of 1×10^{-5} mm Hg has induced the smaller electron density than in H_2 or air, and the largest effect has been obtained in air as ambient. At 700°C, we could see no influence of the ambient. The relation between carrier concentration and heat treatment time, as shown in Fig. 2, was obtained by heating in vacuum and quenching. When specimens which showed an increase in hole concentration by heating at 700°C were heated at 500°C, they turned to n-type by the induced electrons. They were again turned to p-type by heating at 700°C. These cycles were reversible provided to heating times were successively prolonged.

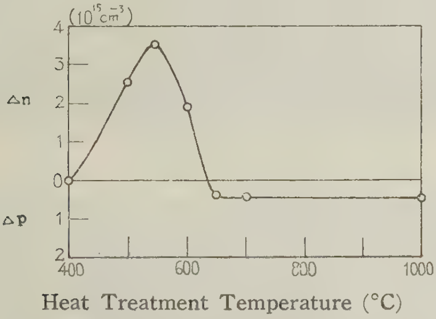

Fig. 1. Relation between the heat treatment temperature and induced electron concentration (Δn) or hole's (Δp).

Table I. Thermally induced carrier concentrations of silicon cooled at various rates after heating for 50 minutes in hydrogen gas. Minus signs represent the increase in holes.

Heating temperature (°C)	500			700		
Cooling rate (°C/min.)	quench	23	5	quench	50	6
Change of carrier density (10^{15} cm^{-3})	2.57	4.35	4.59	−0.41	−0.25	0.89

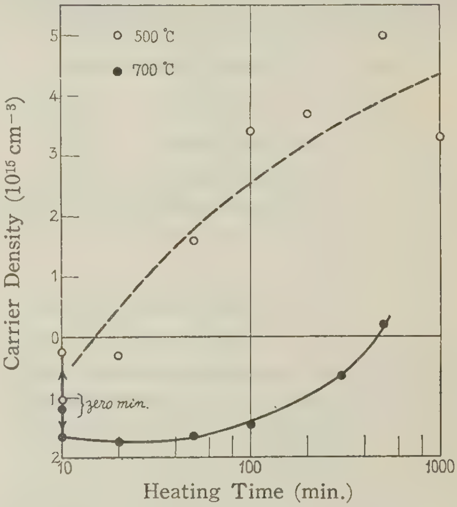

Fig. 2. Changes of carrier density by the heat treatment time in vacuum.

In order to interpret the complicated changes mentioned above, it seems better to consider that the phenomena observed in the case of low temperature treatment (under 650°C) are different in their origin to that observed in the case of high temperature treatment (above 650°C). In the former case, some kinds of surface impurities such as copper[2-3] in germanium may play a part of roles in the mechanisms. In the latter case, the lattice defcts of Schottky or Frenkel type would take part in the generation of holes[4].

These phenomena depend also on the conditions of preparing the sample. At the present situation it is proper to reserve the decisive conclusions on the mechanism of these phenomena.

The author wished to express his gratitude to Dr. G. M. Hatoyama, the members of his laboratory, and Mr. M. Kikuchi for various inspiring discussions, and Dr. T. Momota and Mr. T. Suzuki for their encouragements.

On the Hall Effect in Bismuth at Low Temperature

By Hirosi HASEGAWA, Sigeru NAKANO
Department of Physics, Tokyo University
and Natsuki HASHITSUME
Department of Physics, Ochanomizu University

(Received October 29, 1956)

The galvano- and thermomagnetic properties of several metals show oscillatory behavior against magnetic field at liquid helium temperatures[1], which is similar to the de Haas-van Alphen oscillation. One of the characteristics of the field variation of these transport phenomena is, however, that these also have the monotonic part of the field dependence relatively steep in comparison with the susceptibility curves. The measurements of the Hall voltage in bismuth by J. M. Reynolds et al[2] show that the envelope is proportional to H^δ, where δ takes values between 2 and 3 under magnetic field up to 8 kilogauss. In their analysis of data, this dependence has not been accounted for, and the oscillatory part has been attributed to the periodic change in the number of conduction electrons versus reciprocal field intensity according to Landau-Dingle's formula[3]. We present here an interpretation of the monotonic part and also a remark on the oscillation of the Hall effect against field.

The galvanomagnetic effects of semi-metals are analyzed usually on the basis of the two band model[4], where very large magnetoresistance of these metals is interpreted as a result of the compensation of electrons and holes in contributing to the Hall field and also of their long mean free paths. In liquid helium temperatures and under strong magnetic field where the circular frequency ω_c of carriers is much larger than collision frequency $1/\tau$, the slight difference in number of electrons and holes alters the field dependence of Hall effect qualitatively from that expected under the condition $\omega_c\tau<1$[4].

In the case of bismuth it turns out that the excess of electrons less than 1% is sufficient to cause a rapid increase of the Hall voltage, what is actually observed by experiment. Reynolds' data were reanalyzed on this model, and we obtained an estimation of the difference as follows;

$$\Delta n=(3.7\pm0.3)\times10^{15}\,\mathrm{cm}^{-3}\ \text{at}\ 4.2°\mathrm{K}.$$

Assuming the concentration of conduction electrons to be $n=10^{18}\,\mathrm{cm}^{-3}$, we can estimate another parameter

$$\mu_1\mu_2/\mu_1+\mu_2=(2.8\pm0.3)\times10^6\,\mathrm{cm}^2/\text{volt sec}.$$

where μ_1 and μ_2 are the mobilities of an electron and a hole respectively which correspond to the respective maximum mass in the direction perpendicular to the principal axis, whereas the mobility estimated from residual resistance at vanishing field corresponds to the minimum mass.

The above-mentioned excess of electrons Δn would arise presumably from the ionization, say, of impurities. In the range of magnetic field used in experiments the distribution of charge carriers is determined almost always between the upper and the lower band themselves, because the ionization energy would not be affected appreciably by the increase of field intensity. If, for instance, some electrons fall into the lower band, the number of electrons in the upper band changes, but the difference Δn should not change. Therefore, even if the distribution of carriers is changed periodically with increasing field, the condition

$$\Delta n=\text{independent of } H$$

should be satisfied. This means that the oscillation of a conductivity tensor versus $1/H$ should occur at least through the second order terms which relate to the relaxation processes. If the oscillation is attributed to Δn in the expression of the Hall coefficient, we shall obtain a too rapid increase of the amplitude of oscillation, which contradicts with experimental data[6]. Similar remark has been made by M. C. Steele[1] in connection with the analysis of his experimental data in antimony.

Detailed calculations and discussions of the more basic problem of the transport theory under strong magnetic field will be presented later. The authors would like to express our thanks to Professor R. Kubo for his suggestions on this problem.

Spiral Etch Pits on Germanium Surface

By Makoto Kikuchi and Seiichi Denda
Electrotechnical Laboratory, Tokyo, Japan

(Received October 27, 1956)

Spiral etch pits have been formed on (111) germanium surface. It is already reported by Ellis[1] that this type of etch pits can be formed by using special kind of etching solution, i.e., bubbling Cl_2 in the mixture of KOH and H_2O at 0°C. We have succeeded, however, to form this kind of etch pits using rather usual solutions, i.e., the combination of HNO_3, HF, HCl, and H_2O_2.

Figs. 1 and 2 are the photographs of the spiral pits of left-hand and right-hand screw type, respectively. It has been confirmed that the density of this type of etch pits is at least two or three orders of magnitude smaller than the other kinds which are formed by ordinary etching.

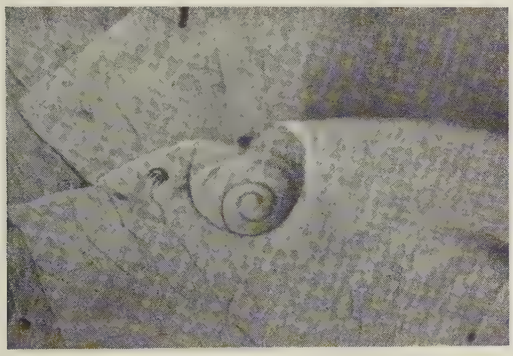

Fig. 1. Left-hand type spiral etch pit.

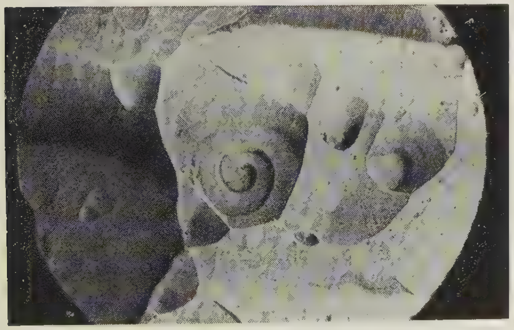

Fig. 2. Right-hand type spiral etch pit.

It must also be noticed that the etches which are effective in forming the pits of closed terraces[2] is quite useless to form the spiral pits.

Fig. 3 shows a pair of spiral etch pits, one is left-hand and the other is right-hand screw type.

It has been experienced that the number and the structure of etch pits critically depend on the relative amounts and combination of etching solutions, temperature, the treatment of the germanium surface before the etching, and on some important but unknown factors. The details are now being investigated.

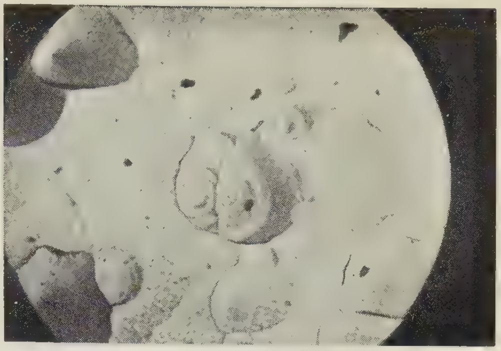

Fig. 3. A pair of spiral etch pits.

On the Release of Alkaline Earth Metals by the Electron Dissociation of Oxide Films Evaporated from the Oxide Coated Cathodes

By Tetsuji Imai and Isao Mitsufuji
Electrical Communication Laboratory, Nippon Telegraph & Telephone Public Corporation, Tokyo, Japan

(Received October 23, 1956)

It was pointed out by Sproull[1] that a large quantity of condensable gas which is enough to cause a glow discharge is present in the anode-cathode space of the oxide-coated cathode magnetrons.

The author observed a quite similar phenomenon in the ordinary oxide-coated cathode vacuum tubes in which a electrode contaminated with cathode materials is utilized as the anode. In Fig. 1, variations of gas pressure measured by the external ionization gauge and of anode current are shown together with the schematic indication of the intensity of the glow observed in the anode-cathode space. The glow is analyzed spectroscopically and the several spectral lines of Ba, Sr and a trace of Ca are observed but other lines are not found as shown in Fig. 2.

In Fig. 1, it is noted that though in the first stage (small anode loss) increase of gas pressure measured by the gauge is as large as that of the second stage (large anode loss), glow between the anode and the cathode is observed only in the second stage. This fact implies that the increase of gas pressure observed by the gauge is not the direct cause of the glow. The latter may be attributed to the localized atomic and ionic Ba, Sr and Ca vapours which are left at first on the electron bombarded anode by the preferential removal of oxygen of the deposited oxide materials such as BaO, SrO and CaO and then released from the anode by sublimation.

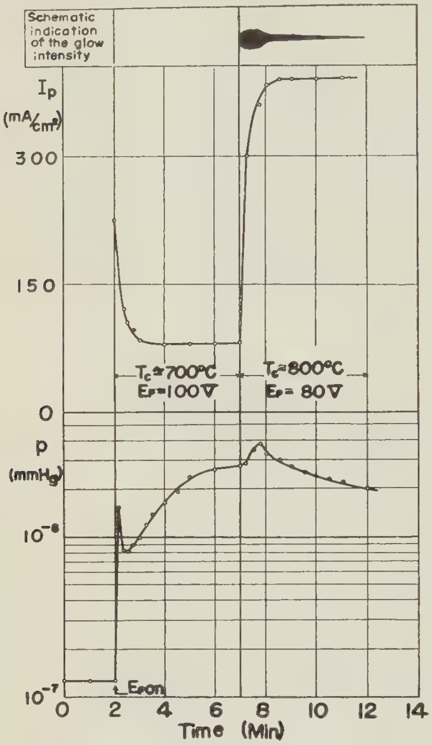

Fig. 1. Variations of anode current and gas pressure caused by electron bombardment of the open caovered with deposited oxide materials.

The releasing energy of Ba at the electron dissociation of the BaO cathodes is obtained by S. Yoshida and others²⁾ by the use of radioactive isotope. In this method, the electron bombardment is undertaken at various cathode temperatures and the quantities of Ba deposited on the outer electrodes are counted for each case. Therefore, the releasing energy obtained by this temperature dependency may be attributed reasonably to the sublimation energy of the Ba atoms or ions dissociated from BaO.

It is pointed out further that not only BaO but also considerably large quantity of SrO evaporate from the oxide coated cathode in contradiction to the previous supposition of the preferential evaporation of BaO only³⁾.

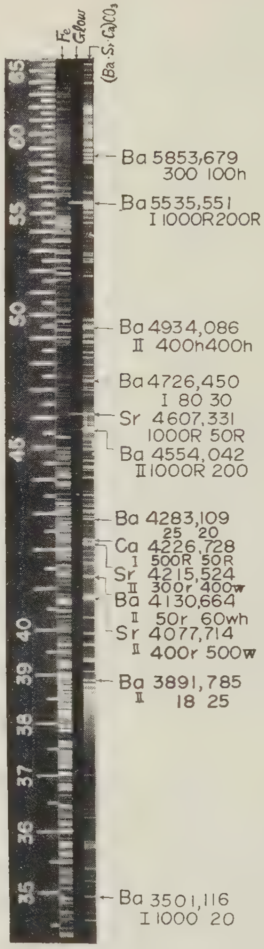

Fig. 2. Spectroscopical analysis of the glow.

Temperature Dependence of Electron Spin Resonance Absorption of Thiophenol in Sulfuric Acid

By Yasaburo YOKOZAWA and Isao MIYASHITA

Research Institute of Applied Electricity, Hokkaido University

(Received October 13, 1956)

Electron spin resonance absorption has been observed in free radicals embracing unpaired electrons. The resonance frequency ν in the static magnetic field H is given by

$$h\nu = g\beta H. \tag{1}$$

As the intensity of resonance absorption is proportional to the magnetic susceptibility χ,

$$\chi = \frac{Ng^2\beta^2 S(S+1)}{3kT}, \tag{2}$$

where S is the electronic spin quantum number and N the density of the unpaired electrons, it is important to examine the temperature dependence of the resonance absorption intensity.

The present writers have examined the temperature dependence of the absorption intensity of thiophenol (C_6H_5SH) in sulfuric acid. This absorption has been reported to consist of two parts, the g values being 2.015 and 2.008, respectively.[1]

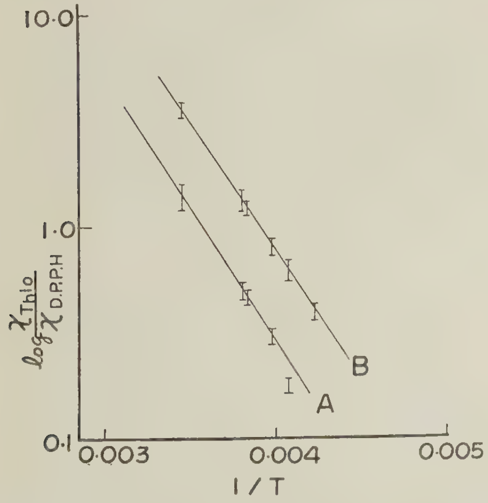

Fig. 1. The temperature dependency of resonance intensity of thiophenol in sulfuric acid. Ordinate: the logarithm of the ratio of the absorption intensity of the sample to that of D.P.P.H.. Abscissa: the reciprocal of absolute temperature.

The measurements were carried out at a frequency about 9000 mc/sec, covering the range from room temperature to liquid-nitrogen temperature. The absorptions were detected by the method of magnetic field modulation and the derivative of absorption curves were recorded using a lock-in amplifier. The absorption intensities were determined comparing the absorption area of the sample with that of diphenyl-picryl hydrazyl, inserted into the cavity together with the sample.[2]

The spectroscopic g factros do not change with temperature. The line widths are nearly independent of temperature, while the absorption intensities decrease with decreasing temperature and become too small to be detected under -55°C. One may infer from this that N in Eq. (2) is not constant in this case but dependent upon temperature. The intensity varies with temperature as shown in Fig. 1. In this figure the ratio of absorption intensity of the sample to that of D.P.P.H. is plotted against the reciprocal of absolute temperature. As the absorption intensity of D.P.P.H. is inversely proportional to the absolute temperature[3], this ratio is directly proportional to the density of unpaired electron, *viz* N in Eq. (2).

The two straight lines A and B of almost the same slope within experimental errors are obtained. A and B correspond to the absorptions of two g values, 2.015 and 2.008, respectively. Hence, the activation energies determined from these two slopes result in the same value 5.8 kcal/mol.

In this laboratory similar dependence on temperature was found in the case of perylen in sulfuric acid and it was concluded then that the absorption was arising from the triplet state.[2] In this case of thiophenol it is anticipated that the resonance absorption is also due to the triplet state. But further discussion on this problem will be given in a subsequent paper.

The present writers wish to present our sincere thanks to Professor K. Higasi for his kind interest and encouragement. A part of the expense has been defrayed from a grant by the Ministry of Education.

On the Electronic Structure of Localized Exciton in Alkali Chlorides

By Toshinosuke MUTO and Hiroshi OKUNO

Institute of Science and Technology, University of Tokyo

(Received October 25, 1956)

As a continuation of the previous work[1] on KCl, our method of procedure based on Wannier-Slater equation for perturbed lattice has been extended to all chlorides which have been actually observed experimentally. Our numerical results are shown in the following table.

	κ	m^*/m	$-E'_{\text{cal.}}$	$-E'_{\text{obs.}}$
LiCl	2.75	0.6	0.89 ev	0.86 ev
NaCl	2.25	1.0	1.81	1.83
KCl	2.13	0.85	1.83	1.80
RbCl	2.19	0.7	1.53	1.50
CsCl	2.60	0.9	1.33	1.39

According to our experience in the best-fit procedure of the previous report[1], the effective dielectric constants κ have been tentatively assumed to be the high frequency values. The assigned values of the effective m^* in our procedure are observed to be of the order of magnitude ranging 0.5 m to m in accordance with the available experimental data. Generally speaking, therefore, the comparison shown in the Table seems to be good as far as the approximation in our method of procedure is allowed for. In order to avoid the misunderstanding, however, a few words should be added on our definition of a localized exciton. In fact our localized exciton does concern the exciton state localized around a lattice point only for the short duration of light absorption process but not for a still longer time. For a still longer time, the displacement of surrounding ions, i.e., lattice distortion will give rise to an essential influence on the exciton state.

In this connection, we should like to point out another example of the applicability of the Wannier-Slater equation for perturbed lattice. Pringsheim[2] and others discovered the so-called Greek bands in the longer wave length side of the usual exciton band of KI at low temperatures and such new absorption bands were ascribed to the localized exciton around a negative ion vacancy or a F-center, respectively. For an exciton trapped around a negative ion vacancy, the perturbation potential in the Wannier-Slater equation will become negative of the potential energy due to a Cl^- ion $V_{\text{cl}}(\vec{r}-\vec{n}a)$ in addition to that of a usual exciton $V(r)$.

Then, we have

$$-\frac{h^2}{2m^*}\Delta\psi(\vec{r})+\{V(r)+V_{\text{cl}}(\vec{r}-\vec{n}a)\}\psi(\vec{r})=E'\psi(\vec{r}).$$

The solution of the above equation can be obtained by the ordinary perturbation theory or through a similar method to that in the hydrogen molecule iron problem. The numerical evaluation is now in progress.

The Multipolarity of γ-ray Absorption in ^{12}C(γ, 3α) Reaction produced by (Li, p)γ-rays

By J. MUTO, E. TAKEKOSHI, T. NAKAMURA, A. IMAMURA
and Y. TSUNEOKA

Department of Physics, Faculty of Science, University of Kyoto

(Received September 6, 1956)

The mechanism of the ^{12}C(γ, 3α) reaction for (Li, p)γ-rays has been estimated from a study of 576 stars in nuclear emulsions. By the analysis of the angular distributions and correlation of the α-particles, the multipolarity of the absorption process of (Li, p)γ-rays by the ^{12}C nucleus can be explained by the mixture of two sorts of interaction $E1$ and $E2$. This result is consistent with Goward and Wilkins' conclusion, but our experimental data of the angular distribution of the first α-particles show significant forward asymmetry contrary to their backward asymmetry.

§ 1. Introduction

The reaction ^{12}C(γ, 3α) has been studied by many authors (Hänni, Telegdi & Zünti$^{1)}$, 1948; Nabholz, Stoll & Wäffler$^{2)}$, 1950; Telegdi & Zünti$^{3)}$, 1950; Telegdi$^{4)}$, 1951; Chastel$^{5)}$, 1954) by using the (Li, p)γ-rays, and by others (Eder & Telegdi$^{6)}$, 1952; Goward & Wilkins$^{7)8)}$, 1953, 1955; Liversey & Smith$^{9)}$, 1953; Dawson & Bigham$^{10)}$, 1953; Havliček & Dobovišek$^{11)}$, 1955) with the bremsstrahlung up to several ten MeV.

These experimental studies have shown that the reaction is expressed by the cascade form: ^{12}C(γ, α_1)^{8}Be(α_2)α_3, and demonstrated the general predominance of transitions to the 3 MeV level of ^{8}Be for γ-ray energy below 20 MeV. For the multipole character of the initial γ-ray interaction, Telegdi$^{4)}$ determined, by the energy analysis of carbon star α-particles produced by (Li, p)γ-rays, that it is the mixture of M1 and E2. On the other hand, Goward and Wilkins$^{8)}$ concluded that the γ-ray interaction is the mixture of E1 and E2, by analysing the angular distributions and correlation of cascade α-prongs of the star produced by the bremsstrahlung whose energy interval is from 17.0 MeV to 17.8 MeV.

We have analysed the angular distributions and correlation of carbon star α-prongs in the emulsion produced by (Li, p)γ-rays under the good geometrical condition, arriving at the conclusion that the multipolarity of γ-ray interaction is the mixture of E1 and E2.

§ 2. Procedure

Nuclear emulsions were irradiated for about 10 hours with γ-rays produced by proton bombardment of lithium. The proton beam was accelerated to 500 KV by an accelerator of the Cockcroft-Walton type, and the intensity of magnetically analysed beam was 500 μA. The diameter of thick Li-target was 8 mm. 1.5″×1″ Ilford C2 plates (200 μ thickness) were used. Each plate was arranged in such a manner that a 1 in. edge was 12 cm apart from the target and the 1.5 in. edges parallel to the γ-rays, giving glancing incidence.

Emulsions were processed by low pH amidol developer$^{12)}$, with the purpose of obtaining good discrimination between α-particles and protons, combined with a sufficiently low background, and then located with 2 precent glycerine solution.

The processed emulsions were scanned using "Tiyoda" microscope and "Nippon Kogaku" microscope at a magnification of 600. Detected tracks were measured at a magnification of 1350 or 1500. Each depth measurement (the mean of three readings) was subject to about $\pm 0.3\,\mu$ standard deviation. Errors in horizontal projections were $\pm 0.5\,\mu$.

The shrinkage factor was obtained by measuring the horizontal and vertical components of the lengths of Polonium α-tracks$^{13)}$.

The range-enery relation in C2 plate used was obtained from the range-energy curve corrected with P_0 α.

By momentum-balance analysis[7] 769 stars (momentum unbalance vector $|\Delta P| \leq 1.4$ in (a. m. u. MeV)$^{1/2}$) among the measured 957 stars were treated as ^{12}C(γ, 3α). Fig. 1 shows the histogram of values of the energy-release (E_T) for 769 stars. Then 606 stars, whose energies are $16.0 \text{ MeV} \leq E_T + Q \leq 18.6$ MeV (Q=7.28 MeV), were selected as ^{12}C(γ, 3α) stars produced by 17.6 MeV γ-ray.

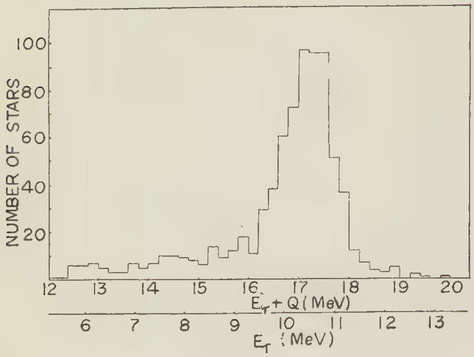

Fig. 1. Energy-release histogram for ^{12}C(γ, 3α).

Values of E^*_{ij} defined by the equation:

$$E^*_{ij} = \frac{1}{8}(P_i - P_j)^2$$

were calculated for 606 stars, where P_i and P_j are the observed vector momenta of α_i and α_j (i, j=1, 2, 3; $i \neq j$). E^*_{23} is the energy released when the unstable ^{8}Be nucleus breaks up into α_2 and α_3. Fig. 2 shows the histogram of E^* values. The histogram of E^* exhibits a pronounced peak at $E^* \simeq 3$ MeV with half-width $\Gamma \sim 1.0$ MeV. In order to assign the three α prongs of a star to α_0, α_2 and α_3, the significant E^* value, E^*_{23}, was taken to be the value nearest to (2.95+0.09) MeV, or the energy of α_1 was taken to be the value

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 2, FEBRUARY, 1957

The Multipolarity of γ-ray Absorption in $^{12}C(\gamma, 3\alpha)$ Reaction produced by (Li, p)γ-rays

By J. MUTO, E. TAKEKOSHI, T. NAKAMURA, A. IMAMURA and Y. TSUNEOKA

Department of Physics, Faculty of Science, University of Kyoto

(Received September 6, 1956)

The mechanism of the $^{12}C(\gamma, 3\alpha)$ reaction for (Li, p)γ-rays has been estimated from a study of 576 stars in nuclear emulsions. By the analysis of the angular distributions and correlation of the α-particles, the multipolarity of the absorption process of (Li, p)γ-rays by the ^{12}C nucleus can be explained by the mixture of two sorts of interaction $E1$ and $E2$. This result is consistent with Goward and Wilkins' conclusion, but our experimental data of the angular distribution of the first α-particles show significant forward asymmetry contrary to their backward asymmetry.

§ 1. Introduction

The reaction $^{12}C(\gamma, 3\alpha)$ has been studied by many authors (Hänni, Telegdi & Zünti1), 1948; Nabholz, Stoll & Wäffler2), 1950; Telegdi & Zünti3), 1950; Telegdi4), 1951; Chastel5), 1954) by using the (Li, p)γ-rays, and by others (Eder & Telegdi6), 1952; Goward & Wilkins7)8), 1953, 1955; Liversey & Smith9), 1953; Dawson & Bigham10), 1953; Havliček & Dobovišek11), 1955) with the bremsstrahlung up to several ten MeV.

These experimental studies have shown that the reaction is expressed by the cascade form: $^{12}C(\gamma, \alpha_1)^8Be(\alpha_2)\alpha_3$, and demonstrated the general predominance of transitions to the 3 MeV level of ^8Be for γ-ray energy below 20 MeV. For the multipole character of the initial γ-ray interaction, Telegdi4) determined, by the energy analysis of carbon star α-particles produced by (Li, p)γ-rays, that it is the mixture of M1 and E2. On the other hand, Goward and Wilkins8) concluded that the γ-ray interaction is the mixture of E1 and E2, by analysing the angular distributions and correlation of cascade α-prongs of the star produced by the bremsstrahlung whose energy interval is from 17.0 MeV to 17.8 MeV.

We have analysed the angular distributions and correlation of carbon star α-prongs in the emulsion produced by (Li, p)γ-rays under the good geometrical condition, arriving at the conclusion that the multipolarity of γ-ray interaction is the mixture of E1 and E2.

§ 2. Procedure

Nuclear emulsions were irradiated for about 10 hours with γ-rays produced by proton bombardment of lithium. The proton beam was accelerated to 500 KV by an accelerator of the Cockcroft-Walton type, and the intensity of magnetically analysed beam was 500 μA. The diameter of thick Li-target was 8 mm. $1.5'' \times 1''$ Ilford C2 plates (200 μ thickness) were used. Each plate was arranged in such a manner that a 1 in. edge was 12 cm apart from the target and the 1.5 in. edges parallel to the γ-rays, giving glancing incidence.

Emulsions were processed by low pH amidol developer12), with the purpose of obtaining good discrimination between α-particles and protons, combined with a sufficiently low background, and then located with 2 precent glycerine solution.

The processed emulsions were scanned using "Tiyoda" microscope and "Nippon Kogaku" microscope at a magnification of 600. Detected tracks were measured at a magnification of 1350 or 1500. Each depth measurement (the mean of three readings) was subject to about $\pm 0.3\,\mu$ standard deviation. Errors in horizontal projections were $\pm 0.5\,\mu$.

The shrinkage factor was obtained by measuring the horizontal and vertical components of the lengths of Polonium α-tracks13).

The range-enery relation in C2 plate used was obtained from the range-energy curve corrected with P_0 α.

By momentum-balance analysis[7] 769 stars (momentum unbalance vector $|\Delta P| \leq 1.4$ in (a. m. u. MeV)$^{1/2}$) among the measured 957 stars were treated as $^{12}\mathrm{C}(\gamma, 3\alpha)$. Fig. 1 shows the histogram of values of the energy-release (E_T) for 769 stars. Then 606 stars, whose energies are 16.0 MeV$\leq E_T + Q \leq$18.6 MeV (Q=7.28 MeV), were selected as $^{12}\mathrm{C}(\gamma, 3\alpha)$ stars produced by 17.6 MeV γ-ray.

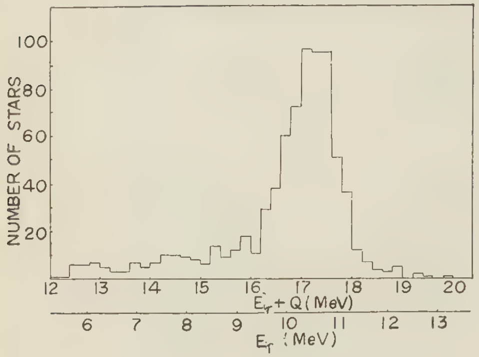

Fig. 1. Energy-release histogram for $^{12}\mathrm{C}(\gamma, 3\alpha)$.

Values of E^*_{ij} defined by the equation:

$$E^*_{ij} = \frac{1}{8}(P_i - P_j)^2$$

were calculated for 606 stars, where P_i and P_j are the observed vector momenta of α_i and α_j ($i, j = 1, 2, 3$; $i \neq j$). E^*_{23} is the energy released when the unstable ^{8}Be nucleus breaks up into α_2 and α_3. Fig. 2 shows the histogram of E^* values. The histogram of E^* exhibits a pronounced peak at $E^* \simeq 3$ MeV with half-width $\Gamma \sim 1.0$ MeV. In order to assign the three α prongs of a star to α_0, α_2 and α_3, the significant E^* value, E^*_{23}, was taken to be the value nearest to (2.95+0.09) MeV, or the energy of α_1 was taken to be the value

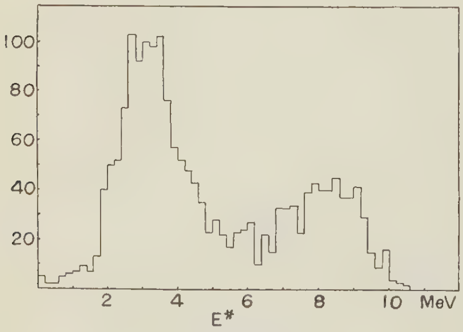

Fig. 2. E^* histograms (three values for each star).

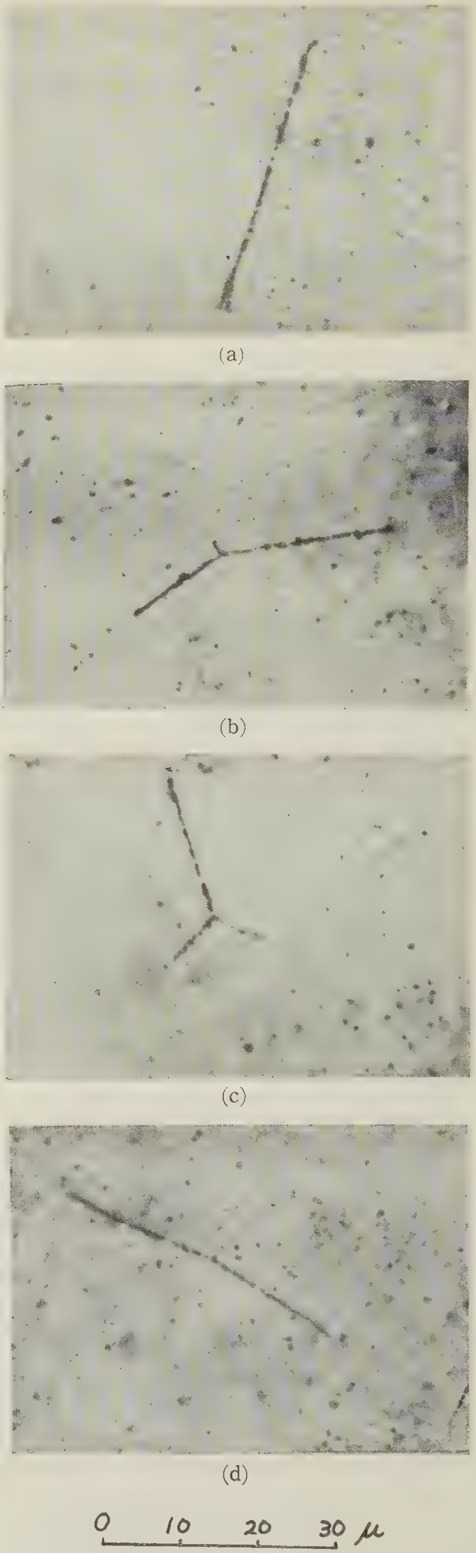

Fig. 3. Microphotographs of carbon star involving the transition to ^{8}B ground state (a) and the first excited state (b) (c) (d).

nearest to $\frac{2}{3}\{17.6-(7.28+3.04)\}$ MeV. Then 576 stars were selected as stars involving the first excited state of ^{8}Be. While 19 stars in the interval $E^* \leq 0.9$ MeV were selected as stars involving the ground state of ^{8}Be. The microphotographs of representative types of carbon star are shown in Fig. 3.

The angle θ_1 of emission of the α_1-particle relative to the direction of the incident γ-ray, as observed in the rest system of the ^{12}C nucleus, the correlation angle θ_C between the direction of break-up of the recoiling ^{8}Be nucleus and the direction of α_1 in the ^{12}C system, and the angle θ_{23} between the direction of break-up of the ^{8}Be nucleus and γ-ray direction are given by the following equations respectively:

$$\theta_1=\psi_1+\tan^{-1}\left[\frac{P_\gamma \sin\psi_1}{3P_1-P_\gamma\cos\psi_1}\right],$$

$$\cos^2\theta_C=\frac{(E^*_{12}-E^*_{13})^2}{E^*_{23}(2E^*_{12}+2E^*_{13}-E^*_{23})},$$

$$\cos^2\theta_{23}=\frac{(P_2\cos\psi_2-P_3\cos\psi_3)^2}{8E^*_{23}},$$

where P_i ($i=1, 2, 3$) is the momentum vector of α_i, P_γ is the momentum of γ-ray and ψ_i ($i=1, 2, 3$) is the observed angle between α_i and the γ-ray. These are shown in Fig. 4.

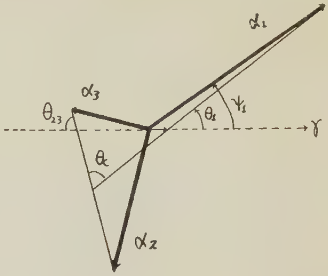

Fig. 4. Velocity vectors of $^{12}C(\gamma\alpha_1)^8Be^*(\alpha_2)\alpha_3$.

θ_0, θ_C and θ_{23} were calculated for 507 stars involving the first excited level of ^{8}Be.

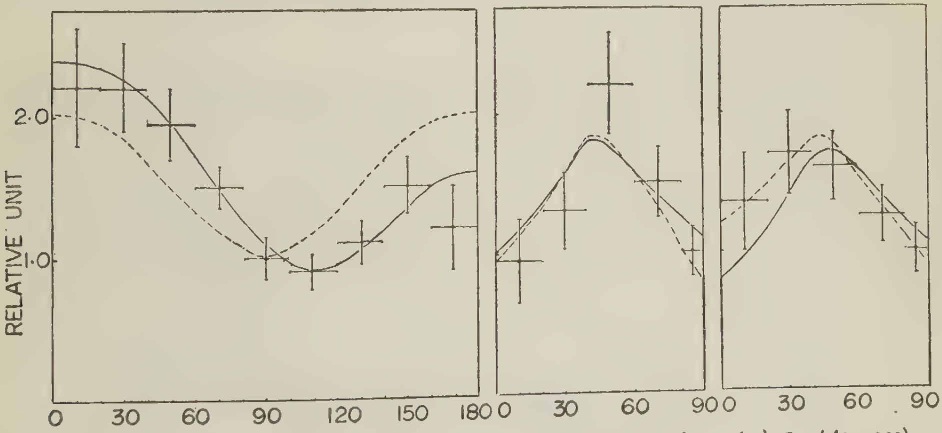
§3. Results and Discussion

The α-particle angular distributions and correlation associated with the first excited state transitions are presented in Fig. 5. These corrected distributions of I (θ_1, θ_C or θ_{23}) values are presented in the form:

$$I(\theta)=N(\theta)\ \mathrm{cosec}\ \theta\ ,$$

where $N(\theta)$ is the number of stars having $\theta(\theta_1, \theta_C$ or $\theta_{23})$ values within the interval 20°. The fraction of randomly oriented $^{12}C(\gamma, 3\alpha)$ stars which escape from an emulsion of 200 μ thickness is 10 percent at $\theta=90°$. In Fig. 5 the vertical lines indicate the purely statistical standard deviations.

In order to compare the experimental results with theory, it was assumed that the 2.95 MeV level of ^{8}Be has spin-parity 2^+, and the $E1$, $M1$ and $E2$ γ-ray interaction were considered. The general theoretical expressions for $I(\theta_1)$, $I(\theta_C)$ and $I(\theta_{23})$ are given in Appendix. It is worth noticing that for mixed $E1+E2$ interactions interference terms $P_1(\cos\theta_1)$, $P_3(\cos\theta_1)$ may be present in $I(\theta_1)$, but $E1+M1$ or $M1+E2$ mixtures have no such interference



(a) θ₁ (degrees) (b) θc (degrees) (c) θ23 (degrees)

Fig. 5. Angular distributions and correlation in the 2.95 MeV transitions. The curves indicate possible theoretical results for a $J=2$ level, and $E1+E2$ (full lines) of $M1+E2$ (dotted lines) γ-ray interactions.

Table I. Transition to 2.95 MeV level of ^{8}Be: Angular Distributions and Correlation Analysis.

γ-ray interaction	ratio to $E2$	unknown parameter	$I(\theta_1)$	$I(\theta\ )$	$I(\theta_{23})$
$E1+E2$	1/2	$\sigma_1=\sigma_3=0.25$ $\sigma_0=\sigma_2=\sigma_4=0.3$ $\cos\eta_{02}=2/3$, $\cos\eta_{13}=1$ $\cos\eta_{04}=-2/3$ $\cos\eta_{24}=-1/3$	$1.4+0.60P_1+0.67P_2$ $-0.20P_3-0.06P_4$	$1.4+0.39P_2-0.78P_4$	$1.4+0.07P_2-0.66P_4$
$M1+E2$	1/2	$\sigma_{M1}=0.5$ $\sigma_0=\sigma_2=\sigma_4=0.3$ $\cos\eta_{02}=2/3$ $\cos\eta_{04}=-2/3$ $\cos\eta_{24}=-1/3$	$1.4+0.68P_2-0.06P_4$	$1.4+0.39P_2-0.84P_4$	$1.4+0.48P_2-0.66P_4$

terms.

The three experimental curves $I(\theta_1)$, $I(\theta_C)$ and $I(\theta_{23})$ could not be consistently explained by each pure interaction $E1$, $M1$ or $E2$ only. Therefore, it was considered that the 17.6 MeV γ-ray is absorbed by mixed levels but not by pure level of ^{12}C. Then the experimental data were approximated, as far as possible, by $E1+M1$, $E1+E2$ and $M1+E2$ interaction mixtures. It was found, however, that $E1+M1$ mixtures are unsatisfactory. Each particular set of parameter values of the $E1+E2$ and $M1+E2$ mixtures are given in Table I. The percentage given in this table should be unreliable, since the assumed values for σ and η may be considerably in error (see Appendix). Fig. 5 illustrates that in $I(\theta_C)$ and $I(\theta_{23})$ the agreement between theory and experiment is good for two mixtures $E1+E2$ and $M1+E2$, but in $I(\theta_1)$ a good agreement is found only for the $E1+E2$ mixture. The strong experimental evidence of asymmetry in $I(\theta_1)$ about $\theta_1=90°$ suggests at least a predominant $E1+E2$ mixture. This result is in agreement with that of Goward and Wilkins$^{8)}$, but our $I(\theta_1)$ distribution shows significant asymmetry contrary to their distribution which shows backward asymmetry in the region 17.0 MeV $\leq E_\gamma \leq$ 17.8 MeV.

Acknowledgments

The authors wish to thank Professor K. Kimura, Professor Y. Fujimoto and members of our laboratory for helpful advices. Their thanks are also due to Mr. J. Iwadare for valuable theoretical discussions, and to Miss N. Shiomi, Miss M. Arisada and Miss K. Ikeda for scanning many plates.

Appendix

The general theoretical expressions for angular distributions and correlation in a three-stage nuclear reaction have been derived by Brinkworth$^{14)}$. This general theory was applied to following special cases.

When the intermediate ^{8}Be state is 2$^+$ in ^{12}C(γ, α_1)^{8}Be(α_2)α_3 reaction, then, for $E1$ γ-ray interaction, we have

$$I(\theta_1)=(\sigma_1+\sigma_3)+[-0.10\sigma_1-0.40\sigma_3+1.47(\sigma_1\sigma_3)^{1/2}\cos\eta_{13}]P_2(\cos\theta_1)\ ,$$

$$\begin{aligned}I(\theta_c)=(\sigma_1+\sigma_3)&+[\sigma_1+1.14\sigma_3-0.71(\sigma_1\sigma_3)^{1/2}\cos\eta_{13}]P_2(\cos\theta_c)\ ,\\&+[0.86\sigma_3-4.22(\sigma_1\sigma_3)^{1/2}\cos\eta_{13}]P_4(\cos\theta_c)\ ,\end{aligned}$$

$$I(\theta_{23})=(\sigma_1+\sigma_3)-[0.50\sigma_1+0.14\sigma_3]P_2(\cos\theta_{23})\ ,$$

where σ_1 and σ_3 are proportional to the intensity of the angular momentum of the $l=1$ and $l=3$ waves respectively, and η_{13} is an arbitrary (unknown) phase angle.

For $M1$ interaction and 2$^+$ ^{8}Be we have

$$I(\theta_1)=\sigma_{M1}+0.50\sigma_{M1}P_2(\cos\theta_1)\ ,$$

$$I(\theta_c)=\sigma_{M1}+0.71\sigma_{M1}P_2(\cos\theta_c)-1.71P_4(\cos\theta_c)\ ,$$

$$I(\theta_{23})=\sigma_{M1}+0.50\sigma_{M1}P_2(\cos\theta_{23})\ .$$

For $E2$ interaction and 2$^+$ ^{8}Be we have

$$\begin{aligned}I(\theta_1)=&(\sigma_0+\sigma_2+\sigma_4)\\&+[0.16\sigma_2+1.90\sigma_4-1.20(\sigma_0\sigma_2)^{1/2}\cos\eta_{02}-0.01(\sigma_0\sigma_4)^{1/2}\cos\eta_{04}-0.54(\sigma_2\sigma_4)^{1/2}\cos\eta_{24}]P_2(\cos\theta_1)\end{aligned}$$

$$
\begin{aligned}
&\quad -[2.14\sigma_2+1.61\sigma_4+9.34(\sigma_0\sigma_4)^{1/2}\cos\eta_{04}-7.98(\sigma_2\sigma_4)^{1/2}\cos\eta_{24}]P_4(\cos\theta_1)\,,\\
I(\theta_c)&=(\sigma_0+\sigma_2+\sigma_4)\\
&\quad +[0.31\sigma_2+1.02\sigma_4-2.43(\sigma_0\sigma_2)^{1/2}\cos\eta_{02}-1.10(\sigma_2\sigma_4)^{1/2}\cos\eta_{24}]P_2(\cos\theta_c)\\

Intensity and Energy Spectrum of Fast Neutrons in Cosmic Radiation

By Saburo MIYAKE, Kensaku HINOTANI and Kan-ichi NUNOGAKI

Institute of Polytechnics, Osaka City University, Osaka

(Received July 9, 1956)

The intensity and the energy spectrum of low energy neutrons at Mt. Norikura (2740 m above sea level and 25°N geomagnetic latitude) were obtained by observing recoil protons with the randomly operated high pressure cloud chamber filled with hydrogen gas at the pressure of 92 atm. The differential energy spectrum for neutrons in the energy range from 1 Mev to 15 Mev was found to be expressed by

$$(1.2\pm40\%)\times10^{-3}\times E^{-1.25\pm0.10}\,\mathrm{cm^{-2}\,sec^{-1}\,sterad^{-1}\,Mev^{-1}}\,.$$

The neutron flux is in conformity with what one would expect from the density of thermal neutrons. Connecting the present data with the others which were obtained by many investigations in different energy ranges, the energy spectrum of neutrons ranging from 1 ev to 10 Bev are discussed.

§ 1. Introduction

The intensity of fast neutrons in cosmic radiation is related to the intensity of the primary radiation and the process of nucleon cascade of the N-component in the atmosphere. It should be noticed that as the low energy neutron component has the largest latitude effect among all others,[1] it is a good indicater for the primary radiations of such energies as to be influenced by the terrestrial magnetic field. On the other hand, one can obtain some information for nucleon cascade in the atmosphere from energy spectrum of greater than 10 Mev.

The absolute intensity of the nucleon component has been derived from the data using a variety of detecting method2). Data of cosmic ray hard showers obtained in multiplate cloud chamber or counter trays, and a positive excess of penetrating particles observed in magnetic could chamber allow an estimation of the intensity of the nucleonic component which has the energy larger than serveral Bev. The data on stars observed in photographic emulsion3) also give an estimation of the nucleon component for the energy larger than about 200 Mev, and the observation by proportional counter gives the proton flux of this energy region4).

The density of the thermal neutrons which have the energy lower than 0.4 ev in the atmosphere has been measured by means of difference method between two geometrically identical BF_3 counters one of which was shielded with cadmium sheet and the other with tin sheet5). Concerning the absolute intensity of the neutrons, however, it is very difficult to show the energy spectrum over the whole energy range because the measurement has been done for the energy range from about 1 ev to 200 Mev, and some of the methods above mentioned are indirect for obtaining the absolute intensity.

In this report, the observation of the neutrons of 1 Mev to 15 Mev at Mt. Norikura (2740 m above sea level and 25°N geomagnetic latitude) will be described and the absolute intensity of the neutron will be discussed making use of other energy ranges which were obtained already by many investigations, considering latitude and altitude effects.

§ 2. Experimental Apparatus and Procedure

A cloud chamber6) filled with high pressure hydrogen gas is suitable for measuring the intensity and the energy distribution of neutrons ranging from 1 to 10 Mev, because it has adequate stopping power and comparatively long sensitive time. The proton tracks observed in our investigation were analysed as recoil protons by neutrons, because other processes, for example, Compton scattering of protons by gamma rays or single prong stars of impurity nuclei are negligible. The experimental conditions of the instrument used are as follows:

1) *Effective volume*

The size of the high pressure cloud chamber which was used is 50 cm in dia, and 20 cm in depth, but the whole volume was not used in our experiment. From the stereoscopic analysis, the positions of the tracks were determined and the distribution map of the positions were obtained. From the map, the volume in which the tracks were distributed uniformly, was determined. The volume was corrected considering the sweeped distance by electric field and the expansion ratio of the chamber. The effective volume was 15.1 ±2.5 liter.

2) *Range-energy relation for proton*

The pressure of inner gas was 92±3 atm, this value was estimated from the range of *mu*-meson of *pi-mu-e* decay and the stopping power of the hydrogen gas. The range energy relation in hydrogen gas was obtained from the range energy relation in air7) and the atomic stopping power ratio8) of hydrogen to air, and is shown in Fig. 1, in which an experimental point of *mu*-meson is also shown.

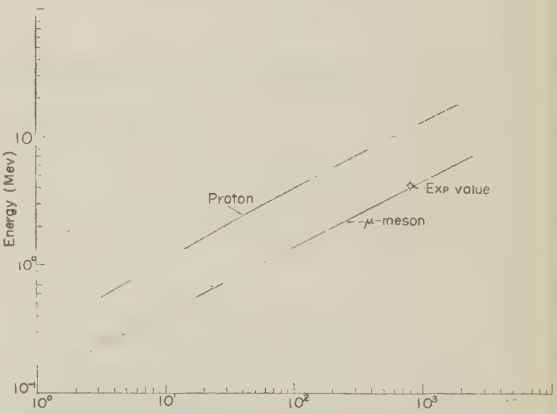

Fig. 1. The range-energy relations for proton and μ-meson in hydrogen gas in NTP. The experimental value of μ-meson range is obtained from the range of 4.1 Mev μ-meson in $\pi-\mu-e$ decay observed in the high pressure cloud chamber.

3) *Sensitive time*

The sensitive time of the chamber depends upon the pressure, the kind of gas contained, the intensity of electric field and the ionization density of the tracks. In the present work, since the recoil proton tracks are heavily ionizing, the sensitive time could be determined easily from the measurement of the track width. If N_0 is the number of ions per unit length produced along a track, the ionization density $I(x)$ at distance x from the track center after the time elapse of time t from the beginning of the diffusion is given by:

$$I(x)=(4\pi Dt)^{-1/2}N_0\exp(-x^2/4Dt) \qquad (1)$$

The 90% width of image, X, is given by:

$$X=4.68(Dt)^{1/2}\,\text{cm} \qquad (2)$$

The width X_0 of the oldest track was estimated from the relation between the integrated number of tracks and their width as shown in Fig. 2. It can be seen from the curve, that the track width is proportional to the square root of t, because the frequency of the recoil protons is assumed to be equal in each time interval. From the track width at the saturation point of the curve, the value of X_0 was determined to be 3.2±0.3 mm, and using $D=1.2\times10^{-3}\,\text{cm}^2\,\text{sec}^{-1}$ (for hydrogen at 92 atm.)[9] the sensitive time was obtained as 3.4±0.6 sec. from Eq. (2).

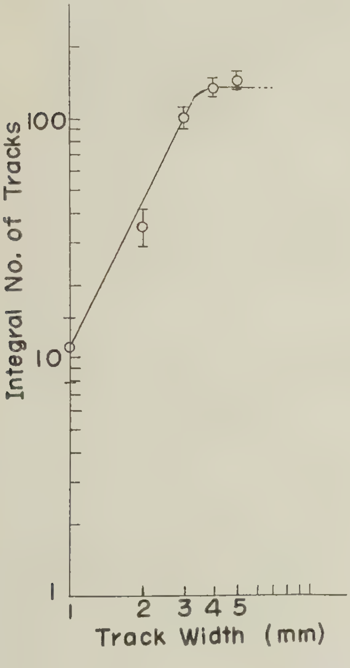

Fig. 2. Integral track width distribution of recoil protons. From the saturated width in this curve, the sensitive time of the chamber was determined.

4) *Effect of surrounding materials*

The observed neutron intensity is affected by the surrounding materials, which consisted of an iron wall of about 8 cm thickness, and water and oil in fore and back section of the chamber, respectively[6]. It was difficult to perform an exact correction owing to the complex geometry of the chamber. So an approximate procedure was taken by assuming the chamber to be a cylinder of average wall thickness, and assuming that the fast neutron in cosmic ray decrease with the absorption path of the geometrical path through the material as in the case of air nuclei[10]. To obtain the intensity of neutron in the air, the correction of 80, 10 and 10% of the total flux for the absorption in the iron wall, water and oil respectively must be applied. Thus, the correction factor of the neutron flux in the chamber to that of outside was estimated to be 1.25. Even if 2.5 times of the geometrical path is assumed for the absorption path, the factor decreases only about 5%.

The effect of the materials on the energy spectrum must also be considered. Little is known concerning this problem and only two facts are known. One is that[11] the difference of rates of production of low energy neutrons in carbon and in the iron by air shower is only 30% per unit weight, while the difference amounts to 130% for carbon and lead, and the other is that there is no process which can be considered to cause a large change of the energy spectrum by iron of such thickness. Thus the observed spectrum can be considered to be nearly equal to that in the atmosphere. (This is acertained by comparing the spectrum with that of nitrogen stars[14].)

§ 3. Experimental Data

1) *Frequency of recoil protons*

252 pairs of the high pressure cloud chamber photographs were scanned and 375 tracks and 532 " point tracks " (this means the tracks shorter than 0.5 cm) of recoil protons which have both ends within the sensitive region of the chamber.

The observed frequency of the tracks must be duely corrected, since the detection efficiency varies according to the track length.

Considering four sections of the cylindrical volume as shown in Fig. 3, the density distribution of the centers of the tracks, whose length is $2l$ and both ends are observed in the measurable volume, $F(r, x, l)$, for each section is easily shown as follows:

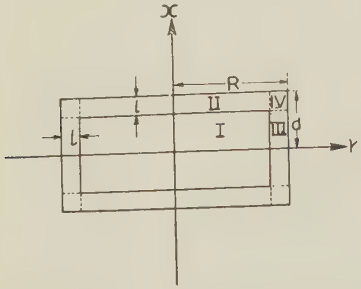

Fig. 3. Cross section of the chamber. The cross section is devided into four sections by track length $2l$. The correction function is determined in each section. x and r axes represents axial and radial directions respectively.

$$F(r, x, l)_1=1 \qquad \text{for section 1}$$

$$F(r, x, l)_2=\frac{d-x}{l} \qquad \text{for section 2}$$

$$F(r, x, l)_3=\frac{R-r}{l} \qquad \text{for section 3}$$

$$F(r, x, l)_4=\frac{(d-x)(R-r)}{l^2} \qquad \text{for section 4}$$

where r and x are radial and axial distances from the center of the chamber, and R and d are radius and half depth of the volume respectively. It was assumed that the angular distribution of the tracks was spherically symmetric, and the diameter of the cylinder was large enough compared to the track length. Error caused by this approximation is about 4% for 10 cm long tracks.

Table I. The observed and corrected No. of the recoil proton tracks.

Energy (Mev.)	Obs. No.	Corrected No.
3.0– 4.0	94	97
4.0– 5.0	86	93
5.0– 6.0	48	54.6
6.0– 7.0	32	39
7.0– 8.0	21	27.7
8.0– 9.0	18	26.7
9.0–10.0	9	14.8
10.0–11.0	11	19.8
11.0–12.0	9	18
12.0–13.0	4	8.8

Use of these functions leads to the correction factor $K(l)$ as follows:

$$\frac{1}{K(l)}=\frac{1}{V}\iint F(r, x, l)\,2\pi r dr\,dx$$

where V is the total volume.

The observed and corrected number of the recoil proton tracks are given in Table I.

2) *Energy distribution of recoil protons*

The differential energy distridution of recoil protons is shown in Fig. 4 and can be expressed by the empirical formula $kE^{-2.0\pm0.1}$. In this figure, it must be noted that the statistical error is small in the energy range lower than 3 Mev but the observed number may not be accurate because of the missing the tracks, as these are very short.

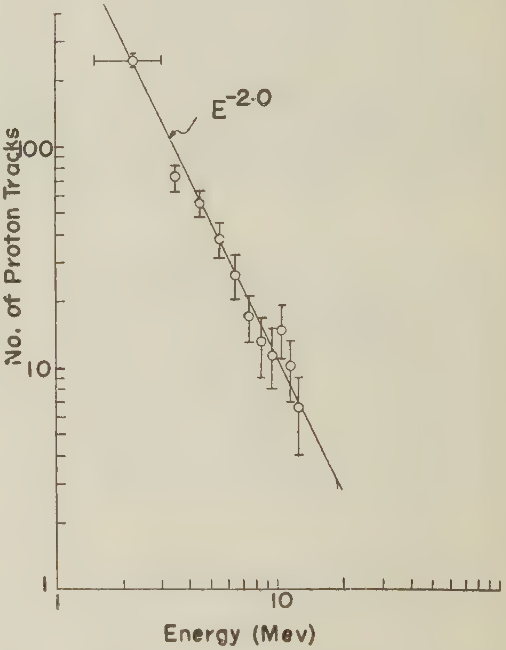

Fig. 4. Differential energy distribution of recoil proton tracks. The solid line is $E^{-2.0}$ obtained by means of the least square.

3) *Angular distribution*

As shown in Fig. 5 the zenith angle distribution of recoil proton tracks seems to be isotropic.

The direction of the motion of a particle can not be determined, unless the recoil protons collide further with hydrogen nuclei in the chamber. The ratio of having the upward and downward directions is estimated to be about 1/4 from the observation of 14

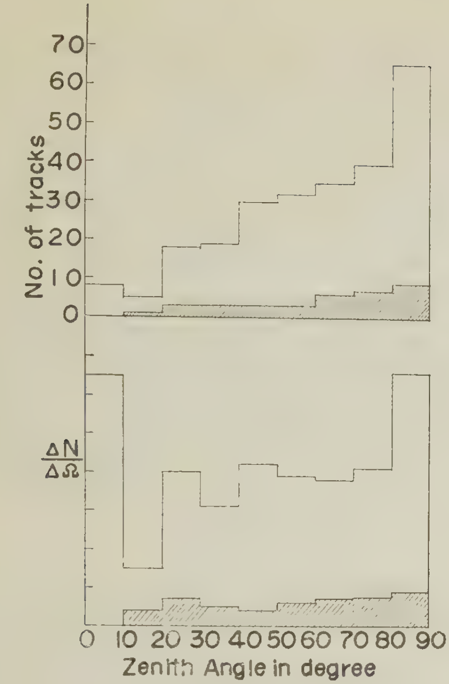

Fig. 5. Zenith angle distribution of the recoil proton tracks. The lower figure shows zenith angle distribution per steradian.

tracks (the tracks of order of 10 Mev).

The angular distribution of primary neutron cannot be determined in detail, but it seems to be isotropic at least in low energy region.

§ 4. Intensity and Spectrum of Neutrons

The intensity and energy distribution of the neutrons were derived from the data of recoil protons as follows.

When the velocity of the neutron is small, the energy, E_p', of the secondary proton in the laboratory system is related to the scattering angle, θ^*, of the neutron in the center of mass system by the equation:

$$E_p' = E_n \frac{1-\cos\theta^*}{2} \qquad (3)$$

On the other hand the differential scattering cross section $\sigma_{np}(E_n)\psi(\theta^*)$, where $\sigma_{np}(E_n)$ is the total cross section and $\psi(\theta^*)d\omega^*$ represents the probability that the neutron is scattered into the solid angle $d\omega^*$ at an angle θ^* to the original direction of its motion, is nerely constant for the neutron energies below about 20 Mev[12]. If this circumstance is combined with Eq. (3), it can be shown that the probability $\sigma(E_n, E_p')dE_p'$ that the energy of the recoil proton lies between E_p' and $E_p'+dE_p'$, is related to the total cross section $\sigma_{np}(E_n)$ by the equation:

$$\sigma(E_n, E_p') = \frac{\sigma_{np}(E_n)}{E_n} \qquad (4)$$

If the cosmic ray neutrons, whose energy spectrum is represented by $N_n(E_n)$, are scattered by protons, the energy spectrum $N_p(E_p')$ of the recoil protons is

$$N_p(E_p') = \int_{E_p'}^{\infty} N_n(E_n)\sigma(E_n, E_p')dE_n\,. \qquad (5)$$

Assuming that the energy spectrum of the cosmic ray neutrons can be expressed in the form of kE_n^{-m}, Eq. (5) is transformed into:

$$N_p(E_p') = k\int_{E_p'}^{\infty} E_n^{-m-1}\sigma_{np}dE_n\,. \qquad (6)$$

The quantum mechanical treatment of neutron proton scattering was given by Wigner[13], who show that the cross section as a function of neutron kinetic energy E_n is given (in the limit of neutron wave length large compared to the range of the neutron proton force) by the expression:

$$\sigma_{np} = \frac{4\pi\hbar^2}{M(1/2E_n + |\mathcal{E}|)}\,, \qquad (7)$$

where $\mathcal{E}$ is the binding energy of the neutron proton system. The above expression was found to agree with the observed cross sections for neutrons of 1 Mev and greater.

In the present work, since $N_p(E_p')$, was the observed as $E_p'^{-2}$ for the energy ranging from 1 Mev to 15 Mev, the energy spectrum of the incident cosmic ray neutrons $N_n(E_n)$ is expressed in the form of

$$E_n^{-1} + \frac{|\mathcal{E}|}{2}E_n^{-2}$$

from Eq. (4) and (5).

To simplify the expression, the cross section σ_{np} is approximated to the form of $E_n^{-1.25}$ which is determined from the experimental data for the energy range 1 Mev to 15 Mev. And therefore, $N_n(E_n)$ is given by the expression $k'E_n^{-1.25}$ which is nearly equal to the above result.

In the practical computation, following value were used

$$N_p(E_p') = kE_p'^{-2}$$
$$= 1.48\times10^{-4}E_p'^{-2}\,\mathrm{cm}^{-3}\,\mathrm{Mev}^{-1}\,\mathrm{sec}^{-1} \qquad (8)$$

$$\sigma_{np} = 10^{-23}E_n^{-0.75}\,\mathrm{cm}^2 \qquad (9)$$

$$\sigma(E_n, E_p') = k'E_n^{-1.75}$$

$$=4.94\times10^{-2}\,E_n^{-1.75}\,\mathrm{cm}^2 \qquad (10)$$

and from Eq. (5) and (8), we obtained;

$$N_n(E_n)=\frac{2k}{k'}\fallingdotseq E^{-1\cdot25}$$

$$=6.0\times10^{-3}\times E^{-1\cdot25}\,\mathrm{cm}^{-2}\,\mathrm{sec}^{-1}\,\mathrm{sterad}^{-1}$$

Assuming that the angular distribution is isotropic, vertical intensity was computed as;

$$9.5\times10^{-4}\times E^{-1\cdot25}\,\mathrm{cm}^{-2}\,\mathrm{sec}^{-1}\,\mathrm{sterad}^{-1}\,\mathrm{Mev}^{-1}.$$

After the correction for the surrounding materials (described in § 2. (4)), the vertical intensity of the neutron at 2740 m above sea level and 25°N is obtained as $1.2\times10^{-3}\times E^{-1\cdot25\pm0\cdot1}\pm40\%$ cm^{-2} sterad^{-1} sec^{-1} Mev^{-1}.

If the energy distribution is expressed in the form of $E/T^2\exp(-E/T)$, as well as in the case of evaporated neutrons from nuclear disintegrations, the mean temperature can be estimated to be about 2.6 Mev at 5 Mev to 10 Mev as shown in Fig. 6. As described in a later section this mean temperature shows that of the original stars of neutrons, and it agrees with the data of nitrogen stars[14] in the same energy region.

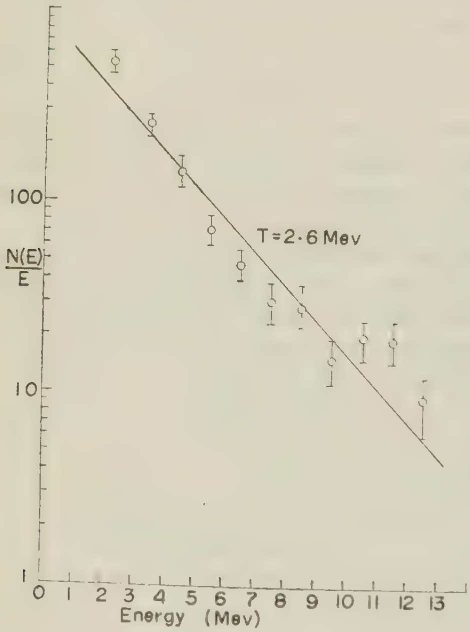

Fig. 6. Energy distribution in the expression of $N(E)\sim E\exp(-E/T)$.
Ordinate: $\log N(E)/E$ in arbitrary scale
Abscissa: E in Mev
The solid line is $T=2.6$ Mev.

§ 5. Discussion

1) *Relation to the data in higher energy region*

There are, unifortunately, no direct observation of the spectrum of neutrons in the energy range from 100 Mev to a few Bev, though the spectrum for the energy region higher than several Bev is considered to be equal to that of protons. So we computed the neutron intensity in the following way. First, the data of the proton spectrum obtained at sea level and at mountain altitude at about 50°N were translated to our altitude (760 g/cm^2) using the absorption path of 140 g/cm^2 to 125 g/cm^2 for 100 Mev to 10 Bev. Secondly the intensity ratio of the neutron to the protons is known to have the form

$$U^2/U^2-(Mc^2)^2$$

where U is the total energy and Mc^2 is a rest energy of nucleon. The form has been derived from emulsion experiments[15] and was used to obtain the neutron intensity. Finally, the latitude effect was considered and 20% decrease was assumed at 1 Bev and about 50% decrease at several hundred Mev was assumed to translate the 50°N values to those at 25°N.

Even though the intensity of a few hundred Mev neutrons by means of the above procedure is not reliable, the spectral curve

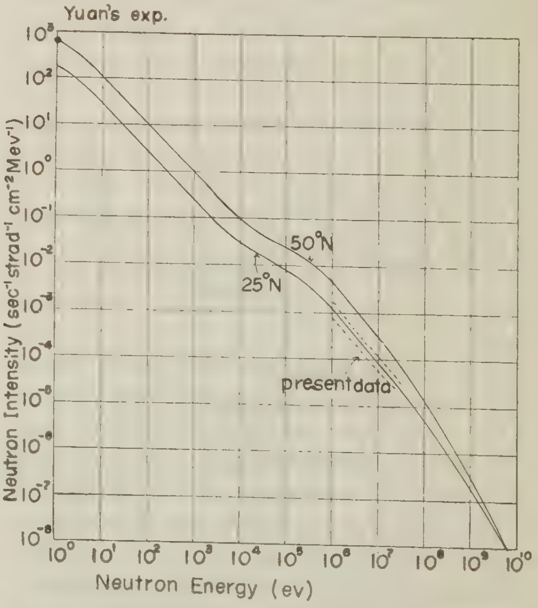

Fig. 7. Differential energy spectrum of neutrons at geomagnetic latitude 50°N and 25°N atmospheric depth 760 g/cm^2, and energy of 1 ev–10^{10} ev.

from 1 Mev to 10 Bev can be obtained by connecting our data to the above values with smooth curve as shown in Fig. 7.

Rossi[16] has calculated the energy spectrum of cosmic ray neutron flux for the energy range from 50 Mev to 1 Bev, and obtained the function

$$N_n(E_n,\ x)=\frac{Ax}{(50+E_n)^2}\exp\left(-x/L\right) \tag{11}$$

It explains the energy dependence of the neutrons of 100 Mev to 1 Bev substantially, but it does not fit to the lower data than about 50 Mev. And the same tendency is shown by the well known expression of the similar type[17];

$$A\exp\left(-x/L\right)(a+b+E)^{-\alpha-1}$$

where a and b are the constants which give the values of proton neutron difference and latitude effect respectively and α is an numerical constant equal to 1.8.

A detailed discussion about the energy spectrum may be difficult because the experimental data on the nuclear interactions in these energy region are very few and the conclusions that one may derive from these data are of a crude and tentative character.

Since the angular distribution varies rapidly in this energy region, total intensity is suitable for discussion rather than the vertical intensity. It is proportional to $E^{-1.6\sim1.8}$ assuming that the angular distribution changes gradually from the isotropic one to the one proportional to $\cos^5\theta$ as the energy changes from several Mev to 1 Bev. For the wide energy range from 1 Mev to 10 Bev the total intensity is approximated as;

$$kE^{-a-b\log E}\ \mathrm{cm}^{-2}\ \mathrm{sec}^{-1}\ \mathrm{Mev}^{-1} \tag{12}$$

where K, a and b are constants 4.8×10^{-3}, 1 and 0.17 respectively.

The energy spectrum at the depth x g/cm², $F(E,\ x)$, is represented by $f(E)\exp(-x/L)$ from the fact that the absorption path is not so sensitive to energy, and $F(E,\ x)$ must be a solution of the equation;

$$\frac{dF(E,\ x)}{dx}=\frac{-1}{\lambda}F(E,\ x)+\frac{1}{\lambda}\int_E^\infty F(E,\ x')g(E',\ E)dE' \tag{13}$$

where λ is a mean free path for inelastic collision, and is thought to be a constant for the energy region. In this equation, proton flux is neglected considering that it does not contribute so much to neutron flux unless the energy is higher than several hundred Mev.

As the generation function $g(E',E)$ is approximately proportional to E^{-1} for given E'[18], Eq. (13) is satisfied by $f(E)=AE^n$. From the initial condition of this equation (there is a data on the secondary protons from high energy stars at 50 g/cm²), $f(E)$ is determined as $AE^{-1\cdot6}$ which is in accord with the present data.

For the detailed expression, Eq. (12), the generating function is of the form $E^{-1}\log E'$ and it explains the tendency of prong number and energy dependence of high energy stars.

Concerning the latitude effect in the energy region of stars, the values of 6–7 obtained by Yagoda et al[19] and by Kaneko et al[20] do not agree with the values 2–3 which were used here and are also shown to be in the low energy region. It is difficult to imagine a mechanism of such large latitude effect, and if we admit such large values we cannot smoothly connect the intensity curves from the present data to high energy data.

2) *Diffusion of neutron in atmosphere*

In the energy region of more than several Mev, in which inelastic collision occurs frequently, the neutron are created from high energy nuclear disintegrations, $(\gamma,\ n)$, $(p,\ n)$, $(n,\ 2n)$, and so on, and some of them are absorbed by the processes of $(n,\ \gamma)$, $(n,\ p)$, $(n,\ \alpha)$ and so on. Fermi's theory of neutron slowing down[21] will be used as the first approximation if we considered the following circumstances. When the energy transfer is small in an inelastic collision $(n,\ n)$, it may be treated as an elastic collision, and when energy transfer is fairly large compared with elastic collision, the process can be considered to be the one which the neutron is absorbed and a slow energy neutron is created.

One dimentional age equation with absorption is written as;

$$\frac{d^2q(x,\ \tau)}{dx^2}-\frac{1}{L'^2}q(x,\ \tau)=\frac{dq(x,\ \tau)}{d\tau} \tag{14}$$

where x is the atmospheric depth, τ the age parameter in Fermi's theory, $L'^2=L_1L_2/3$, (L_2 is absorption mean free path and L_1 a collision mean free path), and finally q is the slowing down density.

Under following initial condition

$$q(x,\ 0)=A(E_0)\exp(-x/L_0) \qquad (15)$$

where $A(E_0)$ is a neutron energy spectrum from the source, and L_0 is the absorption length of the neutron producing radiation. The solution of Eq. (14) is;

$$q(x,\ \tau)=A(E_0)\exp(-x/L_0-(1/L'^2-1/L_0^2)) \qquad (16)$$

where

$$\tau=\frac{7L_1^2}{24\xi}\ln\frac{E_0}{E}$$

and ξ is a energy reduction rate per collision. Then the equation can be written in the following form;

$$q(x,\ E)=A(E_0)\left(\frac{E}{E_0}\right)^n\exp(-x/L_0) \qquad (17)$$

Assuming that $A(E_0)=aE_0^{-m}$ for E_0 ranging from 5 to 10 Mev, we can obtain the expression of neutron flux by integrating Eq. (17) over E_0 larger than E. As the flux is given by;

$$\text{Flux } p(x,\ E)=\text{density } (x,\ E)\times\text{velocity}$$
$$=q(x,\tau)\frac{L_1}{\xi E}, \qquad (18)$$

and since $n+m>1$, we have;

$$p(x,\ E)=\exp(-x/L_0)aE^n\int_E^\infty\frac{dE_0}{E_0^{-n-m+1}}$$
$$=a'E^{-m}\exp(-x/L_0) \qquad (19)$$

where ξ is 0.14 for air nuclei and L_1 is about 18 g.

Thus the observed spectrum is approximately equal to the production spectrum from the source in the energy region which satisfy the assumption and the mean temperature described in the last of Section § 4., may have such meaning.

3) *Relation to the intensity of low energy neutrons*

The absolute absorption rate of slow neutron in air per unit time and mass has been determined in several experiments[5]. From the difference of the density of neutrons whose energies are lower than about 0.4 ev observed by BF_3 counters which are shielded by cadmium and tin respectively, we can estimate the absolute neutron flux, assuming the spectrum given by Placzek[22] which states that the density of low energy neutrons which suffer scattering and absorption by air nuclei is approximately expressed by the following equation;

$$\text{const. } E^{-3/2}\exp\left(-15.5\sqrt{\frac{E_c}{E}}\right) \qquad (20)$$

where E_c is the energy which is $L_1=L_2$ and its value is 6.25×10^{-4} ev in this case.

The intensity at 1 ev shown in Fig. 7 is computed from this spectrum and from Yuan's data, and the points of the curve (25°N) continued to the present data are obtained from Equation (18);

$$A_0\exp(1/L^2\tau)\frac{L_1dE}{\xi E}\exp\left(-15.5\sqrt{\frac{E_c}{E}}\right) \qquad (21)$$

assuming that the source of low energy neutron is given as the intensity at 1 Mev in the present data and that there is no absorption except for the absorption of $1/v$ low in the low energy region.

The curves for 55° and 25°N in Fig. 7 shows good agreement with the latitude effect of 2.9 obtained by Staker[23] for thermal neutrons and of about 3 by Simpson[1] for fast neutrons.

Concerning the source of the thermal neutrons, it may be said that most of them are produced with energies ranging from 1 Mev to 4 Mev because the neutron slowing down density at 1 Mev agrees with that of slow neutrons through it is about one half of the value at 4 Mev. (most of the neutrons from stars have the energy of about 10 Mev, but they will collide with air nuclei about 12 times during the process of slowing down to the energy of 1 Mev and most of them will be absorbed by $(n,\ p)$ and $(n,\ \alpha)$ reactions)

§ 6. Conclusion

The energy spectrum of the neutrons were obtained over the energy range from that of the thermal neutrons to the neutrons of energies of about 10 Bev, and the absolute intensity of the different energy regions was discussed.

It might be considered that the origin of the thermal neutrons is the stars as they are seen in photographic emulsion, but low energy nuclear events as $(\gamma,\ n)$ reaction etc. must also be considered, since the contributions may be comparable to those from the stars.

The spectrum is smooth, and there is no rapid increase for about 10 Mev, that was expected from the data of stars.

The calculation[16] and empirical formula[17] for the intensity of cosmic ray neutrons were checked, and it was found that they were not applicable for wide range of energy, and an expression of the form of $kE^{-a-b\log E}$, was found for the total intensity in the energy range from 1 Mev to 10 Bev.

The integrated value of fast neutrons which originate in the air column of 1 cm² is estimated to be about 5 at 25°N and it was thought to be one half of the value from the data of thermal neutrons.

The authers express their sincere thanks to Prof. Y. Watase for his continual interest and encouragement. This study has been supported in part by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education and from Cosmic Ray Observatory of the University of Tokyo.

Observation of Cosmic-Ray Neutron Intensity at Geomagnetic Latitude 25°N

Part I. Atmospheric Effects

By Masahiro KODAMA*, Kazuaki MURAKAMI* and Yataro SEKIDO

Physical Institute, Nagoya University, Nagoya

(Received August 15, 1956)

The intensity of cosmic-ray neutrons has been continuously observed at sea level and mountain.

The value of absorption mean free path of neutron in the atmosphere, deduced from the barometer effect observed at each station, is 139±5 gr/cm^2, while 136±2 gr/cm^2 was obtained from the intensity difference between two stations at different altitude.

§1. Introduction

Continuous observations of cosmic-ray neutrons were already carried out by Simpson$^{1)}$, Elliot$^{2)}$ and other authors$^{3)}$. The intensity of cosmic-ray neutrons was observed at Nagoya (geomagnetic latitude 25°N, sea level) from September, 1954 to July, 1955 and is being observed at Mt. Norikura (25°N, 2840 m) since August, 1955.

It is plausible that the atmospheric effects on cosmic-ray neutrons are chiefly due to mass absorption. Therefore, in order to confirm this idea, it is important to investigate the atmospheric pressure and temperature effects and altitude dependence.

§2. Instruments

To measure cosmic-ray neutrons, four proportional BF$_3$-counters (filled with normal BF$_3$) were located in a paraffin and lead pile of Simpson's type$^{4)}$, as shown in Fig. 1.

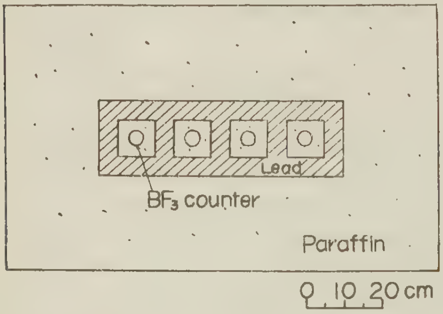

Fig. 1. Structure of lead and paraffin pile.

At the beginning, several kinds of external cathode and internal cathode counters were made, whose walls were made of glass. Using these counters, the following special features$^{5)}$ concerning neutrons were confirmed, namely, gas multiplication for BF_3, the effect of Cd, CH$_2$ and Pb surrounding a counter and the relation between intensities and distances from a neutron source.

The counters used for continuous observation of cosmic-ray neutrons have the size and the characteristics shown in Fig. 2, where the plateau slope is less than 1% per 100 volts.

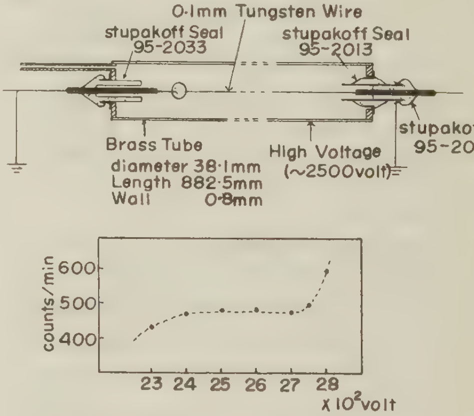

Fig. 2. Construction and characteristics of neutron counter.

The characteristics of our pulse amplifier are as follows. Gain: ~10^5, rise time: 0.2~0.4 μsec, clipping time: 2~3 μsec. The variation of gain is less than 0.3% per 1 volt of line voltage, but this variation has no effect upon the actual observation because of the flatness of the plateau of our counters.

Before starting continuous observation of neutron intensity, it is necessary to measure disturbances from outer noise sources and those due to spurious noise inside. No disturbance was observed in a continuous measurement during about half a year at Nagoya. But about 3 counts per hour of disturbances were recorded at Mt. Norikura, where instantaneous heavy current was being used in some other experiments.

---

* Now at Scientific Research Institute, Tokyo.

Moreover, it is essential to use counters with constant, low background counting rates. The background rate measured at sea level with the counter surrounded by 2 mm thick cadmium is about 2.5%.

§ 3. Atmospheric Effects

(A) Barometric Pressure Effect

In Fig. 3, the variations of cosmic-ray neutron intensity and barometric pressure P during a certain period are shown. To confirm the barometric pressure effect, the data before September, 1954 are added to the data mentioned in § 1. The pressure coefficients for each period are shown in Table I.

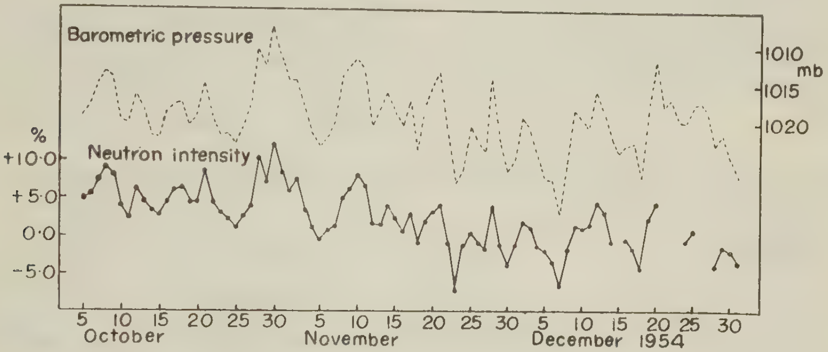

Fig. 3. Daily variations of neutron intensity and barometric pressure.

Table I. Barometric pressure coefficients of cosmic-ray neutron intensity.

Period	Location	Correlation coefficients	Pressure coefficients
June 5—June 7, 1954	Sea level	−0.87	−0.61 (%/mb)
June 8—July 14, 1954	,,	−0.95	−0.65
Aug. 16—Aug. 20, 1954	,,	−0.84	−0.65
Aug. 22—Aug. 24, 1954	,,	−0.99	−0.71
Sep. 3—Sep. 20, 1954	,,	−0.94	−0.66
Sep. 24—Sep. 29, 1954	,,	−0.91	−0.59
Oct. 5—Oct. 31, 1954	,,	−0.97	−0.64
Nov. 1—Nov. 30, 1954	,,	−0.96	−0.73
Dec. 1—Dec. 31, 1954	,,	−0.91	−0.58
Aug. 8—Aug. 31, 1955	Mountain	−0.99	−0.69
Sep. 1—Sep. 30, 1955	,,	−0.97	−0.66
Oct. 1—Oct. 9, 1955	,,	−0.90	−0.56

Since these coefficients were calculated as a simple correlation between the neutron intensity and the barometric pressure, it is possible that these values may contain an error due to other effects than the barometric pressure, for example, the variation of primary cosmic-ray intensity. In such a case, the obtained value $|\beta|$ may be smaller than the true value of the coefficient.

To obtain the true barometer coefficient, an empirical line was determined by the method of least squares between the correlation coefficients r and β obtained for various periods, and the true value was assumed to be the limiting value corresponding to $r \rightarrow 1$. The results are as follows:

$$\beta = -0.72 \pm 0.03\%/\text{mb} ,$$

$$L_p = 139 \pm 5\ \text{gr/cm}^2 ,$$

where L_p is the absorption mean free path estimated from the barometer effect.

(B) Temperature effect

Any atmospheric temperature effect on neutron intensity can hardly be expected theoretically. This was confirmed from our data. The following quantities were used for the indicator of the temperature,

H_{30}: difference of height between 300 mb and 100 mb isobar levels,
H_{13}: difference of height between 1000 mb and 300 mb isobar levels.

The results of the multiple correlation among I_n, P, H_{30} and H_{13} are shown in Table II, where I_n is the neutron intensity not corrected for the barometric pressure P. This result seems to show that there is no significant correlation between neutron intensity and temperature.

Next, the meson intensity I_m was added as an indicator of the variation of primary cosmic-ray intensity. The results of the multiple correlation between I_m, H_{30}, H_{13} and $I_n(P)$ are shown in Table III, where $I_n(P)$ is the neutron intensity corrected for the barometric pressure. The results show that there is no significant correlation between neutron intensities and atmospheric temperatures.

The same conclusion was obtained from the multiple correlation among I_n, P, H_{30}, H_{13} and I_m.

(C) Absorption mean free path

Table II. Partial correlation ceofficients between cosmic-ray neutron intensities and atmospheric temperatures.

Coefficients	Oct. 1954	Nov. 1954	Dec. 1954
$r_{I_n H_{30} P H_{13}}$	$+0.04^{+0.20}_{-0.21}$	$-0.04^{+0.20}_{-0.21}$	$-0.00^{+0.23}_{-0.25}$
$r_{I_n H_{13} P H_{30}}$	$+0.03^{+0.20}_{-0.21}$	$-0.33^{+0.20}_{-0.17}$	$-0.08^{+0.23}_{-0.22}$

Table III. Correlation between neutron and temperature using meson as an indicator of the primary cosmic-ray intensity (Nov.–Dec., 1954)

Coefficients	N	±85°
$r_{I_n H_{30} \cdot I_m H_{13}}$	−0.09	−0.11
$r_{I_n H_{13} \cdot I_m H_{30}}$	−0.08	−0.06

N: Nishina type ion chamber (Tokyo).
±85°: Counter telescope, no absorber, aperture ±85° (Tokyo)

By another method, the absorption mean free path L_{al} can be obtained from the altitude dependence comparing the intensities at Nagoya and Mt. Norikura. The mean values of barometric pressure and neutron intensity $\overline{P}$, $\overline{I_n}$, respectively, and L_{al} are as follows:

	Nagoya	Mt. Norikura
$\overline{I_n}$	1508/hr	10560/hr
$\overline{P}$	1010.4 mb	745.4 mb

$L_{al} = 136 \pm 2$ gr/cm²,

where the counts at both stations are in good agreement with the counts at Climax, considering several factors which may affect the counts, i.e., the latitude dependence of neutron intensity, number of counters, content of B^{10} in BF_3 and altitude dependence.

Because of the good agreement between L_p and L_{al}, we may conclude that the barometer effect on neutron intensity is due exclusively to the mass absorption in the atmosphere.

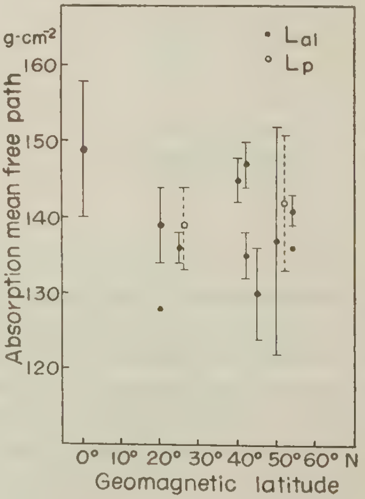

Fig. 4. Latitude dependence of absorption mean free path of cosmic-ray neutron in the atmosphere, where the range of atmospheric depth is 600 ∼ 1000 gr/cm².

Formerly, Simpson[1] concluded that L_{al} has no latitude dependence at the depth more than 700 gr/cm². Similarly we can conclude that there is no latitude dependence of L_p by comparing the values of L_p obtained by him and by us respectively (see Fig. 4).

§ 4. Acknowledgements

We greatly thank to Prof. Hayakawa for his many suggestions about BF_3-counters. And we are grateful to the people of Scientific Research Institute for their co-operation with our observation and for supplying us with meson intensities. In performing the experiment at Mt. Norikura, we are indebted to The Cosmic-Ray Observatory of The University of Tokyo.

Electrical Properties of Nickel Doped Germanium at Low Temperatures*

By Yasuo KANAI and Riro NII
The Electrical Communication Laboratory, Musashinoshi, Tokyo

(Received September 25, 1956)

To study the anomalous phenomena of so-called impurity band conduction in semiconductors, the electrical properties of nickel doped p- and n-type germanium have been measured from room temperature to liquid air temperature. The energy differences between nickel levels and the edges of conduction and valence bands are so large that the anomalous behaviour was found in the temperature range of liquid air. A systematic study was made for the samples with different carrier concentration in nickel levels, and it was concluded that Hung's model was succesful to explain qualitatively the systematic change of the electrical properties of these samples. But to understand the experimental facts quantitatively, it seems to be necessary to develop further theoretical and experimental investigations on this problem.

§ 1. Introduction

a) Survey of the previous investigations on the so-called impurity band conduction.

In 1946, Busch and Labhart¹⁾ discovered anomalous electrical properties on the n-type single crystals of black SiC. They found that the Hall coefficient of their samples did not increase indefinitely as the temperature was lowered, but reached a maximum value at about 200°K and decreased thereafter by orders of magnitude. In the log resistivity versus 1/T curve, they also found a larger slope in the higher temperature range, before the Hall maximum was reached, and a much smaller slope at still lower temperatures. To explain these anomalous behaviours, they assumed that there was a simultaneous conduction in two bands, one was the ordinary conduction band and the other the acceptor band in n-type crystals. Unfortunately, informations about the nature of the impurities in their samples were insufficient to confirm their assumption.

---

* A part of this article has been reported as a short note in the Jour. Phys. Soc. Japan **11** (1956) 83.

In 1950, Hung and Gliessman[2] observed similar anomalies on Sb doped n-type and slow neutron bombarded p-type germanium at the temperature range of liquid helium. To explain their anomalies, Hung[3] also assumed a simultaneous conduction in two bands, and in his case the second band was a donor band in n-type crystals or acceptor band in p-type crystals. Furthermore, assuming that the impurity band was formed at the ground states of the impurity atoms, and the carriers in donor (or acceptor) band were electrons (or holes), he was successful to explain the systematic change of the electrical anomalies at low temperatures in the various specimens, containing different amount of impurities.

Thereafter, Fritzsche and Lark-Horovitz[4] carried out very careful and systematic studies on n- and p-type germanium single crystals doped with Sb, In, or Ga to temperatures as low as 1.5°K. In this case, they observed that the magnetoresistance decreased sharply as the Hall coefficient went through its maximum. In their investigations, the general behaviour of the low temperature anomalies was explainable by Hung's model, although they found a more complicated behaviour of samples with impurity concentrations between about 1×10^{16} and 1×10^{17}/cc.

Anomalies similar to those discovered on SiC and Ge samples have been found recently on p-type indium antimonide[5] at the temperature ranges of liquid helium. In this material, further anomalous behaviour, i.e. negative magnetoresistance (magnetoconductance) effect has been observed in the low temperature ranges[6]. Unfortunately, imformations about the nature of the acceptor center in this material are also insufficient. More recently, similar anomalies were also found on the n-type single crystals of Cd, Cl or Ga doped CdS at about 50°K.[7]

Although the conduction properties of an impurity band have been discussed by several authors[8], a detailed theory has not yet been worked out. In the case of Ge, the anomalous effect has been observed at impurity concentrations below 10^{15}/c.c. As the average distance between impurity atoms is much larger than the estimated orbit radius of the impurity states at such low concentrations, it would be difficult to explain conduction in the impurity states. Atempts have been made to take into account exited impurity states[9] or random distribution of impurity atoms[10]. But a theory which can be applied to the interpretation of experimental results mentioned above with complete satisfaction has not been worked out so far.

b) Objects of this work.

As mentioned above, the mechanism of the so-called impurity band conduction is not clear. Under these circumstances, it seems worth while carrying out some experimental investigations on the low temperature anomalies of semiconductors. There are two main aims of our work; The first one is as follows: The conventional idea about an impurity band conduction tells us that the electrical anomalies are found when the current carriers are trapped to the impurity states as the temperature is lowered. Following this idea, if we use a semiconductor in which the impurity level is so far from the edges of the conduction and valence bands, the anomalies will be found at rather high temperatures. As is well known, Au[11], Fe, Co, Ni and Mn[12] have deep lying acceptor levels in Ge. It may be expected, therefore, that the Ge crystals containing such materials as impurities will exhibit the anomalous electrical properties at higher temperature than the case of previous investigators.

The second aim is as follows: In the previous investigations, there were systematic studies on many samples with different *impurity concentrations* but systematic study on the samples containing different *carrier concentrations* in impurity state has not been worked out so far. As it is seen easily, the conduction properties in an impurity band would depend strongly on the population of carriers in the impurity band, and one would expect that in some cases the carrier in donor state will be holes and that in acceptor state electrons. On the other hand, the reversal of the sign of Hall coefficient has never been observed in any experiments. Hence systematic investigation of samples with different carrier concentrations in impurity state would be worthwhile to understand the conduction properties in impurity band.

§ 2. Experimental Procedures

a) Preparation of the samples.

As mentioned in the previous section, Au, Fe, Co, Ni and Mn have deep lying acceptor levels in Ge. Unfortunately, however, the solubility limit of these elements in Ge is so small[13] that it is not easy to prepare Ge samples containing such an amount of these impurities as to expect the impurity band conduction. Especially, the concentrations of these impurities would be very small in the samples prepared by the usual Czochralski method, because of the annealing process which would occur after the growth of single crystals. Hence, to get the samples in which sufficient amounts of any of these impurities are contained, we must use the method of diffusion of these elements at high temperatures. To obtain a uniform sample by this diffusion method, it is desirable to use an impurity element having large diffusion constant in Ge. Fortunately, the diffusion constant of Ni in Ge is quite large[14], so we decided to use Ni as the impurity element.

The details of the preparation of our samples were as follows: An ingot of As doped n-type Ge (about 50 g weight), whose resistivity was approximately $1\sim0.05\,\Omega$-cm at room temperature, was melted together with a high purity Ni plate (about 50 mg weight), and a single crystal was pulled out from the melt by the Czochralski method. As mentioned above, the crystal prepared by the above procedures contained rather small amounts of Ni, so the major part of the crystal was n-type. After cutting out the end part of the crystal, a thin plate whose thickness was approximately 2 mm was cut with its longitudinal direction parallel to the direction of crystal growth. This thin plate was etched by CP-4 and KCN solutions and then Ni plated by evaporation in vacuum. After heat treatment at 880°C for about several hours in vacuum, this plate was quenched as rapidly as possible. As the result of such treatment, sufficient amounts of Ni diffused into Ge, and converted the major part of the crystal to p-type. As it is seen in Figs. 1 and 2, there were four distinct parts in the crystal. In part I, the concentration of thermal acceptors (N_T), produced in the course of the thermal treatment (whose nature was not clear), was larger than the concentration of donor element As, N_D, so a part of thermal acceptor level was empty, hence this part was p-type and the low temperature resistivity was small. In part II, N_D was larger than N_T but N_D-N_T was smaller than the concentration of Ni, N_N, so a part of the lower Ni level was empty, hence this part was p-type and low tempera-

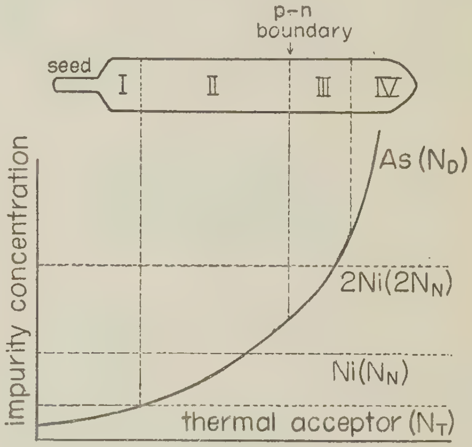

Fig. 1. Schematic representation of the impurity distributions in Ni doped Ge.

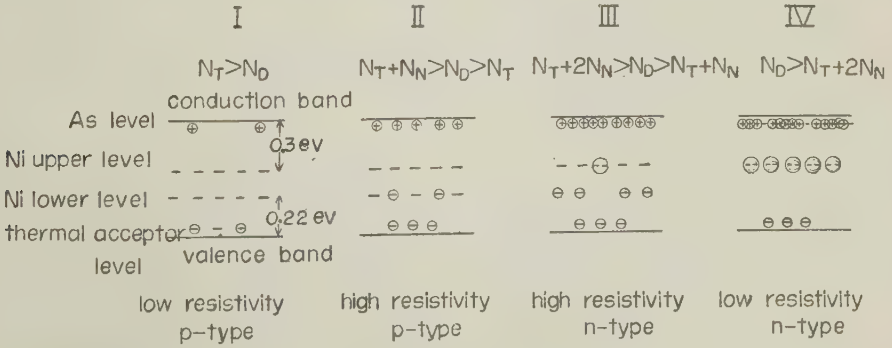

Fig. 2. Schematic representations of energy levels in Ni doped Ge at 0°K.

ture resistivity was high. In part III, N_D-N_T was larger than N_N but smaller than $2N_N$, so a part of the upper Ni level was filled, hence this part was n-type and the low temperature resistivity was high. In part IV, N_D-N_T was larger than $2N_N$, so a part of the donor level was filled, hence this part was n-type and the low temperature resistivity was small.

Then we cut the plate into many rectangular bars in shape approximately $10\times2\times1$ mm³, with its longitudinal axis perpendicular to the direction of crystal growth, and these bars were numbered as shown in Fig. 3. Following the previous considerations, we could expect that the samples cut from parts II and III of the crystal may show the low temperature anomalies, and the concentration of electrons in the Ni levels will gradually increase from the sample 12–1 to 15–2.

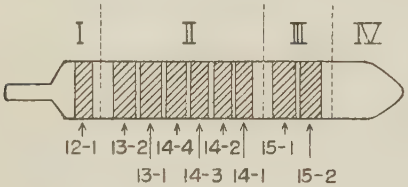

Fig. 3. Numbering of the samples.

b) Measurements

After the surfaces of the samples were ground by No. 180 corundum paper, the both ends of them were electro-plated with Ni, and then current leads were soldered there. The resistivity and Hall probes were made of 0.2 mm diameter Pt wires and pressure contact was made. The measuring equipment consisted of a dc potentiometer, suitable current sources and standard resistances, etc. The temperature was measured by a chromel-alumel thermocouple soldered at one end of the specimen. The magnetic field strength was measured by a flux-meter which was calibrated by the method of radio frequency magnetic resonance of protons. Since the samples were photo sensitive, precaution was taken to keep them in the dark for all measurements.

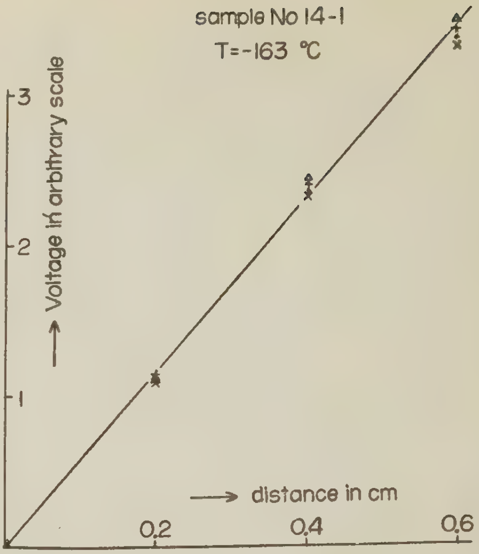

Fig. 4. Voltage drop versus distance in a sample. The sign × · + △ indicate the different cases of measurement.

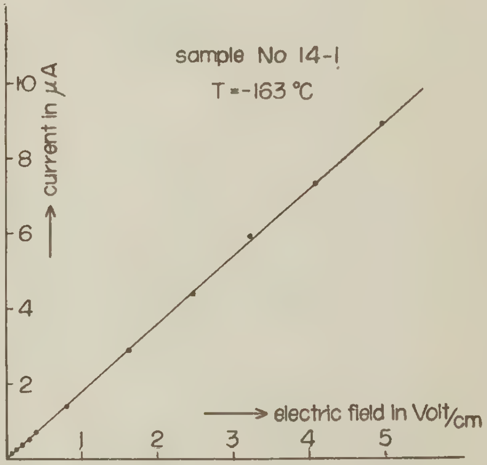

Fig. 5. Current versus voltage characteristics of a sample.

c) Preliminary check of the samples.

Since the inhomogeneity of a sample would make very serious errors in our experiments, we paid our attention as much as possible to this point. Fig. 4 shows an example of the voltage drop along the long axis of a sample at low temperature, and from it one can expect that this sample is homogeneous. In Fig. 5, there is a typical example of current-voltage characteristics of a sample at low temperature, and this shows that there is no breakdown phenomena in this sample.

§ 3. Experimental Results and Discussion

a) Resistivity and Hall effect

The resistivity, ρ, and Hall coefficient, R, versus 1/T curves are shown in Figs. 6 and 7. In Fig. 8, Hall mobility, $\mu=R/\rho$, versus T curves of these samples are shown. These figures show that the anomalous electric behaviours is found at about 170∼120°K in our

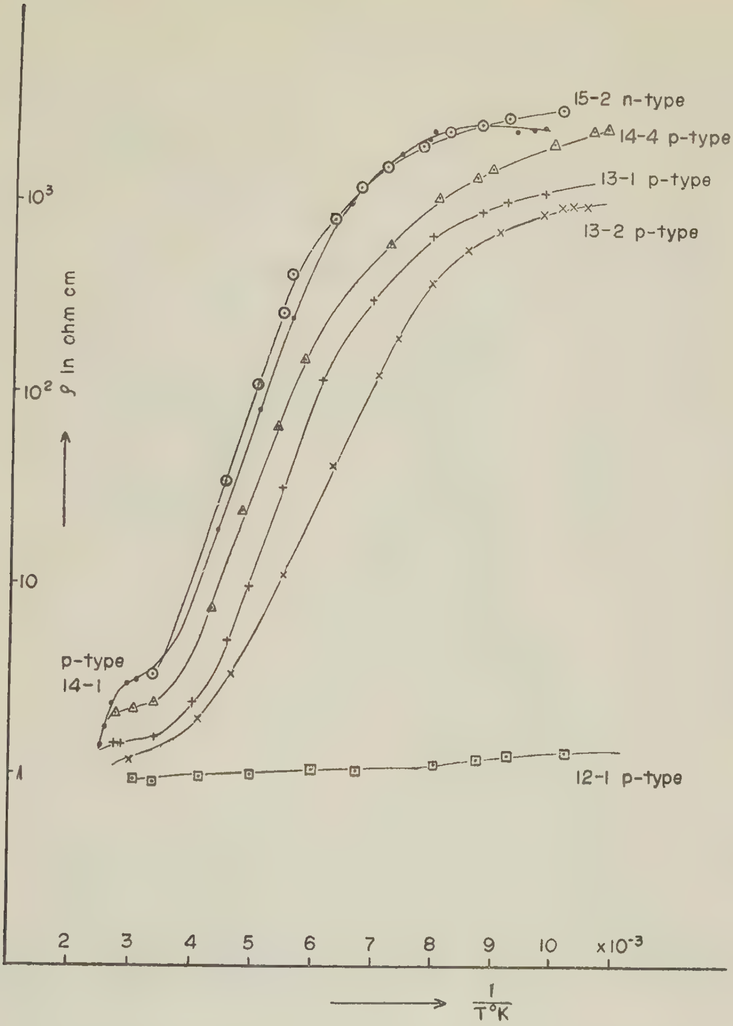

Fig. 6. The resistivity, ρ, versus $1/T$ curves.

samples as we expected above. Furthermore, as the upper Ni level is more apart (about 0.3 ev.) from the conduction band than the lower Ni level (about 0.22 ev.) from the valence band, the anomaly in n-type sample is found at higher temperature than the case of p-type samples. Hence these data suggest that our prediction done in section 1—*b*) is correct, and the first aim of our work was satisfied.

Turning now to our second aim, it can be recognised, at a glance, that there is a systematic change of the slope in the log R versus 1/T curves of p-type samples in the normal behaviour ranges. These behaviours are well understood by considering the different carrier concentrations in the impurity state in these samples, as Dunlap did¹¹⁾ in the analysis of the characteristics of Au doped Ge crystals. Then we shall determine the Ni density from these curves as follows; Consider the Hall curves of a series of p-type samples, ...13–1, 13–2, 12–1..., in which the concentration of electrons (or holes) in lower Ni level is gradually decreasing (or increasing). Then, as one can see in Figs. 6 and 7, the sample 13–2 is high resistivity at low temperature, while 12–1 is low resistivity. Hence we can expect that the density of Ni atoms is nearly equal to the hole density of the sample 13–2 at the exhaustion range (2.7×10^{15}/cc.). This value is consistent with the value obtained by another method¹⁴⁾ (about 2.0×10^{15}/cc.).

We shall next determine the electron (or hole) concentrations in the upper (or lower)

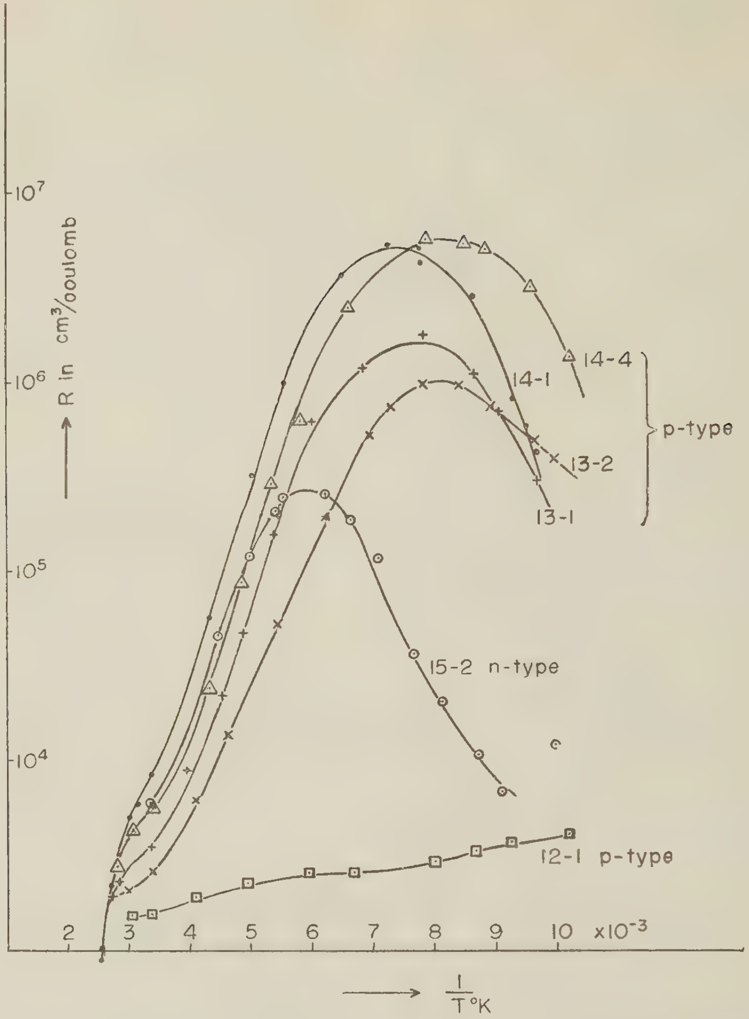

Fig. 7. Hall coefficient, R, versus $1/T$ curves. The applied magnetic field was about 5700 gauss.

Ni level at 0°K, n_0 (or p_0), by the next formula

$$n_0(\text{or } p_0)=3\pi/8ceR_{ex} \tag{3.1}$$

where R_{ex} is the Hall coefficient of the high resistivity sample at the exhaustion range. These values are listed in Table I.

Following Hung's model, ρ and R are given by the next formula;

$$\rho=1/e(n_b\mu_b+n_i\mu_i)$$

$$R=(r_bn_b\mu_b^2+r_in_i\mu_i^2)/e(n_b\mu_b+n_i\mu_i)^2 \tag{3.2}$$

where the suffices b and i refer to the normal and impurity band respectively. In the above expression r is a numerical factor depending upon the statistics and the scattering mechanism of the carriers. Unfortunately, imformation about r_i is quite insufficient, we have assumed $r_b=r_i=3\pi/8$. Furthermore, if we consider the fact that $n_b+n_i=n_0$, then after simple calculations, we can see that the maximum value of R, R_m, occurs at the condition $n_i\mu_i=n_b\mu_b$. Assuming $\mu_i \ll \mu_b$, the following simple relations are obtained at this temperature;

$$\mu_b\simeq 1.7R_m/\rho_m$$

$$\mu_i\simeq 0.85R_{ex}/\rho$$

$$n_i\simeq 7.4\times 10^{18}/R_{ex}$$

$$n_b\simeq 1.85\times 10^{18}/R_m \tag{3.3}$$

where the units of ρ, R, μ and n are ohm-cm, cm³/coulomb, cm²/volt. sec and no./cc. respectively. The numerical values of these quantities for our samples are listed in Table I. The values R_{ex}/ρ of our samples at 100°K,

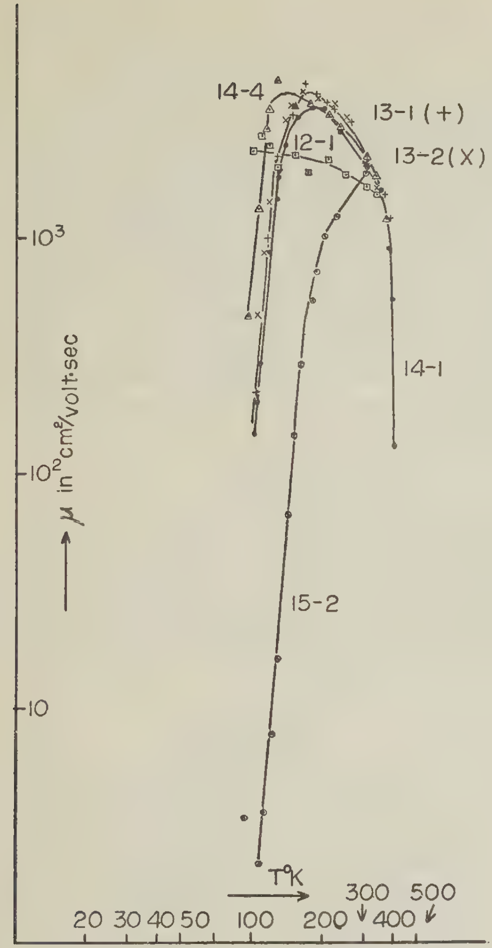

Fig.8. Hall mobility $\mu=R/\rho$ versus T curves.

which are approximately equal to μ_i at 100°K, are also listed there. In this table we can see that the carrier mobility in the impurity band is scarcely affected by the carrier concentrations, and the temperature dependency of it is also small.

Now we notice the shifts of temperature, T_m, at which the Hall maximum occurs, to lower temperature and R_m to lower value as n_0 increases. This tendency can be explained by Hung's model as follows. As we mentioned above, T_m occurs at the condition, $n_i/n_b=\mu_b/\mu_i$, namely, $n_b/n_0 \simeq \mu_i/\mu_b$. Since Table I shows that μ_i/μ_b has a nearly constant value independent of T and n_0, so n_b/n_0 should have a nearly constant value at T_m. On the other hand, as we can see in Fig. 7, the larger n_0, the smaller is the slope of log R versus $1/T$ curve before Hall maximum. Hence we can expect that the larger n_0, the lower temperature is needed to fulfil the condition of $n_b/n_0 \simeq \mu_i/\mu_b$, and in this case n_b is also larger, R_m has a lower value according to the last equation of (3.3).

b) Magnetoresistance

Transverse magnetoresistance $\Delta\rho_t/\rho(0)=\rho(H)_t/\rho(0)-1$ versus $1/T$ curve of sample 14−1 is shown in Fig. 9. As Fritzsche and Lark-Horovitz have pointed out[4)], Hung's model tells us that the next relation must hold in the temperature range of $r_b n_b \mu_b^2 \gg r_i n_i \mu_i^2$;

$$\Delta\rho_t/\rho(0) \simeq BH^2\rho/\rho_b \qquad (3.4)$$

where ρ_b is the value of ρ extrapolated to the low temperature region, and B is a numerical constant. In Fig. 9, this relation is checked for the sample 14-1, and it shows that Hung's model is self-consistent.

In Fig. 10, the angular dependency of magnetoresistance of sample 14-1 at low temperature is shown. One can see that the magnetoresistance is essentially constant for all directions, and this fact indicates that the energy surface in the impurity band is not of spherically symmetric form.

§ 4. Conclusion

As discussed above, our work were carried out as follows: Firstly, as expected from the energy gaps of the Ni levels lying apart from conduction or valence band edges, the low temperature anomalies are found at rather high temperatures. This fact indicates that the carriers in impurity state play an essential role in the anomalous behaviours of semiconductors at low temperatures[15]. Secondly, in spite of the variety of carrier concentrations in impurity state of our samples, we find no great differences in the character of low temperature amomalies. It seems to us that this fact implies that the impurity band is much narrower than KT, so the carriers populate randomly in the energy state of impurity. Hence, contrary to the case of usual wide band, carrier concentration in impurity state may not affect strongly the anomalous electrical properties of the samples. However, even the above consideration does not answer the question why the carriers in donor state behave as electrons and those in acceptor state as holes. We have to conclude, therefore, that the carrier in impurity state plays an essential role in the phenomena of low temperature anomalies in semiconductors, but more detailed imformations than Hung's model about the electronic state of these carriers would be necessary to understand these phenomena completely.

§ 5. Acknowledgement

The authors thank heartily to Dr. Y. Takeda, the chief of the semiconductors research section and to Dr. T. Shindo, the leader of the semiconductor physics group in our laboratory, for the encouragements in the course of this work.

Peripheral Inhomogeneties of the Alloyed Germanium p-n Junction

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received October 12, 1956)

It has been found out that the local photocurrent is not homogeneous on the periphery of an alloyed germanium p-n junction, but there appear peaks at some positions. These peaks appear even for relatively lower reverse bias voltages and some of them disappear when the voltage is increased. When the bias voltage exceeds certain value, there appears another peak at a new position. There is a remarkable difference among these peaks in the voltage dependency of local photocurrent.

Experimental results on these peaks of photocurrent and other related phenomena are given. In the last section, the results are discussed and a physical picture for the understanding of the actual alloyed junctions is suggested.

§ 1. Introduction

In the course of recent development of power diodes and power transisters, it has become an important problem to make alloyed *p–n* junctions as perfect as possible in their characteristics, i.e., to make their electrical characteristics coincide with the theoretically ideal ones. But unfortunately, it turned out to be quite difficult to do it. For instance, the reverse characteristic of an alloyed germanium *p–n* junction does not saturate perfectly as the theory predicts, but it shows ohmic current component, and moreover, it breaks down at much lower voltage than the theoretical breakdown voltage estimated from the bulk resistivity.

Several reasons might be considered to be responsible for these discrepancies, e.g., lattice imperfections, inhomogeneities in the recrystallized regions, etc. Among them, the surface inperfections which occur on and near the periphery of the alloyed In dot may be one of the most important factors. It is the main purpose of this work to observe such peripheral inhomogeneities and discuss their effects on the electrical characteristics of the actual *p–n* junctions.

Recently, Garrett and Brattain[1] observed local photocurrent, and measured its dependence on the position of the small light spot on the germanium surface. In the case of their work, the local photocurrent was measured by scanning the light spot in two dimensions on the surface. We have adopted an improved method for doing this, as follows.

§ 2. Experimental Procedures

To measure the dependence of the local photocurrent i_p on the position of light spot, the light spot was moved along on the peripheral circle of the alloyed In dot as shown in Fig. 1. Practically, the light spot was fixed and the specimen was rotated about the vertical axis through the center of the dot. The position of the light spot was read by the angle of rotation as scaled in Fig. 1 (b).

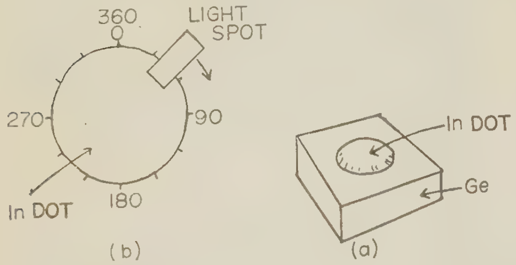

Fig. 1. Movement of light spot. Its position is read by the angle of rotation.

The light spot should have been made as small as possible, but the size of the spot was practically limited by the accuracy in the opitical system and the signal to noise ratio of the detecting circuit. The In electrodes of about 1.5–2 mm in diameter were alloyed on n-type (pulled) germanium single crystals. The diode characteristics of these specimens were not necessarily good, but they served satisfactorily for the purpose of our experiments.

Measuring apparatus is shown schematically in Fig. 2. Light is chopped at 200 cps by a rotating disc, and focused on the periphery. Local photocurrent is read by amplifying a.c. voltage drops across the series resistor.

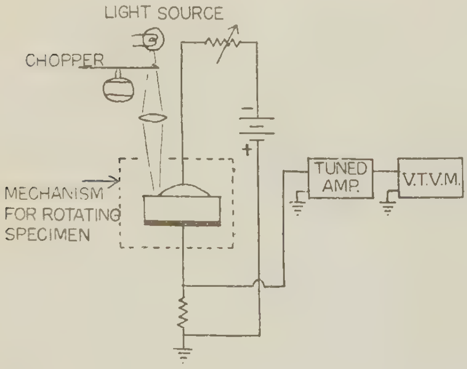

Fig. 2. Schematic representation of experimental apparatus.

§ 3. Experimental Results

A. *Distribution of local photocurrent on the periphery.*

Interesting experimental result which came out first is the fact that the local photocurrent i_p is not constant on the peripheral circle of the In electrode, but it shows some peaks at some positions. Typical result of this effect on the sample No. 0 with etched surface is shown in Fig. 3. It must be noticed that the value of i_p is in arbitary unit and has important meaning only in relative magnitude.

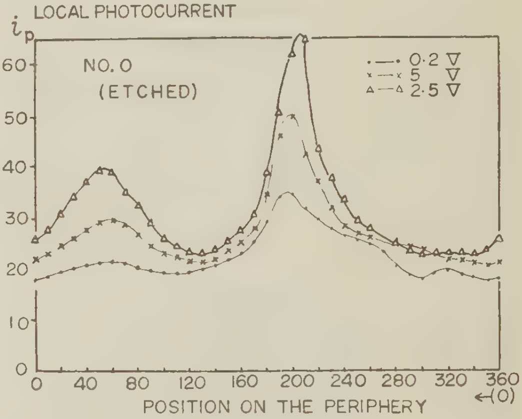

Fig. 3. Peripheral distribution of the local photocurrent i_p.

As is shown in Fig. 3, i_p depends on the bias voltage only at the peaks, and it remains almost constant in the regions between the peaks. Since the measured values of i_p is quite accurate and the curves are also quite reproducible, the experimental results will be shown by curves only, without plotting each points. When the surface is slightly etched and rinsed in de-ionized water, some of these peaks disappear, but some of them remain at the same position.

B. *Making peaks by surface treatments*

It has been found out that the above mentioned peaks of i_p can be made to occur by certain surface treatments. First, a small drop of impure water was put on a position, where there was no peak before the treatment. Typical result is shown in Fig. 4. In this case, a drop of impure water is put on the position "270". The peak appears there (as shown by the broken line), and it remains after the water is dried (dotted line). It must be noticed that in any case, the sharpness of peak is softened by the finite size of the light spot and the wetted area, and the diffusion of holes.

In the experiment of Fig. 4, the reverse characteristic of the junction varies as shown in Fig. 5, where the curves I, II and III correspond to the original, wet, and after dried conditions, respectively.

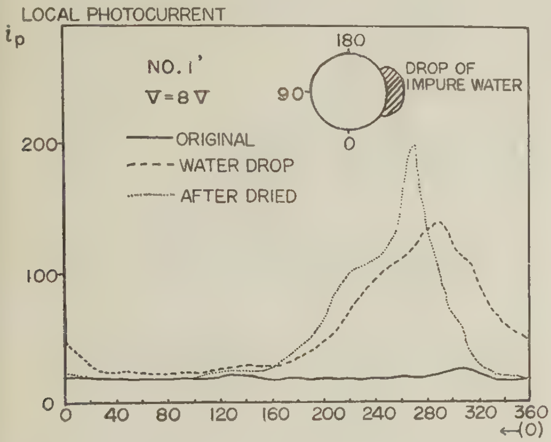

Fig. 4. Appearance of a peak of i_p by a drop of impure water on the periphery.

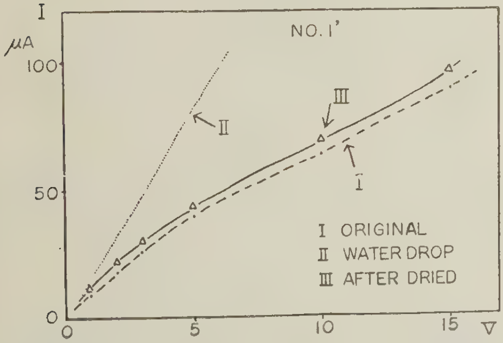

Fig. 5. Diode characteristis corresponding to the conditions of Fig. 4.

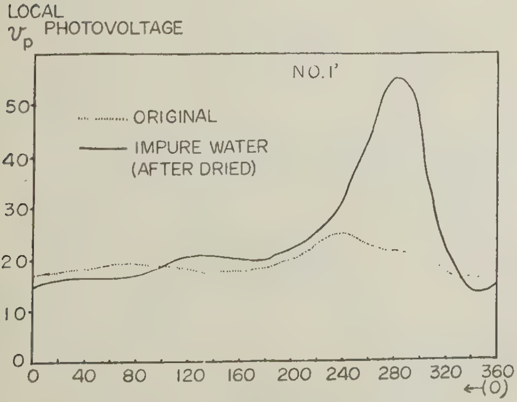

Fig. 6. Peripheral distribution of local photovoltage v_p before and after the water drop treatment of Fig. 4 and Fig. 5.

Fig. 6 is the distribution of local photovoltage v_p before and after the surface treatment mentioned above, where the paek appears at the treated position. In the case of such surface treatments, the peak of v_p appeared at the treated position. But we could not find out definite correlation between the distribution of the photocurrent i_p and the photovoltage v_p *in general*.

Other surface treatments were tried. The same results could be obtained by the copper nitrate solution, but it was impossible to make peaks appear by using de-ionized water. Anyhow, these peaks made by above-mentioned surface treatments could easily be put off by rinsing with pure water.

C. *Variation of i_p distribution with bias voltage*

The distribution of local photocurrent i_p on the periphery has been found to be dependent on the bias voltage. The experimental results are shown in Figs. 7 and 8. In the case of sample No. 1 whose characteristic is as shown in Fig. 7, the distribution of i_p is varied by the bias voltage as shown in Fig. 8. When the voltage reaches 25 volts, two peaks disappear and a sharp peak appears at a new positions. This phenomenon is reproducible and these peaks appear at definite positions.

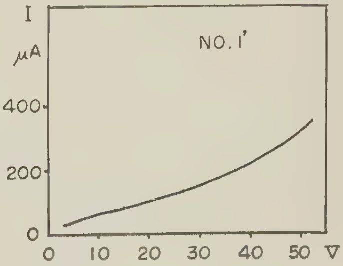

Fig. 7. Reverse characteristic of sample No. 1'.

It must be emphasized here, that the peaks in i_p distribution curve can be clearly classified into two groups. These two types of peaks are different in the voltage dependence of i_p on the bias voltage.

One of them is shown in Fig. 9, where i_p varies almost linearly with the voltage. This

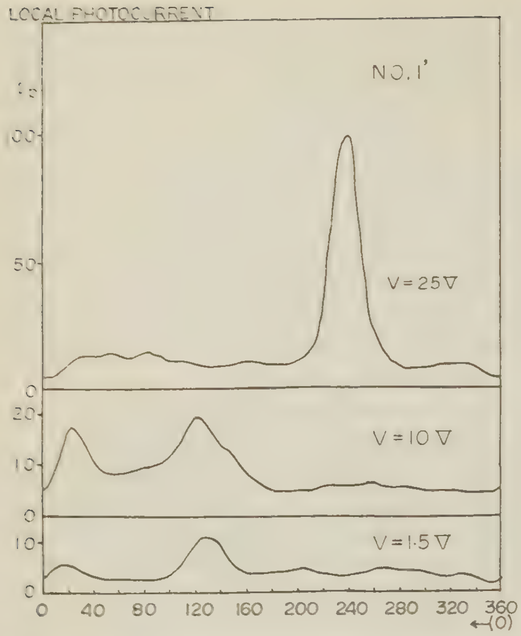

Fig. 8. Variation of i_p distribution with the bias voltage.

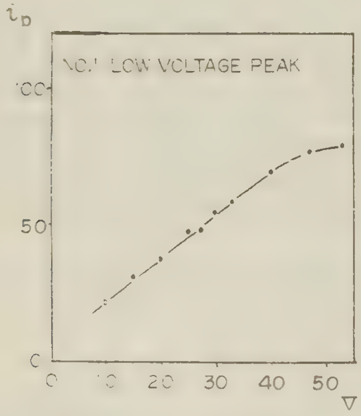

Fig. 9. Dependence of i_p on bias voltage at the "ohmic peak", or "low-voltage peak".

type of peaks are called "ohmic peaks", or "low-voltage peaks", since they appear for relatively low bias voltages. The peaks in Fig. 8 for bias voltages of 1.5 V and 10 V belong to this group. As is shown in Fig. 9, i_p tends to saturate above 45 V.

The other type of peaks are called "avalanche peaks" or "high-voltage peaks", and a typical example is shown in Fig. 10. i_p remains almost constant below 25 V, but it increases at about 30 V quite sharply, the curve being strictly distinguished from the former type. It tends to saturate above 40 V.

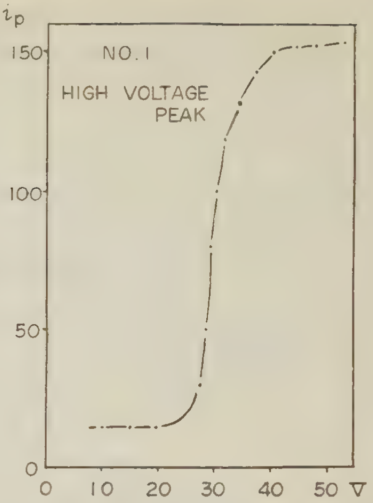

Fig. 10. Dependence of i_p on bias voltage at the "avalanche peak", or "high-voltage peak".

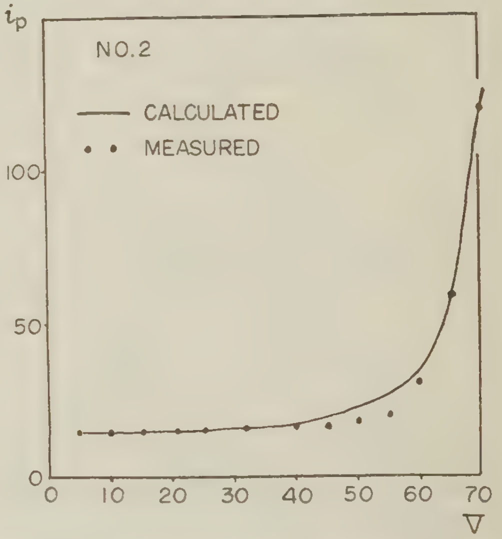

Fig. 11. Lower voltage part of the i_p-V curve of the avalanche type. Solid line represents calculated curve from Eq. (1).

The rapidly rising part of the curve of this type for sample No. 2 is shown in Fig. 11, where the solid line is a theoretical curve based on the avalanche mechanism, i.e.,

$$i_p=\frac{A}{1-(V/V_B)^n}. \tag{1}$$

A is a constant, V_B is a critical voltage, and n can be put to be equal to 3 for n-type germanium[2].

D. *"Creep" phenomenon*

In actual diodes and transistors, it is often observed that the current under the constant reverse voltage varies with time. This phenomenon is called " creep " or " drift ". In our samples, some of them showed considerable creep as shown in Fig. 12 (a). This is the result of creep under the reverse bias of 45 V for about 7 minutes. It has been observed that the i_p distribution varies during the creep is going on. Fig. 12 (b) and (c) correspond to the condition of before and after the creep, respectively. As is shown, the peak appears at different positions for two conditions.

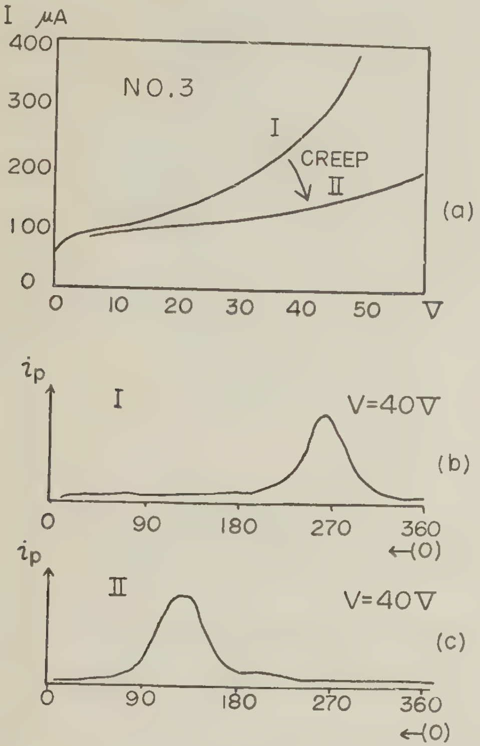

Fig. 12. (a) Creep phenomenon in the reverse characteristic. (b) i_p distribution for the condition I, before the creep. (c) i_p distribution for the condition II, after the creep.

Fig. 13 shows other experimental results of creep phenomenon. In this case, 40 V of reverse bias is applied to the diode, and the diode current I and the local photocurrent i_p are measured for 4 minutes. i_p measured here (at position 105) corresponds to the " ohmic peak " and it increases, while the diode current I decreases with time. After switching off the voltage, local photovoltage is observed at the same position for 40 seconds. The result is shown by the solid line in Fig. 13. The broken line (A) in the same figure represents the photovoltage v_p at the position 220, which corresponds to the " avalanche peak ". In some cases, v_p decreases with time also for the " avalanche peak ".

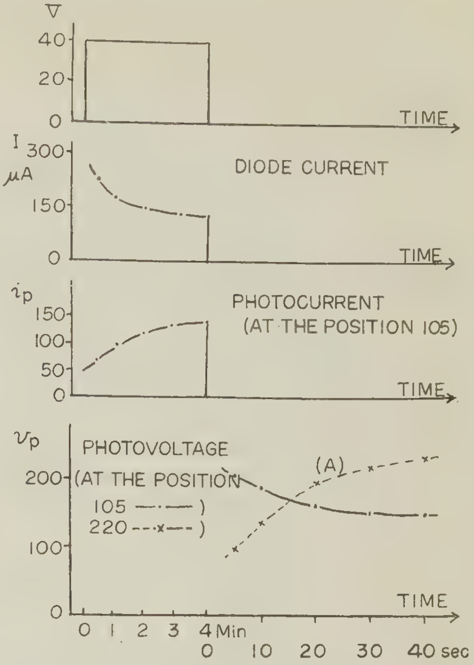

Fig. 13. Creep phenomenon, variation of the diode current I and i_p during the creep, and the recovery of local photovoltage v_p.

E. *Effect of castor oil*

When the surface of the diode is covered with caster oil, the distribution of i_p varies as shown in Fig. 14. One of two peaks in the original disappears in the oil, and the i_p becomes several times larger than the

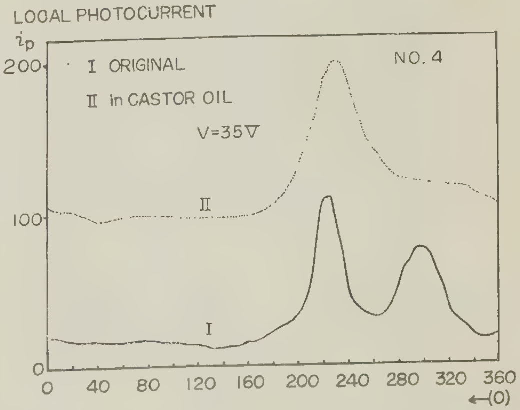

Fig. 14. Distribution of i_p before and after the castor oil is put on the surface.

orignal at every point on the periphery. These results are in agreement with the results of Garrett et al[2].

§ 4. Discussion

It has been confirmed that there exist some inhomogeneities on the periphery of alloyed In dot of germanium *p-n* junction. They are observed as the peaks of local photocurrent, and can be classified into two types, i.e., the "ohmic" peaks and the "avalanche" peaks.

In general, the reverse characteristic of actual diode differs from the theoretical one, and the reverse current seems to contain ohmic current component and rapidly rising current component. Hence, above mentioned experimental results will give some information to solve these discrepancies.

First, we may consider that the dependence of i_p on the bias voltage is the replica of the dependence of the local current flowing through that small spot on the periphery. "Ohmic" peak of i_p, therefore, arises from the ohmic charactor of that spot. These ohmic spots will contribute ohmic current components to the total diode current.

In the same way, the spot of "avalanche" peak of i_p contributes local current whose characteristic is just like shown in Fig. 10. The breakdown voltage V_B of these spots are dependent on the local conditions of the bulk resistivity, surface energy scheme, some kinds of imperfections on the surface and in the bulk, etc..

One of the most important factors affecting these conditions may be the ions on and in the vicinity of the periphery of In dot, which are influenced or controlled by the surface treatments and ambients. As a matter of fact, we have observed "avalanche" peak, whose V_B was varied from less than 10 V to above 75 V by the surface and ambient conditions. Moreover, it may be considered that most of the deterioration of the junction devices occur in the same way as shown in Fig. 4 and 5.

The results of Fig. 8 may be explained on the above mentioned physical picture. As the voltage is increased, one of the "avalanche" spots will break down at first, causing the readjustment of the distribution of the local currents.

In the same way, the "creep" may also be explained taking such inhomogeneities into account. Under certain constant bias voltage, the distribution of ions on the periphery will be varied gradually, which in turn tends to change the distribution of local currents.

In general, our physical picture will be modellized as shown in Fig. 15, where "avalanche" spot A and "ohmic" spots B_1, and B_2 are in parallel with ideal diode spots. The characteristic of these spots are shown in Fig. 16. Hence the total current I may be expresed in the form;

$$I=\sum_j \lambda_{Aj} j_{Aj}(V_{Bj})+\sum_j \lambda_{Bj} j_{Bj}+\sum_j \lambda_{Cj} j_{Cj}, \quad (2)$$

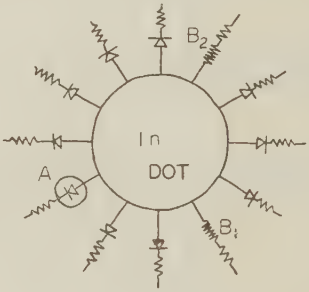

Fig. 15. Physical model of the actual junction.

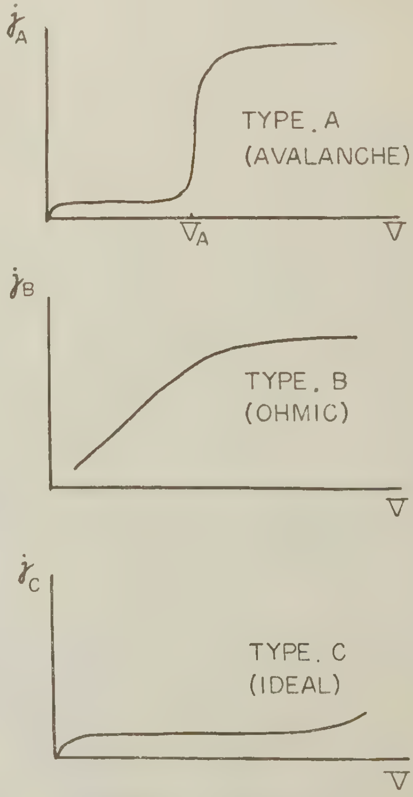

Fig. 16. Characteristic of local current at avalanche, ohmic, and ideal spots, respectively.

where λ_{Aj}'s are fractional area of the spots, V_B is the breakdown voltage of the spots, and j_{Aj}, j_{Bj} and j_{Cj} respresent the current densities of the avalanche, ohmic, and ideal diode components, respectively. Thus the problems of the discrepancies between actual and ideal diode characteristics may be reduced to the relative importance of the coefficients λ's in Eq. (2).

The inhomogeneities which were observed in our experiments on the periphery of the In dot, may also exist in the junction area in the bulk. It was, however, not checked in this work. The discussions on the detailed mechanisms of the influence of surface ions on the characteristics of the alloyed germanium *p–n* junction are also kept untouched in this report.

§ 5. Conclusion

Employing a measuring technique of the local photocurrent, it has been confirmed that there exist two kinds of inhomogeneities on the periphery of the alloyed In dot which cause the diode characteristic to be worse than the ideal one.

§ 6. Acknowledgment

The author wishes to express his thanks to Mr. N. Narukami for the preparation of measuring circuits, and to the members of his group for interesting discussions.

Observation of the Grain Boundary in Soap Bubble Raft.
Part III. The Grain Boundary in Vibrating State

By Einosuke FUKUSHIMA
Department of Physics, Tokyo Metropolitan University, Tokyo
and Akiya OOKAWA*
Department of Physics and Chemistry, Gakushuin University.
Mejiro, Tokyo

(Read October 30, 1955; Received November 5, 1956)

It was reported previously that the bubble raft model under mechanical vibration shows characteristics corresponding to the thermal agitation in the real crystals. With the same device, observations are made on the static as well as the dynamical features of the grain boundary in bubble raft under vibration. In the process of increasing the reduced temperature, the diffused hole (*B*-type) boundary transforms itself to the dislocation (*A*-type or *C*-type) boundary, and vice versa. The transformation temperature varies depending on the angle of misorientation between the grains. In relation to these observations, it is suggested that the marked correspondence between the dislocation theory and the experiment as to the grain boundary energy is but a natural consequence. Preliminary discussions are tried on the molecular mechanism of the transformation between the incoherent and the coherent boundaries, and on the probable causes of the hysteresis effect observed.

§ 1. Introduction

The grain boundary in the metal crystals has a structure depending on the angle of misorientation between the neighbouring two grains and the orientation of the dividing boundary.

The symmetrical tilt boundary of small misorientation angle is constituted of parallel edge dislocations, the seperation L between the constituent dislocations being given by

---

* Research member of the Kobayashi Institute of Physical Research, Kokubunji, Tokyo.

$$L=a/2\sin(\theta/2)\,, \qquad (1)$$

a being the distance between the net planes. The angle of misorientation θ is shown in Table I for some integer values of L/a. As was suggested by Burgers[1] at first, this type of the grain boundary displaces itself in normal direction to the boundary under shearing stress. Between the amount of boundary displacement D and the relative displacement S between the two grains parallel to the boundary, we have the relation

$$S/D=2\tan(\theta/2) \qquad (2)$$

due to Shockley and Read[2]. This relation is verified quantitatively by the experiment of Washburn and Parker[3] on zinc crystal.

With increasing the misorientation angle θ the separation L between the dislocations decreases as shown in Table I, and the increased interference between the dislocations results in the degeneration of the dislocation structure for the grain boundary of the angle of misorientation larger than about 20°. For the larger angle grain boundary, other types of the boundary structure are proposed, such as the diffused hole boundary[4] or the island boundary[5] constituted of regions in good-fit and those in bad-fit.

Table I.

θ	9°34′	11°30′	14°28′	19°14′	29°	60°
L/a	6	5	4	3	2	1

The grain boundary in the soap bubble raft has been studied by Lomer and Nye[6] and the present authors[7]. Summing up the observations of the latter, the grain boundary is classified as shown in Table II. It can be seen that the small angle symmetrical boundary (type A) is constituted of parallel dislocations, but that the larger angle grain boundary (type B) is constituted of diffused holes and that the unsymmetrical boundary of small angle of misorientation (type C) is constituted of regions in good-fit and those in bad-fit. Thus we have, in spite of the apparent defects of the two-dimensional bubble raft model devoid of the thermal agitation, the much expectation of good correspondence between the boundaries in real crystal and those in the soap bubble raft.

The bubble raft model, hithertofore used, is to correspond to a state of the real crystal at very low temperature, as the model lacks the mode corresponding to the thermal vibration in real crystals. On our recent observations on the bubble raft in a vibrating state[8], however, we could detect that the bubble raft under vibration proximates to the real crystal with thermal vibration. It was reported that the bubble raft under vibration expands itself and each type of the lattice imperfections, such as the vacant site, the interstitial bubble and the dislocation, takes more diffused structure than in static state. Here, it is reported on the characteristics of the grain boundary in the bubble raft in vibrating state.

§ 2. Experimental Method

The iron base plate of 1.5 *mm* thickness is excited by an electromagnet by *a. c.* of 90 *cps*. The raft is set in vibration through the sustaining soap solution. The diameter of the bubble used is about 1 *mm*, the behaviour of raft of such a bubble size being said to correspond to the real crystal copper. We could set, by means of the thermal expanions of the raft, an experimental formula[8]

$$T=1356\exp[-3.96(1-W/W_m)] \qquad (3)$$

between the reduced temperature T°K of the raft under vibration at an input power W, W_m being the critical input power where the raft melts. Accordingly, the bubble raft excited by an input power W is to correspond to the real crystal copper at the reduced temperature T by formula (3).

To obtain the neighbouring grains at desired relative angle of misorientation, two frames were used, each holding each raft grains. It is feared with the device if these frames, through constraints on the grain, might have unfavourable effects on the observed boundary structure and on the effect due to vibration. Repeating the observations, the one with frames and the other without the frames, however, we could check the effect of the frames negligible. In the respect, the usage of the frames is but for experimental convenience.

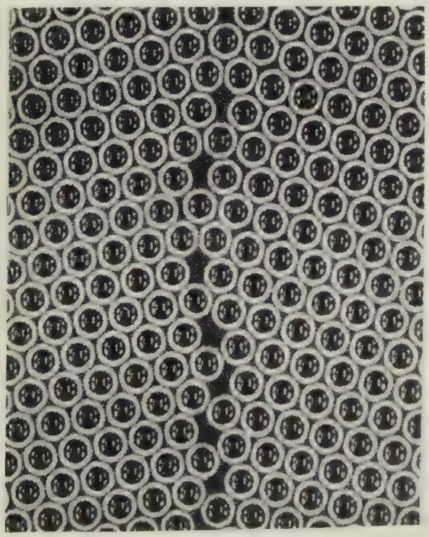
The sustaining liquid is kept at constant real temperature as possible. The critical input power W_m is read before and after each set of observations and the mean value of these is used in Eq. (3) to derive the reduced temperature for each input power W in each set of observations.

§ 3. Results Obtained

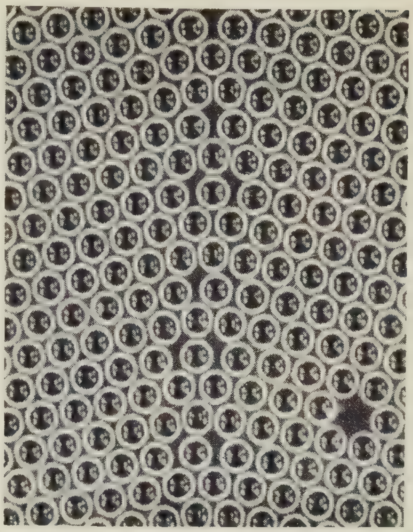
(1) *Transformation of boundary structure at elevated temperature*

The grain boundary shows the characteristic structure depending on the angle of misorientation θ and the reduced temperature T. For each angle of misorientation, comparative description is made between the structure at low temperature without vibration and the structure at elevated temperature of about 800°C under vibration.

For the angle of misorientation θ smaller than 15°, the boundary is of A-type, constituted of parallel dislocations $(01\bar{1})' \perp (01\bar{1})$*, both at low temperature and at high temperature. The grain boundary of misorientation angle between 15°∼20° is constituted of dislocations and diffused holes at low temperature, but, increasing the temperature, the diffused holes transform themselves soon to the dislocations and we have the boundary of type A, constituted of parallel dislocations only. In the case of the boundary with θ exceeding 20°, the *B*-type boundary at low temperature transforms itself to the *A*-type boundary at high temperature. Fig. 1 (a) and (b) show respectively the boundary at low temperature and that at high temperature for $\theta=25°$. The separation between the constituent dislocations in (b) is two to three bubbles, in accord with Table I. Fig. 2 shows the *A*-type boundary for $\theta=32°$ constituted of dislocations of two bubbles separation at $T=800°C$.



(a)



(b)

Fig. 1. Grain boundary with misorientation angle $\theta=25°$ (a) at low temperature without vibration, showing *B*-type and (b) at about 800°C under vibration, showing *A*-type ($d=1.0$ mm). d is the diameter of the bubble.

For θ exceeding 32°, the dislocation boundary at elevated temperature includes not only the parallel dislocations $(01\bar{1})' \perp (0\bar{1}\bar{1})$ but also the non-parallel dislocations $(01\bar{1})' \perp (1\bar{1}0)$ and

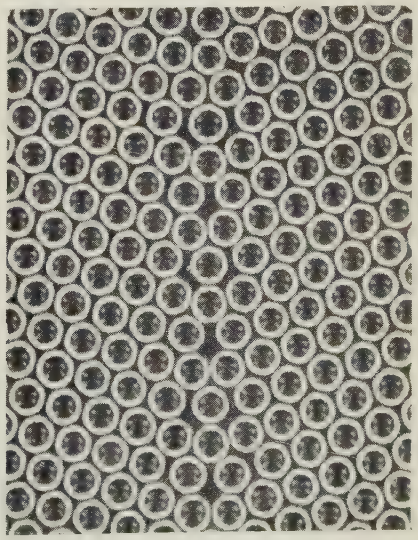


Fig. 2. Parallel dislocation boundary with $\theta=32°$ at about 800°C.

---

* About the notation, refer to the reference cited 7).

$(1\bar{1}0)' \perp (01\bar{1})$, and for θ exceeding 38°, the dislocation boundary has no $(10\bar{1})' \perp (01\bar{1})$ dislocations, thus forming the *C*-type boundary. Fig. 3 shows the dislocation boundory for $\theta = 37°30'$ at $T = 800°C$, the constituent dislocations marked at one side.

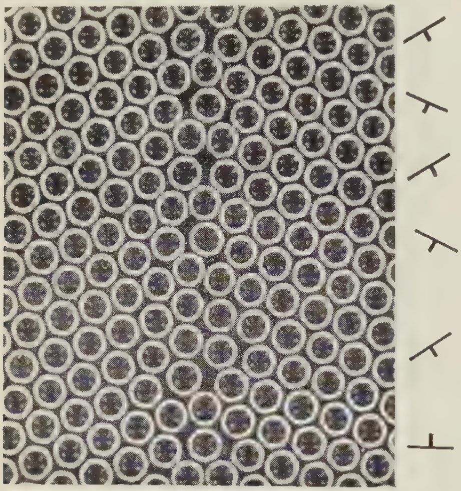

Fig. 3. Non parallel dislocation boundary with $\theta = 37°30'$ at about 800°C. Marks at the right side show the sort of dislocations.

For θ exceeding 45°, the boundary is of type *C* at low temperature as well as at high temperature. It is note-worthy, however, that, when kept for a long time at elevated temperature, in place of the alternating sort of constituent dislocations in linear alignment characteristic to the *C*-type boundary at low temperature, the constituent dislocations of the same sort each tend to coagulate to form a local symmetrical tilt boundaries, thus resulting to a zig-zag boundary in total.

(2) *Dynamical feature*

Under applied shearing stress to displace one grain relative to the other along the boundary, each type of the grain boundary responses specifically, as shown in Table II. Now, the transformation of the boundary structure from the *B*-type to the *A*-type or the *C*-type in the heating process and the inverse transformation

15°~45°	B	diffused hole	viscous flow along boundary
45°~60°	C	non-parallel dislocations	slip along boundary, with dislocation reaction

Fig. 4 shows the boundary for $\theta=32°$ at low temperature. (a) is the initial state and (b) is the state after upwards motion of the right grain relative to the left one by five bubbles. The white bars are the standards to indicate the relative displacement between the grains. It is apparent that the grain boundary stays stationary and the two grains flow viscously along the boundary, typically to the *B*-type boundary. Fig. 5 shows, in contrast, the same boundary at elevated temperature (*ca.* 750°C). Starting from the initial state (a), the right grain in the state (b) is displaced upwards relative to the left one by 1.8 bubbles. In this case, the grain boundary moves in normal direction to the boundary orientation rightwards by 3.2 bubbles, typically to the *A*-type boundary. That each of the constituent dislocations move conservatively along the respective slip lines can be seen with reference to the slip lines marked $\bar{2}$, $\bar{1}$, 0, 1 and 2 in the figure. Quantitatively, we have $S/D=0.56$ for $S=1.8$ bubbles and $D=3.2$ bubbles and $2\tan(\theta/2)=0.572$, thus in comformity with Eq. (2). The boundary for θ not exceeding 38° behaves substantially as the *A*-type boundary.

The boundary for θ exceeding 38° behaves typically to the *C*-type boundary, where the grains flow relatively along the boundary, while the constituent dislocations change their sorts repeatedly, thus reflecting the underlying reactions between the constituent and the transient dislocations. The boundary for θ between 32° and 38° shows combined characteristics for the *A*-type and the *C*-type boundaries, where the relation (2) is no more satisfied quantitatively.

(3) *Relation between the transformation temperature and the angle of misorientation*

The boundary for $\theta=0°\sim15°$ is of *A*-type and that for $\theta=45°\sim60°$ is of *C*-type already without the vibration, that is, at low temperature. The transformation between the types of the boundary is characteristic for the boundary of $\theta=15°\sim45°$. The reduced temperature of transformation, however, depends on the angle of misorientations between the neighbouring grains.

The *B*-type boundary of θ near 20° and that of θ near 45° transform to the *A*-type boundary and the *C*-type boundary, respectively, at moderate temperature. But the *B*-type boundary of θ near 30° does not transform to the

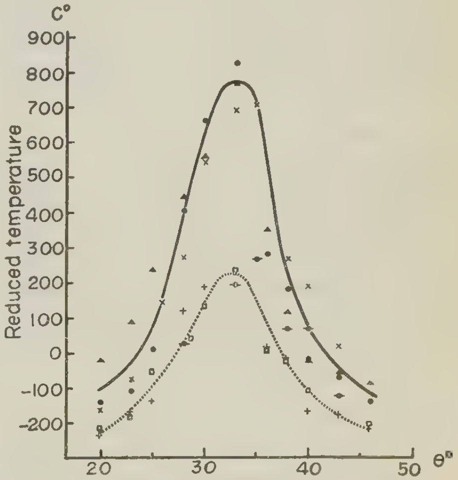

Fig. 6. The transformation temperature of the boundary for each angle of misorientation, full line showing the process from *B*-type to *A* or *C*-type and dotted line that from *A* or *C*-type to *B*-type. × ◆ 1st, ● + 2nd and ▲ □ 3rd observation.

A-type boundary before an elevated temperature is reached. The transformation temperature of the boundary for each angle of misorientation is shown in Fig. 6, where the full line marks the point where the diffused hole (B-type) boundary transforms to the dislocation (A-type or C-type) boundary in the process of increasing the input power or the reduced temperature. The curve has a maximum of about 750°C for $\theta=32°$. Thus we have, at temperatures exceeding *ca.* 800°C, the tilt grain boundary constituted of the dislocations, irrespective of the angle of misorientation and the orientation of the boundary itself.

That the range of θ between 15° and 20°, and the range between 40° and 45° are excluded from Fig. 6 is merely because of the undetermined ambiguity in the initial stage. In realizing the diffused hole boundary or the dislocation boundary to start, an effect similar to a kind of local heating is unavoidable in process of forming the initial boundary by hand-manipulation with fine needle.

In the process of decreasing the input power or the reduced temperature, the dislocation boundary transforms to the B-type boundary at temperatures lower than the transformation temperatures marked in the heating process. The dotted line in Fig. 6 marks the transformation temperatures in the cooling process. The amount of this hysteresis effect is most prominent for θ near 32°. At lower temperature attained after a cycle of heating and cooling, the boundaries for $\theta=15°\sim20°$ and those for $\theta=40°\sim45°$ are of A-type and of C-type, respectively.

Speaking in general, in spite of the relatively large scattering of the experimental points in Fig. 6, the transformation temperature between the diffused hole boundary and the dislocation boundary varies descriminatively with the angle of misorientation between the neighbouring grains.

(4) *Discussions*

(*a*) *On the transformation between the hole boundary and the dislocation boundary*

The transformation between the diffused hole boundary and the dislocation boundary in the processes of increasing and decreasing the input power of exciting the vibration may be likened to a sort of phase transformation in the heating and cooling processes in common sense. On the abnormal hysteresis nature of the transformation, it will be discussed later.

It was shown in a previous article[8] that the mechanical vibration given to the bubble model has some resemblances to the thermal agitation of the real crystal, and that the expansion of the raft and the increasing diffuseness of local imperfection characteristic to each type of the lattice imperfections are qualitatively in accord with the presumption of the characteristic frequency modified by the raft expansion and the degree of local imperfection, respectively. In thermodynamical language, the bubble raft in the vibrating state is realized in the state of minimum free energy.

The boundary in a raft without vibration has its stable form as shown in Table II for each range of the angle of misorientation, which corresponds respectively to the state of minimum potential energy. But in a raft under vibration, as is apparent from Fig. 6, the stable range of the misorientation angle for each specy of the boundary types is different from that in a static raft, thus reflecting the predominance of the state of minimum free energy.

If we approximate a bubble along the boundary with a linear harmonic oscillator of characteristic frequency ν at potential energy ε, the free energy per bubble at a temperature T°K is given, with the high temperature approximation $h\nu \ll kT$, by

$$f=\varepsilon-kT\log(kT/h\nu)\,, \tag{4}$$

k and h being the Boltzmann's and the Planck's constants, respectively. Specifying the quantities for the incoherent (B-type) boundary by the suffix i and those for the coherent (A-type or C-type) boundary by the suffix c, we have

$$\left.\begin{array}{l} f_i(T)=\varepsilon_i-kT\log(kT/h\nu_i) \\ f_c(T)=\varepsilon_c-kT\log(kT/h\nu_c) \end{array}\right\}. \tag{5}$$

To these approximations, the transformation temperature T_t between the incoherent and the coherent boundaries is determined by the thermodynamical condition

$$f_i(T_t)=f_c(T_t)\,, \tag{6}$$

from which it follows

$$T_t=\frac{\varepsilon_c-\varepsilon_i}{k}\Big/\log\frac{\nu_i}{\nu_c}\,. \tag{7}$$

As to the potential energies ε_i and ε_c, it is natural with reference to Table II to expect $\varepsilon_i < \varepsilon_c$ for the range $15° < \theta < 45°$ of the angle of misorientation. As to the characteristic frequencies ν_i and ν_c, however, our insight is too poor to estimate the ratio between them. To the effect of having the coherent boundary stable at higher temperature, it is required to presume $\nu_i > \nu_c$.

It goes without saying that the above treatment is too elementary to represent the real boundary system. While the relative sharpness of the incoherent boundary provides the convenience of marking the bubbles on surface of the boundary, the intrinsic breadth of the coherent boundary constituted of dislocations prohibits such conveniences, and we can not dispense with calculations of the characteristic frequency spectrum of such an imperfect crystals. In the present stage in short of such a knowledge on the frequency spectrum, however, we are far from understanding the molecular mechanism of transformation between the boundary types.

That the transformation temperature depends on the angle of misorientation as shown in Fig. 6 is due to variance with the angle of both the potential energies ε_i, ε_c and the characteristic frequencies ν_i, ν_c, but the relative predominance between them is hardly to predict in the present stage.

(b) *On the observation of the grain boundary energy*

The grain boundary in general has an excess boundary energy over the perfect crystal, due to misfit of atoms along the boundary. As the interfacial excess free energy is equivalent to a kind of surface tension, we have the convenience of measuring the relative value of the excess boundary energies of each set of three interfaces by the procedure of observing the angles between them in equilibrium⁹⁾. Thus we can determine experimentaly the excess boundary energy γ per unit area varying with the angle of misorientation θ. For a given angle of misorientation, the boundary energy varies in general but negligibly with the orientation of the boundary itself, except for such special θ's as corresponding to the case of two grains in twin relation to each other.

On the other hand, on the supposition of the dislocation boundary, the boundary energy γ per unit area of a symmetrical tilt boundary is to vary²⁾,¹⁰⁾ for small angle of misorientation θ, according to

$$\gamma = \gamma_0 \theta (A - \log \theta) , \qquad (8)$$

where the term $\gamma_0 A \theta$ corresponds to the misfit energy in the cores of the constituent dislocations, and the term $-\gamma_0 \theta$ long θ to the strain energy in short range.

The theoretical formula (8) is shown in Fig. 7 with the experimental points on lead⁹⁾,

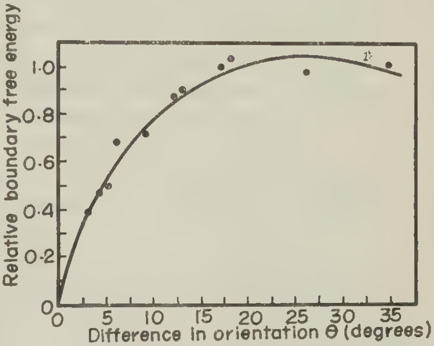

Fig. 7. The relation between boundary free energy and misorientation angle; 1. theoretical curve; ● experimental value of Aust and Chalmers on lead.

where it is to be noted that the formula is in good accord with the experimental data throughout the whole range of the angle of misorientation.

Now, the seperation L between the dislocations constituting the dislocation boundary decreases with the angle of misorientation as shown in Table I, and the increasing interference between the constituent dislocations unstabilizes the dislocation structure, to have in effect the hole boundary stable for the range $15° < \theta < 45°$ (see Table II). Accordingly, from the viewpoint of the previous classification of the boundary type (Table II). stable for each range of the angle of misorientation, the good correspondense between the dislocation theory and the experiment throughout the whole range of the angle as shown in Fig. 7 seems rather fortuitous.

The present observation with the grain boundary in the bubble raft under vibration, however, reveals that, at the higher temperature, the dislocation boundary is the more favoured to the hole boundary (see Fig. 6). The circumstances suggest that the experimental condition in the process of determining the grain boundary energies was in favour to the dislocation boundary than to the hole boundary.

Recalling on the experimental procedure, we notice the annealing processes of specimen with grain boundaries at elevated temperature, that is to the purpose of setting the relative orientation between the grain boundaries in equilibrium under the relevant surface tensions. It is then of high probability that the grain boundary energy estimated from the measured angles in equilibrium at such a high temperature corresponds rather to the dislocation boundaries stable at the high temperature. Thus the good correspondence between the dislocation theory and the experiment as shown in Fig. 7 is but natural consequence of the grain boundary constituted of dislocations, stabilized thermodynamically at the higher temperature.

(*c*) *On the hysteresis of the transformation*

The hysteresis effect as to the transformation temperature in the heating and the cooling processes is hardly avoidable in the present stage of our experimentation. It is of much interest to know if such a hysteresis effect might be characteristic for the real metal crystals too.

In the respect, however, we must be modest to stress on the correspondence between the present model and the real crystals. We can indeed enumerate some factors as to the undesired defects of our present model, such as the viscous resistance between neighbouring bubbles in the process of relative rearrangement, the minute inhomogeneity in the bubble size issueing to the impurity effect, and the monochromaticity of the exciting vibration replacing the thermal vibration in real crystal. Among these possibilities, it can not yet be decided on the predominant origin of the hysteresis effect and accordingly on the correspondence between the raft model and the real crystal as to this effect.

The authors are indebted to Mr. T. Zempô for the earnest experimental assistance throughout the present work. This work was supported by the Scientific Research Fund granted by the Ministry of Education.

An X-Ray Tube with a Rotating Anode and an Earthed Cathode

Shozo SAWADA, Ine TAKOO and Shin'ichi FUJII

Institute of Science and Technology, University of Tokyo

(Received July 23, 1956)

An x-ray tube with a rotating anode and an electro-static lens was constructed, in which the cathode instead of the anode was earthed. Each of the Cu and Fe characteristic rays is obtained without breaking vacuum. An adjustment of position of a camera can be made with quite security, since the total area on the side of a window emitting x-rays is earthed. By this tube, photographs of metals and oxides can be taken in 10 sec and 1 min respectively, using Cu radiation filtered by a nickel foil, the voltage and the current being 50 kV and 30 mA respectively, when the electron beam is focussed in an area of 0.25 mm × 0.75 mm by a biasing voltage of about 600 V.

§1. Introduction

Recently the necessity of intense source of x-rays is increasing more and more in the research work of chemical physics, i.e., in the determination of crystal structure of organic compounds, that of inorganic ones at high or low temperatures, the quantitative measurement of diffuse scattering by crystals, etc.

Hitherto, we have had three methods of obtaining an intense source of x-rays[1),2),3)]. In the first one, the power input to the unit area of anticathode is increased by its movement; in the second one, the specific load on the anticathode is increased by focussing the electron beam attacking it and thus the effective flux of x-rays passing through the slit s further increased[7),8)]; and the movement of anticathode and the focussing of electron beam are combined in the third one. Each of these three methods has merits and demerits respectively and especially the second one has its utility not only in increasing the intensity of a source of x-rays but also in investigating the structure of grain boundaries in metals, the inhomogeneity in crystals of high polymers, etc.

The brightness of a source of x-rays is determined not by the total load but by the pecific load on the anticathode. The first method increases the specific load by increasng the total load itself and the second one by reducing the size of focus. Although in he first one we can increase the total load rbitrarily, at least in principle, by increasing he dimension of anticathode, then the apparatus must become very enormous. In the second one there is a defect that we can only supply extremely small total load on the anticathode if we reduce the size of focus too much. Thus the third method in which the merits of both of the first and second ones are utilized seems the most profitoble in obtaining a high brightness by a relatively small apparatus.

Electro-static or electro-magnetic lenses are usually used for the focussing of electron beam and Ehrenberg and Spear[7)] showed that a high brightness was obtained in a small x-ray tube with an electro-static lens when its cathode instead of its anode was earthed—that is, they could take a photograph of ZnO in one minute by Cu radiation filtered by a nickel foil, using a Seemann-Bohlin type camera, when the focus was reduced down to 40μ by a biasing voltage of about 50 V, the tube voltage and the electron current being 50 kV and 300–500 μA (the maximum specific load being 11 kW/mm^2)*. We can easily understand why the focussing is more easy in an earthed cathode type tube than in an earthed anode type one, if we compare the potential distribution in both cases.

In all of the moving anode type x-ray tubes which have already been reported, the anticathode was always earthed, since it was rather troublesome to insulate the moving part from earth. Considering the above mentioned situation, however, it is expected that an enough intense source of x-ray would be obtained by a relatively small apparatus with a rotating anode in which the electron beam is focussed only by an electro-static lens and the electron current is about 30 mA, when not the anode but the cathode is earthed. We have constructed such type of x-ray tube and it has become clear that this tube has the expected ability.

---

* The specific load is generally less than this in moving anode type tubes.

§ 2. Structure

Fig. 1, 2 and 3 show an elevation, a plan and a side view in the direction of emission of x-ray, of our apparatus, where *AA′*, BB′ and *CC′* are 500 mm, 230 mm and 320 mm respectively. ① is a compound cylindrical anticathode of 60 mm diameter and 22 mm breadth. The fixed right half is made of copper and the left half is attached to the right one by a screw through a rubber packing and accordingly it can easily be substituted by another one, especially of different metal. Now we have one made of iron at this position. ② is a brass tube supportin the anticathode, ③ are bearings*, ④ are stop of thrust, ⑤ is a thrust bearing and the anod is rotated by a d.c. motor (1/4 H and a pulley ⑥ through doub belts** which are long enoug for insulation. Cooling wate flows in from ⑦, goes throug a pipe ⑧ concentric with ②, i jetted upon the inner surface o the lateral part of anticathod from a narrow gap between tw parallel discs ⑨, goes bac between ② and ⑧ and flow out from ⑩. Cooling water i circulated through a tank an a gear pump which are mounte on an insulated table. Or w can use water works by the ai of vinyl tubes long enough fo insulation. ⑪ and ⑫ are Wilso seals stopping leakage of water

⑬ is a lid of vacuum and ha a two stage Wilson seal ⑭. flange ⑮ adapting to ⑬ is fixe to a plank ⑰ which stands on fou

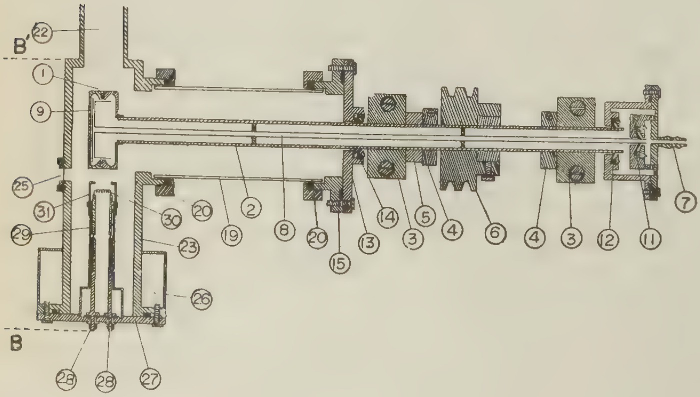

Fig. 2. A Plan.

---

* Plane bearing are used in orde to avoid vibrations. The amplitud of a vibration of the anticathod is kept less than 0.008 mm.

** Since the anticathode is damaged during a stop of rotation of onl several seconds, double belts ar used to avoid an accident due to break of one belt.

insulators. A plate ⑱ bearing the anode upon it can move back and forth along a rail engraved on the lateral sides of ⑰. We can put the anode out of the tube, if we release three bolts on ⑬ and let ⑱ go back.

⑲ is a hard glass tube for insulation and is fixed by rings ⑳. ㉑ is a body of tube surrounding the anticathode ① and has a leading pipe ㉒ to a vacuum pump, a cathode part ㉓, a viewing window ㉔ and a window ㉕ ejecting x-rays. ㉕ is covered by a cellophane film. ㉖ is a water-cooling pipe, ㉗ is a lid of vacuum and two bars ㉘ holding a horizontal fiilament ㉚ and a pipe ㉙ holding a grid ㉛ are fixed to ㉗, the former insulatedly and the latter directly. The distance between the filament and anticathode can be changed by adjusting each plug at the middle of each ㉘ and also the grid can be slided along ㉙. ㉜ is a high tension terminal, ㉝ is an earth terminal and ㉞ is a leading pipe a to vacuum gauge.

§ 3. Characteristics and Abilities

By this apparatus each of Cu and Fe characteristic rays are obtained by a displacement of ⑱, without breaking vacuum. The position of anticathode can be determined by a scale engraved on ⑰ and further we can see it directly through ㉔. ㉔ is also useful in supervising the damage of anticathode.

The other merit of this apparatus is that the total area on the side of the window ㉕ is earthed and accordingly an adjustment of position of a camera can be made with quite security.

The distance between the anticathode and the filament is 11 mm and that between the filament and an aderture (3 mm × 9 mm) of the grid is 1 mm. These values, determined by taking account of published data until now[5),7)], seem to be adequate.

The filament is a coil of W wire of 0.20mm diameter, the diameter and the length of which are 1 mm and 3 mm respectively.

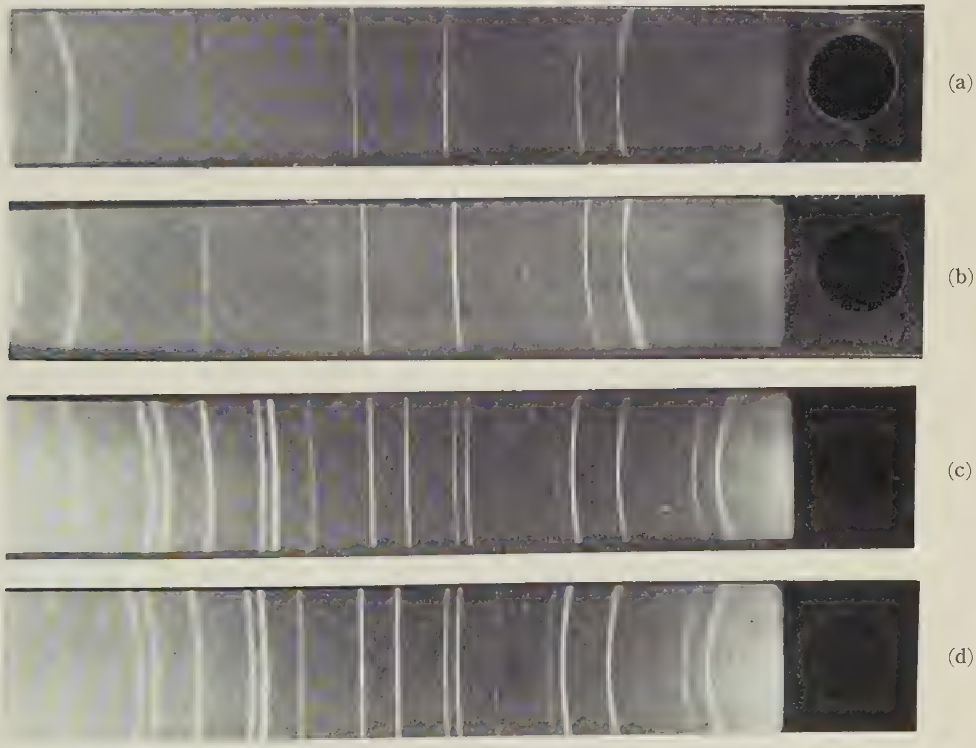

Fig. 4. Photographs taken by CuK radiation filtered by a nickel foil using a camera of 80 mm diameter. (50 kV, 30 mA).

(a)	Ni	10 sec.
(b)	Ni	20 sec.
(c)	PbTho$_3$	1 min.
(d)	PbTho$_3$	2 min.

Electrons emitted from this filament is focussed on the lateral surface of the anticathode in an area of about 0.25 mm × 0.75 mm by a biasing voltage of about 600 V and hence the dimension of x-ray source is about 0.25 mm × 0.25 mm, when the axis of camera makes about 20° to the lateral surface of the anticathode in a horizontal plane.

Although the adequate number of revolution of the anode has not yet been studied thoroughly, the usually adopted value is 1000 rev/min.

In Figs. 4 (a), (b), (c) and (d), we show photographs of Ni and $PbThO_3$ taken by Cu characteristic ray filtered by a nickel foil, using an ordinary powder camera of 80 mm diameter, the voltage and the current being 50 kV and 30 mA respectively. The time of exposure were 10 sec, 20 sec, 1 min and 2 min respectively and no damage was observed on the anticathode. The present value of specific load is 6 kW/mm² and is not so high. The result that the necessary time of exposure is very short, regardless the relatively low value of specific load, seems to show us that the increase of total load rather than the extreme decrease of focus size (less than 0.2 mm) is effective to the shortening of exposure time, as far as the diameter of slit is about 0.5 mm.

It is expected that we would have a more intense source of x-rays if we increase the electron current up to about 100 mA by using a more large anticathode and oscillate it in the direction of its axis in addition to the ordinary rotation of it. Such type of apparatus is now under construction at our laboratory.

Electron Diffraction Study on Polish Layers of Gold I

By Masao KURIYAMA, Kazutake KOHRA* and Satio TAKAGI
Institute of Physics, College of General Education,
University of Tokyo,
Komaba, Meguroku, Tokyo

(Received September 22, 1956)

Polish layers of gold were examined by means of the transmission method of electron diffraction. Line breadths were measured at various stages of polishing. The mean grain size and the mean strain were determined using Hall's method (Proc. Phys. Soc A **62** (1949), 741) for medium polish layers which produce broad ring patterns. The grain size was also determined from the electron micrograph and from the number of spots on a spotty diffraction ring obtained from a minute region of the specimen. The values obtained from those different methods agree in order of magnitude with each other.

Even at medium stages of polishing, the specimen is polished so heavily as to gain grain size 80 Å and strain 3.6%. The grain size rapidly decreases as polishing proceeds. At the final stage of polishing broad ring patterns change into the halo pattern composed of three haloes. The Bragg spacing corresponding to the most inner halo is 4.08 Å, agreeing with the results obtained by Nonaka and Kohra by the reflexion method (J. Phys. Soc. **9** (1954), 512).

§1. Introduction

When polished metallic surfaces are examined by electron diffraction at successive stages of polishing, normal sharp Debye-Scherrer rings initially given by an unpolished surface gradually become broader and finally change into a few haloes[1]. The broadening of rings is usually observed in *X*-ray diffraction patterns from cold worked metals and is attributed to small sizes of crystal grains and to inhomogeneous strains[2]-[8]. The halo pattern, on the other hand, is not obtained from cold worked metals, but only from heavily polished layers of metal. This layer, called the "Beilby layer", was supposed to be amorphous by Beilby before the discovery of electron diffraction[9]. Many investigations have been done on the structure of the Beilby layer by the reflexion method of electron diffraction[1],[10]. Most workers have obtained diffraction patterns consisting of two haloes and have deduced some kind of amorphous structure for the polish layer on metals.

Cochrane[11] first obtained transmission patterns from polish layer of gold and observed another halo *outside* the two haloes mentioned above. Afterwards, Raether and his collabolator[12][13] carried out extensive studies by means of the transmission method. They suggested that crystal size in the upper most layer of heavily polished metals is as small as one or two unit cells in dimension and pointed out from the line broadening that the distortion takes no appreciable role.

It seems unlikely, however, to the present authors that crystallites subjected to heavy polishing are not appreciably distorted. In order to determine the distortion in crystallites, it is necessary to measure exactly the breadth of several Debye-Scherrer rings and particularly to examine their dependence on the scattering angle. This study cannot be performed on the Beilby layer obtained at the final stage, but on specimens at medium stages of polishing where at least several inner rings are clearly resolved. Nevertheless, this study will throw some light on the structure of the Beilby layer. For this purpose, the transmission method is adopted, since it is not only more appropriate for the quantitative analysis than the reflexion method, but also convenient for obtaining direct electron micrographs and selected area microdiffraction.

In the present work, the grain size and the magnitude of strain in the crystallites are obtained, and the values of the grain size are compared with those obtained directly from electron micrograph and from the number of spots on a spotty ring of the microdiffraction pattern.

---

* Now at Fritz-Haber Institut der Max-Planck Gesellschaft.

Recently, Nonaka and one of the authors (K.K.)[14] pointed out the occurence of another halo *inside* the two haloes by the reflexion method. This point is confirmed in the present work by the transmission method.

A more direct method to study the structure of the Beilby layer is to determine the radial distribution function of atoms from measured intensities of halo patterns. In the second part of this work, the results of the study will be given and the structure of Beilby layer will be discussed in more detail.

§ 2. Experimental

Gold was chosen as specimen because of its chemical stability especially against oxidation. Thin polycrystalline films were made on zinc plates by the electro-deposition method following Kranert and Raether[12]. Thin single-crystal-like films were also made by the electro-deposition on single-crystal copper. The thickness of films was about 500 Å. In order to prevent specimens from oxidation and recrystallization by the temperature rise during polishing, the film was polished under benzene by chamois leather without any polishing materials. Polishing was performed in the same manner as was done by Nonaka and Kohra[14]. During the polishing the whole area of the specimen was pushed onto the surface of the rotating disk with a uniform pressure 5 or 200 g/cm². The polishing speed varied from 5 to 250 cm/sec.

At various stages of polishing, films were examined by means of the transmission method of electron diffraction. The electron diffraction camera is of a usual type with a focusing lens and the specimen-to-plate distance of 15 cm. Two slits were used before the specimen which was supported on a fine platinum or brass gauze. The first slit which was 0.1 mm in diameter was used for reducing the aperture of the incident beam and the second which was 0.5 mm in diameter, for getting rid of the irregular scattering from the periphery of the first.

The photometry was performed using a series of diffraction photographs of the same specimen which were taken successively with different exposures. Intensity distribution curves were obtained from microphotometer traces by the method employed by Karle and Karle[15].

Some of the specimens were also examined after various heat treatments. The specimens on platinum gauze were heated *in vacuo* in the diffraction camera or in air in another furnace. Electron micrographs of some specimens were taken, and a selected area ($\sim 1\mu \times 1\mu$) microdiffraction of each was obtained.

§ 3. Result

Upon slight polishing, sharp spots initially given by single-crystal-like films are replaced by Debye-Scherrer rings with arcings showing preferred orientations. On further polishing preferred orientations rapidly weaken and rings become broader. Breadths of the rings are measured for lightly polished single-crystal-like films showing only slight preferred orientations and for polycrystalline films polished to a medium extent. The results are given in § 4.

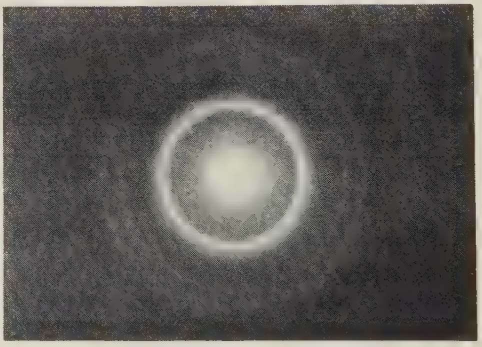

Fig. 1. a. Broad ring pattern from the polish layer of gold. The polishing pressure is 200 g/cm², and the polishing time, 8 hours.

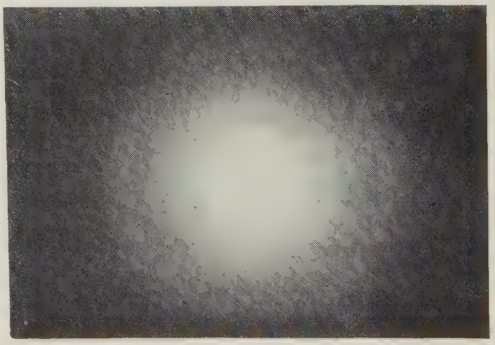

Fig. 1. b. Halo pattern from the polish layer of gold. The polishing pressure is 200 g/cm², and the time, more than 15 hours.

At the final stage of polishing the film yields the characteristic halo pattern of polish layer. The Bragg spacing corresponding to each halo is listed in Table I together with the results obtained by Cochrane[11] and by Nonaka and Kohra[14] and with the spacings of crystalline gold. As was already described, a new halo is observed inside the usually known two haloes. In addition to these three haloes, the innermost halo whose spacing was about 10 Å sometimes appeared around the incident spot. This halo was especially visible during the process of annealing. It may be due to the small angle scattering from severely distorted crystals. A similar hump was observed in the intensity distribution of the pattern from a foil of supercooled gold by Suzuki[16].

Table I. Bragg spacings of halo pattern

Beilby layer			Crystalline gold	
Present results	Nonaka Kohra (reflexion)	Cochrane		
4.08 Å	4.1 Å	.... Å	(4.07) Å	(100)
			2.35	(111)
2.22	2.25	2.10		
			2.04	(200)
			1.44	(220)
1.24	1.24	1.30		
			1.23	(311)
		0.96	1.18	(222)

Five specimens giving halo patterns were annealed in the diffraction camera at temperatures 250°, 325° and 400°C. At 325°C, for instance, annealing for more than twenty minutes began to barely reveal broad Debye-Scherrer rings in the obscure halo pattern. After about an hour the pattern became the broad Deye-Scherrer rings. The broadening of the rings implies the existence of crystal grains of about 100 Å in size with appreciable distortions. The rings became sharper as annealing proceeded. The Bragg spacings of these rings were confirmed to agree with those of gold within the experimental error.

§4. Line Broadening

Intensity curves of broad ring patterns were divided into individual peaks corresponding to each of the reflexions, assuming a symmetrical profile for each peak (Fig. 2). We shall not concern with the line profiles of peaks, but with half value breadths of these peaks. The true breadth was obtained simply by subtracting the geometrical broadening from the observed one; the former being determined experimentally from sharp Debye-Scherrer rings given by the same specimen after prolonged annealing[17),18)].

Breadths of lines thus obtained correspond to grain size of about 15–20 Å, if only the size effect is assumed to be responsible for the line broadening. However, this conclusion is not correct as is shown in the following. When line breadths are plotted against radii of the rings (Fig. 3), the points corresponding to each of the diffraction rings are scattered along a straight line intersecting the vertical axis at a point apart from the origin. This is due to the fact that both the particle size and the strain are effective to the line broadening.

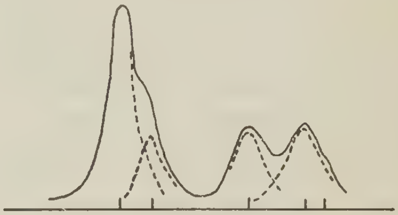

Fig. 2. Intensity distribution curve and line profiles obtained from the broad ring pattern. (Specimen no. 3)

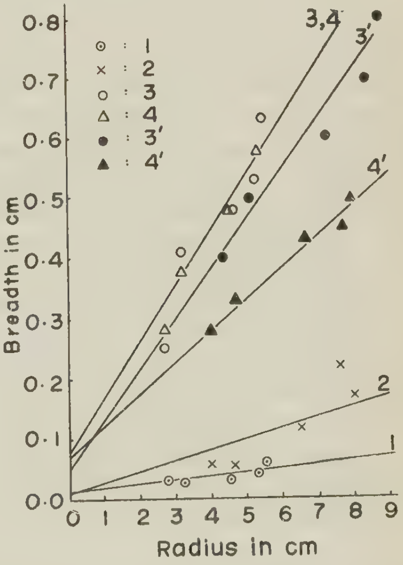

Fig. 3. Variation of line breadth with radius. Numerals in the figure are specimen numbers. (The breadth and the radius are expressed in a magnified scale.)

Hall [19] pointed out that if both causes of broadening were operative, the individual contributions to breadths could be added for a commonly occuring line shape*, thus

$$\frac{\beta\cos\theta}{\lambda}=\frac{1}{t}+2\eta\frac{\sin\theta}{\lambda} \qquad (1)$$

where θ is Bragg angle of a reflexion; λ, the wave length of the radiation; t, the apparent particle size and η, a coefficient relating to the strain distribution. In the case of electron diffraction, θ is usually small and (1) becomes

$$B=\frac{\lambda L}{t}+\eta r \qquad (2)$$

where B is the line breadth on the photographic plate, L, the specimen-to-plate distanc and r, the radius of the ring. If the strai distribution is isotropic, η is independent o the indices of reflexion, and is given by

$$\eta=(2\pi\overline{e^2_{xx}})^{1/2} \qquad (3$$

where e_{xx} is the tensile strain and the ba means the mean value. Straight lines in Fig 3 imply that the strain rather than the stres distribution is isotropic in this case. If th stress distribution were isotropic, a straigh line would be obtained by plotting the breadth against r/E_{hkl} where E_{hkl} is Young's modulu in (hkl) direction. This plotting was tried. The points did not lie even on a smooth curve.

Table II. Mean size and strain in polished gold films

Specimen number	Polishing pressure	Polishing time	Time of observation	Mean size		Strain from (2)
				from (2)	form electron micrographs	
1	5 g/cm²	2 hours	Immediately after polishing	....	....	0.3%
2	5	3		....	....	0.7
3	200	8		80 Å	....	3.6
4	200	8		80	....	3.6
3′	200	8	About two weeks after polishing	150	200 Å	3.3
4′	200	8		130	100 and 300 Å	2.1

The values of particle size and the root mean square of the strain obtained from Fig. 3 for different specimens are tabulated in Table II. At early stages of polishing (specimens 1 and 2) the grain size is too large to be determined from line breadths and the mean strain is of the order of 0.1%. At a more advanced stage (specimens 3 and 4), the grain size is reduced to about 100 Å and the mean strain increased to 2–3%. After being left at the room temperature for about two weeks (specimens 3′ and 4′) the films recrystallize to varying extent.

§ 5. Electron Micrographs

Some of the specimens giving broad rings were observed by an electron microscope. A typical micrograph is shown in Fig. 4a. Most of the grains appearing in a micrograph are of the same degree in size except specimen 4′. Selecting many grains at random, we directly obtained their mean size which is shown i Table II. Specimen 4′ is composed of two kind of grains (Table II).

At the same time, microdiffraction pattern were obtained from minute portions, abou $1\mu\times1\mu$ in size, of specimens. An example i shown in Fig. 4b. It is seen that the ring are composed of many spots. The mean siz of grains can be obtained[21] also from th number of spots on a ring. The estimate value is 200–300 Å, assuming the spherica shape and the uniform distortion.

§ 6. Discussion and Conclusion

Hall's formula (2) is derived under the assumption that the size broadening β_p and th strain broadening β_s can be directly added t make the total broadening β. This assumption is proved to be valid when broadenin functions are of the Cauchy form $1/(1+k^2x^2)$ If these are of Gaussian form, the square o total broadening is expressed as $\beta_p^2+\beta_s^2$. A accurate determination, however, of the lin profile is difficult in the present experimen The results in §§ 4 and 5 have inferred tha the linear relation holds between the breadt

---

* We have tacitly made use of this additivity assumption in deriving the true breadth from the observed one.

Fig. 4. a. Electron micrograph. (Specimen no. 4′)

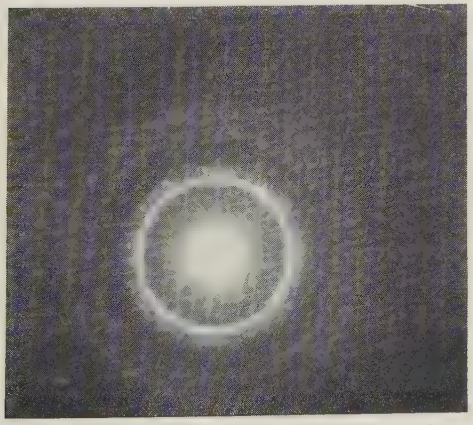

Fig. 4. b. Electron diffraction patterns from a minute portion ($1 \times 1\ \mu^2$) in the above micrograph.

and the radius of rings and the values of the grain size obtained by three different methods do not show significant difference. On the other hand, the trial based on the assumption of Gaussian form showed that the grain size differs from the values obtained by the two other methods. It can be said, accordingly, that Hall's method is reliable as the first approximation in the present case and the value of the strain obtained by this method may be understood to be reliable as much as the value of the grain size.

From the observation given in §§ 4 and 5, the following conclusions on polish layers can be deduced. Even at the medium stage of polishing, the grain size can attain the value of 80 Å, and the strain, that of 3.6%. The value of size and that of strain are ten or hundred times smaller, and about five times larger, respectively than the values usually obtained from cold worked metals. Williamson and Hall⁽⁷⁾, for example, have observed from the line broadening of Al that the value of the grain size is 0.2 μ and that of the strain breadth is 0.6%. This value of strain roughly corresponds to yield stress and may be regarded as the limit value in the usual cold work. The value 3.6% of the strain in polished films corresponds to the stress several times larger than the yield stress. Such a large strain can exist in a crystallite as small as are examined in the present experiment[22)].

The present result that the line breadth varies with radii so that a considerable amount of strain remains in crystallites at least in the medium stage of polishing differs to that of Kranert and Raether[12)]. This point will be discussed further in Part II of this study.

It is possible that the line broadening of the type similar to the strain broadening is caused by the presence of impurities making a solid solution with gold with varying local content. If this is the case, the position of the peaks will be shifted by approximately equal amount to the half breadth of the line. Such a shift was not found in any of the broad ring patterns, nor in the extremely sharp rings obtained from the specimen after prolonged annealing at 450°C.

The authors thanks are due to Mr. T. Suzuki for his suggestions concerning experimental techniques, to Mr. K. Suzuki of the Tokyo Institute of Technology for the use of the microphotometer, and to the Hitachi Central Research Laboratory for obtaining the electron micrographs.

On the Magnetic Properties of Nickel-Arsenide Type Crystals[*]

By Tokutaro HIRONE and Kengo ADACHI

The Research Institute for Iron, Steel and Other Metals
Tohoku University, Sendai

(Received October 20, 1956)

The formation of the ordered arrangement of the magnetic moments of cations (spin ordering or spin arrangement) in the crystal lattice of the nickel-arsenide type is studied theoretically with the molecular field approximation, taking into account interaction between pairs of cations, which form the first, second or third neighbours in the crystal lattice. Various types of spin arrangement in this structure with two kinds of cations are derived. Based on the results obtained the magnetic properties of the compounds are discussed. The theory is applied as a typical example to the interpretation of the magnetism of the ternary solid solution of manganese-chromium-antimony system.

§1. Introduction

It has been known that a number of compounds formed from transition metals and the elements of V_a or VI_a group in the periodic table have nickel-arsenide type crystal structure at or near the stoichiometric composition (1:1), and that many of them show interesting magnetic behaviours. As shown in Fig. 1, the crystal lattice of the nickel-arsenide type is composed of a simple hexagonal lattice of metallic ions and of a close-packed hexagonal lattice of metalloid ions, both lattices interpenetrating into each other. The magnetism in such a crystal structure may be considered to be attributed to the moments of metallic ions; in this case it may be necessary to take account of the exchange coupling between the third neighbouring cations as well as the first and the second. (cf. the positions of metalloid ions as illustrated in Fig. 1) The relative magnitude of these interactions will be considered to be the leading factor determining the magnetic properties of the compounds. In the present paper, we shall discuss the spin ordering in the case of a stoichiometric nickel-arsenide type compound with two different kinds of cations, and apply the results to the interpretation of the anomalous behaviours of magnetism which were observed in some nickel-arsenide compounds.

§ 2. Types of Spin Ordering in the Compounds with the Nickel-Arsenide Structure

In order to discuss the spin ordering (the ordered arrangement of the magnetic moments of cations) in the crystal lattice of the nickel-arsenide structure, we divide the metallic lattice into six sublattices, $\alpha_1, \beta_1, \cdots \gamma_2$ as shown in Fig. 1, because here we have three kinds of interactions mentioned in the introduction and the hexagonal symmetry of the structure.

According to Van Vleck's and Smart's[1)] theory based upon the molecular field approximation, the most stable type of spin ordering is determined by the relative magnitude of the three different interactions mentioned above. In the case of just one kind of cation, we have four types of spin ordering as shown in Fig. 2. If the crystalline magnetic anisotropy is neglected, the ferromagnetic or antiferromagnetic Curie points for these types are given as follows.

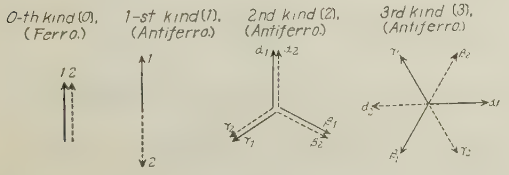

Fig. 2. The stable spin orderings.

$$\left.\begin{array}{lll} \text{0-th} & \text{kind} & T_{c0}=c(\Gamma^1+\Gamma^2+\Gamma^3) \\ \text{1st} & \text{kind} & T_{c1}=c(-\Gamma^1+\Gamma^2-\Gamma^3) \\ \text{2nd} & \text{kind} & T_{c2}=c\left(\Gamma^1-\dfrac{\Gamma^2}{2}-\dfrac{\Gamma^3}{2}\right) \\ \text{3rd} & \text{kind} & T_{c3}=c\left(-\Gamma^1-\dfrac{\Gamma^2}{2}+\dfrac{\Gamma^3}{2}\right) \end{array}\right\} \quad (1)$$

In these expressions $\Gamma^\nu=2z^\nu J^\nu(g\beta)^{-1}$ ($\nu=1, 2$ and 3) means the molecular field coefficients due to the pair of ν-th neighbour ions, z^ν and J^ν are the coordination number and the exchange interactions due to ν-th neighbour respectively and $c=\frac{g\beta}{3k}s(s+1)$ is the ionic Curie constant. The stable types of ordering are specified by the values of different interaction coefficients between neighbouring cations. In Fig. 3 the stable ranges of these types of ordering are illustrated with respect to the values of these exchange integrals between neighbouring pair of ions. The ratio θ/T_{ci} is also shown in the same figure, where $\theta=c(\Gamma^1+\Gamma^2+\Gamma^3)$ means the paramagnetic (asymptotic) Curie point. The transition between different ordering types observed in the compounds such as MnAs and MnBi[1)] (ferromagnetic⇄antiferromagnetic) should be considered from the results indicated in Fig. 3.

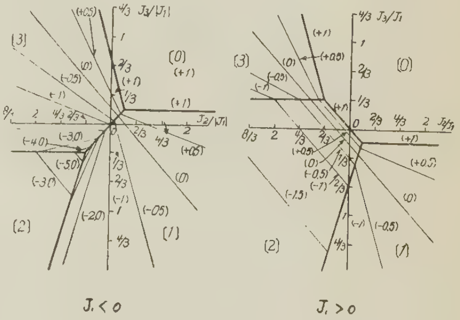

Fig. 3. The types of stable spin ordering and (θ/T_{ci}) values for the magnitude of each exchange integral for neighbouring pair of cations.

§ 3. Triangular Spin Arrangement Due to Mixing of Different Kinds of Cation

In the compounds of nickel-arsenide type, it will occur that several kinds of metallic ions are found in the same cation lattice. For instance, the manganese atom in the compound MnSb can be substituted by chromium atom in any desired composition ($Mn_{1-x}Cr_xSb$)2). Also the binary compound of nickel-arsenide type is not always composed at the stoichiometric concentration (1:1) of metal and metalloid element, but the compounds with off-stoichiometric concentrations are frequently found. In such cases, we may assume without introducing any serious error, that each anion has the same valence; thus it might be presumed that the mixed states of the two kinds of cation valence are present in the off-stoichiometric cases. In the case of pyrrhotite3), $FeS_{1+\delta}$, for example, both the ferrous and ferric ions will occupy the cation lattice.

In the case of the substitutional type above mentioned, it will be shown that the resultant spin moments of cations on different sublattices are not necessarily parallel or antiparallel but they will sometimes form an angular coupling depending on the presence of the various kinds of exchange interactions. Assuming such angular arrangements of spins, Yafet-Kittel4), Kishi5) and Lotgering6) explained the magnetism of ferrites, manganites*) and some sulphides and oxides. We shall now discuss the magnetic behaviour of the compound with nickel-arsenide structure above mentioned from the same point of view.

For simplicity, it will be assumed that the two kinds of ions occupy the cation sites completely at random and further that no vacant sites are present in the lattice. If the mean magnetic moment of the a-ion on α_1-sublattice is denoted by $s_a^{\alpha_1}$ and so forth, then the molecular field acting on an a-ion on α_1-sublattice, $\boldsymbol{H}_a^{\alpha_1}$, etc. are expressed by

$$\begin{aligned}\boldsymbol{H}_a^{\alpha_1}=&\Gamma_{aa}^1\boldsymbol{s}_a^{\alpha_2}+\frac{\Gamma_{aa}^2}{2}(\boldsymbol{s}_a^{\beta_1}+\boldsymbol{s}_a^{\gamma_1})\\&+\frac{\Gamma_{aa}^3}{2}(\boldsymbol{s}_a^{\beta_2}+\boldsymbol{s}_a^{\gamma_2})+\Gamma_{ab}^1\boldsymbol{s}_b^{\alpha_2}\\&+\frac{\Gamma_{ab}^2}{2}(\boldsymbol{s}_b^{\beta_1}+\boldsymbol{s}_b^{\gamma_1})\frac{\Gamma_{ab}^3}{2}(\boldsymbol{s}_b^{\beta_2}+\boldsymbol{s}_b^{\gamma_2}),\ \text{etc.,}\end{aligned}\tag{2}$$

and

$$\boldsymbol{s}_a^{\alpha_1}=x_a s_a^0 B_{s_a^0}\left[\frac{g\beta}{kT}s_a^0(\boldsymbol{H}_a^{\alpha_1}+\boldsymbol{H})\right],\ \text{etc.}\tag{3}$$

In these expressions x_a, x_b and s_a^0, s_b^0 are the concentrations and spin quantum numbers of a and b-ions respectively, and $B_{s^0}[\ \ ]$ means the Brillouin function.

To obtain the coupling energy on the basis of equations (2) and (3), the orientations of $s_a^{\alpha_1}$ etc. must be expressed explicitly. If the orientation of the resultant magnetic moment of the a-ions on the α_1-sublattice is expressed by polar coordinates θ_a, φ_a and that of b-ions by θ_b, φ_b respectively, then the orientations of other moments are expressed as given in Table I. The direction of the polar axis is taken arbitrary owing to the isotropic nature of the exchange coupling, although it is actually determined by the crystalline magnetic anisotropy. Neglecting the terms of the magnetic anisotropy energy, the magnetic coupling energy can be obtained as follows:

$$\begin{aligned}E(\theta_a,\theta_b,\varphi_a,\varphi_b)=&-\frac{1}{2}\frac{1}{6}\sum_{ab}\sum_{\alpha_1\cdots\gamma_2}\boldsymbol{s}_a^{\alpha_1}\boldsymbol{H}_a^{\alpha_1}\\=&-\frac{1}{2}\Bigg[s_a^2x_a^2\Big\{[\mathcal{E}_a(\Gamma_{aa}^1+\Gamma_{aa}^3)+\Gamma_{aa}^2]\cos^2\theta_a\\&+\Big[\Big(\Gamma_{aa}^1-\frac{\Gamma_{aa}^3}{2}\Big)\cos^2\varphi_a-\frac{\Gamma_{aa}^2}{2}\Big]\sin^2\theta_a\Big\}\\&+s_b^2x_b^2\Big\{[\mathcal{E}_b(\Gamma_{bb}^1+\Gamma_{bb}^3)+\Gamma_{bb}^2]\cos^2\theta_b\\&+\Big[\Big(\Gamma_{bb}^1-\frac{\Gamma_{bb}^3}{2}\Big)\cos^2\varphi_b-\frac{\Gamma_{bb}^2}{2}\Big]\sin^2\theta_b\Big\}\\&+2s_as_bx_ax_b\Big\{[\mathcal{E}_c(\Gamma_{ab}^1+\Gamma_{ab}^3)+\mathcal{E}_c'\Gamma_{ab}^2]\cos\theta_a\cos\theta,\\&+\Big[\Big(\Gamma_{ab}^1-\frac{\Gamma_{ab}^3}{2}\Big)\cos(\varphi_a+\varphi_b)\\&-\frac{\Gamma_{ab}^2}{2}\cos(\varphi_a-\varphi_b)\Big]\sin\theta_a\sin\theta_b\Big\}\Bigg],\end{aligned}\tag{4}$$

where $\mathcal{E}$'s take the values ±1 depending on the types of spin arrangement.

The stable positions of θ and φ are determined by the minimum point of the coupling

---

*) Dr. Kishi applied with success the concept of the triangular arrangement to the explanations of the magnetic properties of the compounds with perovskite structure, La-Ca manganite and La-Sr cobaltite. His results for the manganite system however disagree with the results of neutron diffraction study of this system recently observed by Wollan and Koehler [Phys. Rev. **100** (1955) 545].

Table I. The orientation scheme of the spins of a and b ions on sublattices.

Sublattice	a-ion		b-ion	
α_1	θ_a	φ_a,	θ_b,	φ_b,
β_1	θ_a,	$\frac{2}{3}\pi+\varphi_a$,	θ_b,	$\frac{2}{3}\pi+\varphi_b$,
γ_1	θ_a,	$\frac{4}{3}\pi+\varphi_a$,	θ_b,	$\frac{4}{3}\pi+\varphi_b$,
α_2	θ_a or $\pi-\theta_a$,	$-\varphi_a$,	θ_b or $\pi-\theta_b$,	$-\varphi_b$,
β_2	θ_a or $\pi-\theta_a$,	$\frac{2}{3}\pi-\varphi_a$,	θ_b or $\pi-\theta_b$,	$\frac{2}{3}\pi-\varphi_b$,
γ_2	θ_a or $\pi-\theta_a$,	$\frac{4}{3}\pi-\varphi_a$,	θ_b or $\pi-\theta_b$,	$\frac{4}{3}\pi-\varphi_b$.

energy (4). A short calculation will show that the values of θ's and φ's for the minimum energy occur when

$$\left.\begin{aligned} &\varphi_a=\varphi_b=0 \quad \text{or} \quad \pm\pi \quad \text{or} \quad \pm\frac{\pi}{2}: \\ \text{and} \\ &0<\theta_a \quad \text{and} \quad \theta_b<\pi\,, \end{aligned}\right\}$$

or

$$\left.\begin{aligned} &\theta_a=\theta_b=0 \quad \text{or} \quad \pm\pi \quad \text{or} \quad \pm\frac{\pi}{2}: \\ \text{and} \\ &0<\varphi_a \quad \text{and} \quad \varphi_b<\pi\,. \end{aligned}\right\}$$

In the former case the angular arrangement above mentioned occurs from the difference between θ_a and θ_b, while in the latter case, it is caused by φ's. Now the case of the triangular arrangement in θ will be considered first. Using the following abbreviations

$$\left.\begin{aligned} A&=\mathcal{E}_a(\Gamma_{aa}{}^1+\Gamma_{aa}{}^3)-\delta_a\left(\Gamma_{aa}{}^1-\frac{\Gamma_{aa}{}^3}{2}\right)+\frac{3}{2}\Gamma_{aa}{}^2, \\ B&=\mathcal{E}_b(\Gamma_{bb}{}^1+\Gamma_{bb}{}^3)-\delta_b\left(\Gamma_{bb}{}^1-\frac{\Gamma_{bb}{}^3}{2}\right)+\frac{3}{2}\Gamma_{bb}{}^2, \\ C_1&=\mathcal{E}_c(\Gamma_{ab}{}^1+\Gamma_{ab}{}^3)+\mathcal{E}_c'\Gamma_{ab}{}^2\,, \\ C_2&=\delta_c\left(\Gamma_{ab1}-\frac{\Gamma_{ab}{}^3}{2}\right)-\delta_c'\frac{\Gamma_{ab}{}^2}{2}\,, \end{aligned}\right\} \tag{5}$$

and denoting $s_b x_b/s_a x_a$ by y, the energy formula (4) can be rewritten as the following equation,

$$\begin{aligned} E(\theta_a,\theta_b)=-\frac{1}{2}s_a{}^2x_a{}^2[&A\cos^2\theta_a+By^2\cos^2\theta_b \\ &+2y(C_1\cos\theta_a\cos\theta_b+C_2\sin\theta_a\sin\theta_b)]+\text{const.}, \end{aligned} \tag{6}$$

where δ's can take either of the values ± 1. The added constant does not depend on θ and φ. Then the extremum condition for the energy, $\partial E/\partial\theta_a=\partial E/\partial\theta_b=0$, lead to the following simultaneous equations for θ_a and θ_b,

$$\left.\begin{aligned} &(A\cos\theta_a+yC_1\cos\theta_b)\sin\theta_a \\ &\quad -yC_2\cos\theta_a\sin\theta_b=0\,, \\ &-C_2\cos\theta_b\sin\theta_a \\ &\quad +(yB\cos\theta_b+C_1\cos\theta_a)\sin\theta_b=0\,. \end{aligned}\right\} \tag{7}$$

Of course these equations have the solutions $\theta_a=\theta_b=0$ or $\pm\pi$ or $\pm\frac{\pi}{2}$, but they have besides these another solution satisfying the following equation,

$$\begin{aligned} &AC_1\cos^2\theta_a+y^2BC_1\cos^2\theta_b \\ &\quad +y(AB+C_1{}^2-C_2{}^2)\cos\theta_a\cos\theta_b=0\,. \end{aligned} \tag{8}$$

From equations (7) and (8), θ_a and θ_b are obtained as follows;

$$\left.\begin{aligned} \cos^2\theta_a&=\frac{y^2-Q^2}{P^2-Q^2}\,, \\ \cos^2\theta_b&=\frac{P}{y^2}\cos^2\theta_a\,, \end{aligned}\right\} \tag{9}$$

where

$$\left.\begin{aligned} P&=\frac{1}{2BC_1}[-(AB+C_1{}^2-C_2{}^2) \\ &\qquad \pm\sqrt{(AB+C_1{}^2-C_2{}^2)^2-4ABC_1{}^2}], \\ Q&=\frac{A}{C_2}+\frac{C_1}{C_2}P\,. \end{aligned}\right\} \tag{10}$$

In equation (9), $y=P$ and $y=Q$ gives $\theta_a=\theta_b=0$ or $\pm\pi$ and $\theta_a=\theta_b=\pm\frac{\pi}{2}$ respectively. For the occurrence of the triangular arrangement in θ the signs of A and B should be different from each other, and also $P \lesseqgtr y \lesseqgtr Q$ $(P, Q > 0)$ should hold. In the ranges of $y \gtrless P, Q$ usual ferrimagnetic theory as developed by Néel[7] can be applied.

In Fig. 4 the types of spin angular arrangement and the values of ε's and φ's for each type are illustrated. In the case of F_1 all the resultant moments are parallel to each other (ferromagnetic), which in F_2 the resultant moments of a-ions are antiparallel to those of b-ions (ferrimagnetic). In the cases of A_1 and A_2, the moments of a-ions on the sublattices $1(\alpha_1, \beta_1, \gamma_1)$ are antiparallel to those of the same ions on the sublattices $2(\alpha_2, \beta_2, \gamma_2)$, and the same is said for those of b-ions, so that the system as a whole has no resultant moment (antiferromagnetic). TF_1, TF_2 and TA_1, TA_2 are the ferrimagnetic and antiferromagnetic triangular arrangements respectively, which are derived from F_1, F_2 and A_1 A_2 states. The cone in the figure means three resultant moments with the same θ value on the triad of the sublattices $(\alpha_1, \beta_1, \gamma_1)$ of $(\alpha_2, \beta_2, \gamma_2)$. The same can be said for the configurations f_1, f_2, a_1, a_2 and their T-states of triangular arrangement in φ (antiferromagnetic).

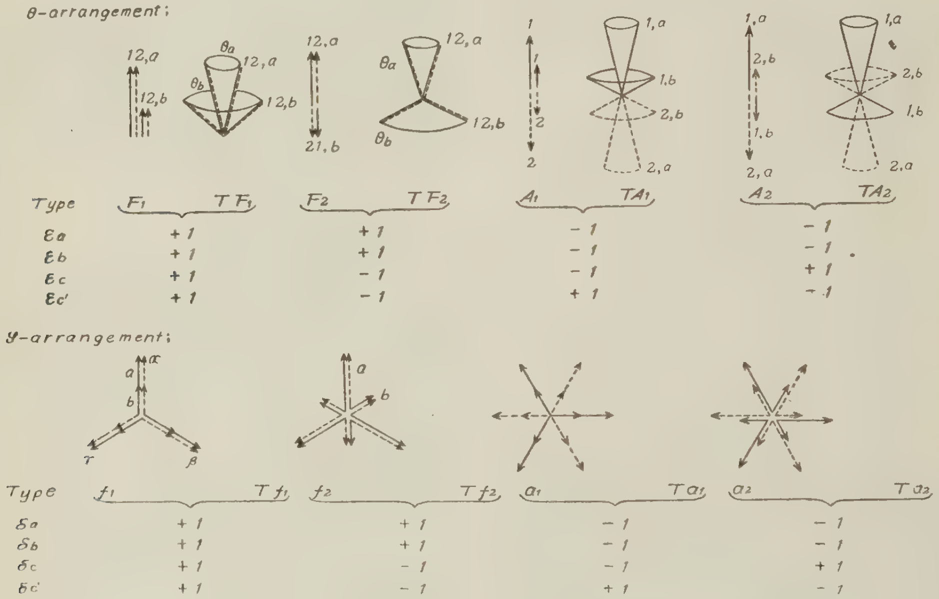

Fig. 4. Types of triangular spin arrangements.

It is to be noted that in such a case as the nickel arsenide structure here discussed, discontinuous transitions between each type of arrangement can occur with the change of the temperature or of the composition of the system, and the compound undergoes thereby discontinuous changes of magnetic properties.

§ 4. The Magnetic Properties of Compounds with Triangular Spin Arrangement

The change of magnetic properties caused by the rise of temperature and the change of cation concentration in the crystal lattice now in consideration (§ 3) can be derived from the minimum condition of the energy due to spin angular arrangement as mentioned above. Neglecting the terms of the crystalline magnetic anisotropy, we will proceed to work out expressions for some magnetic properties in the case of the triangular arrangement in θ.

a) Magnetization *vs* concentration relation at absolute zero.

The spontaneous magnetization $\sigma_0(x)$ at absolute zero of temperature in the case of the triangular arrangement, is given by

$$\sigma_0 = s_a{}^0 x_a \cos\theta_a \pm s_b{}^0 x_b \cos\theta_b$$
$$= (1 \pm P)\sqrt{\frac{(s_b{}^0 x_b)^2 - (s_a{}^0 x_a)^2 Q^2}{P^2 - Q^2}}, \qquad (11)$$

where + and − signs correspond to TF_1 and TF_2 respectively.

b) Magnetization *vs* temperature relation.

Based on the equations (2) and (3) the molecular fields acting on a- and b-ion can be written as follows,

$$\left.\begin{aligned} H_a&=(A\cos^2\theta_a+a)s_a x_a \\ &\quad+(C_1\cos\theta_a\cos\theta_b+C_2\sin\theta_a\sin\theta_b)s_b x_b\,, \\ H_b&=(C_1\cos\theta_a\cos\theta_b+C_2\sin\theta_a\sin\theta_b)s_a x_a \\ &\quad+(B\cos^2\theta_b+b)s_b x_b\,. \end{aligned}\right\} \tag{12}$$

In these equations a and b represent the following expressions,

$$\left.\begin{aligned} a&=\delta_a\left(\Gamma_{aa}{}^1-\frac{\Gamma_{aa}{}^3}{2}\right)-\frac{\Gamma_{aa}{}^2}{2}\,, \\ b&=\delta_b\left(\Gamma_{bb}{}^1-\frac{\Gamma_{bb}{}^3}{2}\right)-\frac{\Gamma_{bb}{}^2}{2}\,, \end{aligned}\right\} \tag{13}$$

Then (12) can be put in the following form by using the definition of y and (9),

$$\left.\begin{aligned} H_a&=s_a x_a(\alpha_1 y^2+\alpha_2)\,, \\ H_b&=s_b x_b(\beta_1 y^{-2}+\beta_2)\,, \end{aligned}\right\} \tag{14}$$

where α_1, α_2, β_1 and β_2 are given by

$$\left.\begin{aligned} \alpha_1&=(A+PC_1-QC_2)(P^2-Q^2)^{-1} \\ \alpha_2&=a+QC_2-Q^2(A+PC_1-QC_2)(P^2-Q^2)^{-1}\,, \\ \beta_1&=-Q^2(B+P^{-1}C_1-Q^{-1}C_2)(P^2-Q^2)^{-1}\,, \\ \beta_2&=b+Q^{-1}C_2 \\ &\quad+P^2(B+P^{-1}C_1-Q^{-1}C_2)(P^2-Q^2)^{-1}. \end{aligned}\right\} \tag{15}$$

Then the mean spin moments of a- and b-ions, $s_a(T)$ and $s_b(T)$, are expressed by

$$\left.\begin{aligned} s_a(T)&=s_a{}^0 B_{s_a^0}\left[\frac{g\beta}{kT}\{(\alpha_1 y^2+\alpha_2)x_a s_a+H\}\right], \\ s_b(T)&=s_b{}^0 B_{s_b^0}\left[\frac{g\beta}{kT}\{(\beta_1 y^{-2}+\beta_2)x_b s_b+H\}\right], \end{aligned}\right\} \tag{16}$$

respectively. Hence by putting $H=0$ and eliminating y, s_a and s_b can be determined as functions of temperature. The magnetization for TF type can then be written as

$$\sigma(T)=s_a(T)x_a\cos\theta_a(T)\pm s_b(T)x_b\cos\theta_b(T)\,. \tag{17}$$

The magnetic susceptibility above the Curie point is obtained by the usual procedure. For the antiferromagnetic case the susceptibility below the Néel point will not be treated here, since the calculation requires the knowledge of magnetic anisotropy, for which we have not at present enough experimental data as far as the antiferromagnetic compounds with nickel arsenide structure are concerned.

c) Curie point *vs* concentration.

The Curie temperature T_c of this system can be obtained by the high temperature expansion of the right hand side of equation (16) and by elimination of y. Thus it is determined by solving the following equation for T_c;

$$\Theta_a\Theta_b-\alpha_2 x_a\Theta_b-\beta_2 x_b\Theta_a-(\alpha_1\beta_1-\alpha_2\beta_2)x_a x_b=0 \tag{18}$$

where Θ_a and Θ_b means $3kT_c\{s_a{}^0(s_a{}^0+1)g\beta\}^{-1}$ and $3kT_c\{s_b{}^0(s_b{}^0+1)g\beta\}^{-1}$ respectively.

d) Specific heat.

In this theory it is shown that the change of spin directions at the transition point does not introduce any entropy change of the system, hence the discontinuous transformation between each type of angular arrangement does not accompany any latent heat.

§ 5. Applications

As a typical example of triangular spin arrangement in nickel arsenide structure, the magnetism of $Mn_{1-x}Cr_xSb$ system will at first be discussed. According to the experimental results hitherto presented MnSb is a ferromagnetic substance with the Curie point at 587°K, while CrSb is an antiferromagnetic one with the Néel point at 713°K. It has been known that their type of spin ordering are of 0-th kind and of 1st kind respectively and that their easy axis of magnetization is the c-axis[8),9)] for both compounds. According to the recent investigation[2)], both compounds form a homogeneous solid solution over all ranges of concentration. X-ray analysis shows that no superstructure of vacant sites in the crystal lattice are formed in these compounds. In this system the ferro-, ferri- and antiferromagnetic phases have been found in the proper concentration and temperature rangs respectively. It has been reported that the ferromagnetism of manganese antimonide transforms into ferrimagnetic type when the manganese atom is substituted by chromium. With further increase of chromium content, however, an antiferromagnetic temperature range appears above the ferrimagnetic Curie temperature. With further addition of chromium the range of antiferromagnetic ordering becomes remarkably wider.

The magnetic properties of this system above mentioned cannot be explained by the ferrimagnetic theory based exclusively on the antiparallel orientation of spins. Now such a behaviour above mentioned will be reproduced theoretically by the results obtained in § 4. It might be reasonable to assume the spin arrangement of the following type with reference to some experimental evidence: In this case the interactions between a pair of Mn ions and that between a Mn–Cr pair may be assumed to be both ferromagnetic and that of Cr–Cr antiferromagnetic. Hence it is to be expected that at the Mn rich side the triangular spin arrangement of TF$_1$ type (ferrimagnetic) appears and also at the Cr rich side, antiferromagnetic triangular arrangement, e.g. of TA$_2$ type, will occur. On the basis of the theory developed in the previous section, assuming the ionic states of mangnese and chromium in this system to be $Mn^{3+}(s^0=0)$ and $Cr^{3+}(s^0=3/2)$ respectively, some magnetic behaviours, such as the change of saturation moment with concentration, thermomagnetic curves and the magnetic phase diagram can be derived by the use of the above equations with suitable choice of the values of exchange interactions between neighbouring ions. In Fig. 3 the relation between the saturation moment and concentration is shown. The curves for TF$_1$ state in this figure is obtained by taking the values, $P=1/12(x=0.1)$ and $Q=3(x=0.8)$ in equation (11). Also the magnetic phase diagram as illustrated in Fig. 6 is obtained on the basis of equations (16) and (18). In the antiferromagnetic region of this figure the types of spin arrangement TA$_2$ are assumed, and the values of constants in equation (18) are taken as $\alpha_2=0.97$, $\beta_2=0.68$ and $\alpha_1\beta_1=1.61$ in the TF$_1$-state and $\alpha_2=25.0$, $\beta_2=2.0$ and $\alpha_1\beta_1=7.1$ in the TA$_2$-state in the unit of $3kT_c\{2(2+1)g\beta\}^{-1}$ (i.e. T_c of MnSb). The normal ferrimagnetic theory holds for the F$_1$- and A$_2$-states in both figures. In these figures experimental data for the compounds Mn$_{1-x}$Cr$_x$Sb are shown. As they shows these points show satisfactory agreement with the theoretical curves.

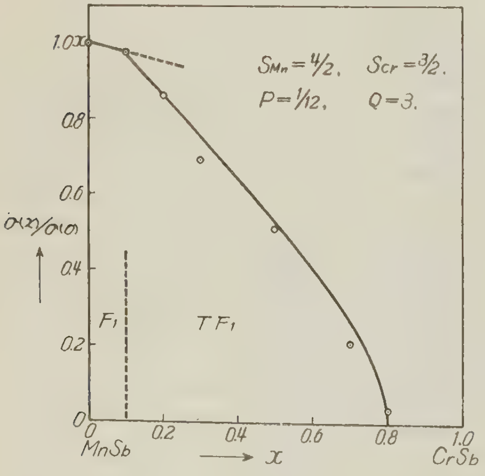

Fig. 5. The saturation moments of Mn$_{1-x}$Cr$_x$Sb system.

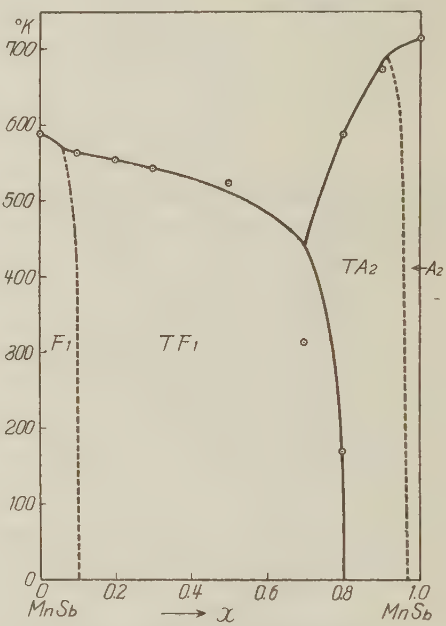

Fig. 6. The magnetic phase diagram of Mn$_{1-x}$Cr$_x$Sb system.

It is to be noted here that, as discussed in § 4, by the theoretical result above mentioned the discontinuous transition between different types of spin arrangement is also expected. As mentioned in § 3, three stable or metastable orientation in φ_a and φ_b, namely 0, $\pi/2$, π are obtained. With the rise of temperature (or concentration change), the transition between different orientation will occur. In such a case the values of θ_a and θ_b corresponding to the value of φ's will change discontinuously. Thus the discontinuous change of magnetism will follow. Such a discontinuous change may explain the abrupt appearance of spontaneous magnetization as found during heating the compound $CrS_{1.17}$[10] (for example TA$\rightleftarrows$TF type transition) though a more detailed study is required before to be conclusive.

Thus it is possible to explain various magnetic behaviours of the compounds with nickel arsenide structure from the present theory. However, in the actual cases, several factors, which are not taken into account in the present discussion, will affect the magnetic behaviours of the compounds. The order-disorder change in the arrangement of vacant sites and ions has been confirmed to be present in some compounds of nickel arsenide type with off-stoichiometric compositions and such a change will affect the molecular field distribution. The magnetic anisotropy energy will also specify the direction of spin arrangement with respect to the crystallographic axes and will give an influence on the magnetic susceptibility as well as parasitic ferromagnetism of compounds. Recently, Goodenough11) has proposed an explanation of the magnetism of La–Ca manganite by using the concept of covalent bonding. This might be to be considered also in our problem. Full studies of neutron diffraction analysis of spin arrangement of nickel arsenide type magnetic substances are most desirable.

Theory of the Para-Ortho Conversion in Solid Deuterium

By Kazuko MOTIZUKI
Department of Physics, Ōsaka University

(Received November 10, 1956)

The rate of para-ortho conversion in solid deuterium (D_2) is calculated taking two types of interactions, i.e., the magnetic dipole-dipole interaction between D_2 molecules and the coupling between the nuclear quadrupole moments of one D_2 molecule and the total quadrupole moment of the other molecule. It is found that both interactions make about the same contributions to the para-ortho conversion if only the interactions among para molecules are taken into account. However, the ortho molecules with $I=2$ also interact magnetically with para molecules and convert them into ortho molecules. The calculated conversion rate due to the para-para interactions is found to be 0.01 % per hour times c^2, where c is the para concentration, while that due to the para-ortho interactions to be 0.01 % per hour times $c(1-c)$, so that the c^2 termes eventually cancel each other, leaving a total conversion rate which is proportional to c.

§1. Introduction

In a preceding paper1) (quoted as (I)) the rate of ortho-para conversion in solid hydrogen (H_2) was calculated taking magnetic dipole-dipole interactions between ortho-molecules into consideration. When an ortho-molecule converts into a para-molecule, the rotational state of this molecule changes from $J=1$ to $J=0$, and the difference of the energies of these states is taken up by the lattice vibrations. The Debye approximation was made for the lattice vibrations and it was found that the two phonon emission process was dominant. The result obtained (2 % per hour) was in good agreement with the experiment.*

In this paper a similar calculation of the rate of conversion in solid deuterium (D_2) will be given. One point of difference between H_2 and D_2 is the difference in their statistical characters. In the case of hydrogen molecule, the nuclei have spins of magnitude 1/2 and obey the Fermi-Dirac statistics. The ground state of the hydrogen molecule is para state (both the rotational and total spin quantum numbers are zero) and the first excited state is ortho state (rotational and total spin quantum numbers are both 1). On the other hand, in the case of deuterium, the nuclei have spins of magnitude 1 and obey the Bose statistics. The ground state of deuterium has zero rotational quantum number and its resultant spin quantum number is either zero or two. The energy splitting between these spin states ($I=0$ and $I=2$) is negligible compared with the energy splitting of the rotational states. The first excited state of D_2 has $J=1$ and $I=1$. The former states are called ortho and the latter state para.

There are two types of interactions causing the transition between para and ortho states. The first type is the magnetic dipole-dipole interaction between D_2 molecules and consists of two kinds of interaction as in the case of H_2: interaction between nuclear spins of one molecule and those of the other molecule and interaction between the rotational magnetic moment of one molecule and the nuclear spins of the other molecule. The second is the coupling between the nuclear quadrupole moment and the total quadrupole moment of the other molecule. Both are present in the interactions among para-molecules, while there is evidently only the first kind of interaction between para-molecules and the ortho-molecules with $I=2$. Therefore, the para-concentration, c, should change with time as

$$\frac{dc}{dt}=-kc^2-k'c(1-c)\ . \tag{1.1}$$

The result of the present calculation shows that the both interactions make about the same contributions to k and the value of it is 0.01 % per hour, which is much smaller than the corresponding value for H_2 (2 % per hour). The value of k' is found to be almost the same as that of k, so that we have practically $dc/dt=-kc$.

Furthermore, the effect of a small amount of dissolved oxygen molecules is studied. As in the case of H_2, the conversion rate is greatly enhanced by the magnetic dipole interaction between the oxygen molecules and the nuclei of the hydrogen molecules.

§ 2. Wave Functions and Interactions

The lowest rotational state of D_2 is a state in which the wave function of the nuclear spins is symmetrical and the total spin angular momentum I is either zero or two. In the next higher rotational state, $J=1$, the wave function of the nuclear spins is antisymmetrical, the total spin angular momentum I being 1. The former states, $J=0$, $I=0$ and $J=0$, $I=2$, belong to ortho-D_2 and the latter state, $J=1$, $I=1$, to para-D_2. The abundance ratio of ortho to para in normal deuterium gas is 6:3.

The nuclear spin functions of a D nucleus will be denoted as ϕ_{+1}, ϕ_0 and ϕ_{-1}. The total wave functions φ_0, $\varphi_{1,\pm M}$ ($M=0, 1$) and $\varphi_{2,\pm M}$ ($M=0, 1, 2$) of the states of total spin 0, 1 and 2 are then given by

$$\varphi_0=\frac{1}{\sqrt{3}}[\phi_{+1}(1)\phi_{-1}(2)-\phi_0(1)\phi_0(2)+\phi_{-1}(1)\phi_{+1}(2)] \qquad (I=0) \tag{2.1}$$

$$\varphi_{1,\pm1}=\frac{1}{\sqrt{2}}[\phi_0(1)\phi_{\pm1}(2)-\phi_{\pm1}(1)\phi_0(2)] \tag{2.2}$$

$$\varphi_{1,0}=\frac{1}{\sqrt{2}}[\phi_{-1}(1)\phi_{+1}(2)-\phi_{+1}(1)\phi_{-1}(2)] \qquad (I=1)$$

$$\varphi_{2,\pm2}=\phi_{\pm1}(1)\phi_{\pm1}(2)$$

$$\varphi_{2,\pm1}=\frac{1}{\sqrt{2}}[\phi_0(1)\phi_{\pm1}(2)+\phi_{\pm1}(1)\phi_0(2)] \tag{2.3}$$

$$\varphi_{2,0}=\frac{1}{\sqrt{6}}[\phi_{+1}(1)\phi_{-1}(2)+2\phi_0(1)\phi_0(2)$$

---

* The conversion rate of 0.9 % per hour observed by Hill is for normal hydrogen, not for the reaction constant k, as was misquoted in paper (I). Thus, k is $(3/2)^2$ times 0.9 % per hour, i.e. 2.0 % per hour. This comes in close agreement with Polanyi and Cremer's value (1.75 %) and our theoretical value (1.94 %). The writer is indebted to Dr. R. Hill for calling attention to this fact.

$$+\phi_{-1}(1)\phi_{+1}(2)] \qquad (I=2)$$

Rotational wave functions are

for the state $J=0$

$$\psi_0=1/2 \qquad (2.4)$$

for the state $J=1$

$$\psi_{1,1}=-\frac{1}{2}\left(\frac{3}{2\pi}\right)^{1/2}\sin\theta e^{i\varphi}$$

$$\psi_{1,0}=\left(\frac{3}{4\pi}\right)^{1/2}\cos\theta \qquad (2.5)$$

$$\psi_{1,-1}=\frac{1}{2}\left(\frac{3}{2\pi}\right)^{1/2}\sin\theta e^{-i\varphi}$$

where θ, φ denote the polar and azimuthal angles of the molecular axis. The polar axis can be taken arbitrarily in the space.

In the case of H_2, the interactions which cause the ortho-para conversion are the spin-spin and spin-rotational magnetic dipole-dipole interactions between ortho-molecules. In paper (I), we denoted these two interactions by H_{ss} and H_{rs}, respectively, and their expressions were given by (2.5), (2.7) of the paper. In the case of D_2, the nuclei have nuclear quadrupole moment, so the quadrupole interaction also contributes to the conversion. This quadrupole interaction is the coupling between the nuclear quadrupole moments of one D_2 molecule and the electric field gradients at these nuclei produced by the total quadrupole momet of another D_2 molecule.

The electric coulomb potential V at the nucleus 1 of the b-molecule due to the charge distribution of the a-molecule is

$$V=\sum_i \frac{e_i}{R_i}$$

where $\sum_i$ represents the sum over the charges belonging to the a-molecule and R_i denotes the distance between that charge i and nucleus 1 of the b-molecule. The potential V can be expanded as follows:

$$V=\frac{1}{R_{a,b1}}\sum_i e_i+\frac{1}{R^2_{a,b1}}\sum_i e_i\rho_i P_1(\cos\Theta_i)$$
$$+\frac{1}{R^3_{a,b1}}\sum_i e_i\rho_i^2 P_2(\cos\Theta_i)\ldots \quad (2.6)$$

For the notation, see Fig. 1. The first and second terms represent the potential due to the total charge and electric dipole of the a-molecule, which must vanish since D_2 molecule is neutral and has no electric dipole moment. The third term represents the potential due to the quadrupole moment of the a-molecule and this is what we need. We write this as V_Q. With the use of the angle Θ defined in

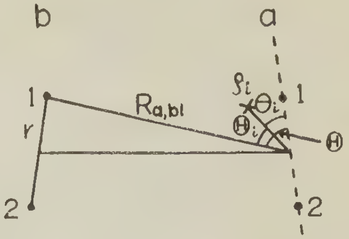

Fig. 1.

Fig. 1, V_Q can be written simply as

$$V_Q=\frac{1}{4}eQ_{D_2}(3\cos^2\Theta-1)\frac{1}{R^3_{a,b1}}, \qquad (2.7)$$

where Q_{D_2} represents the quadrupole moment of a D_2 molecule. The angle changes with the rotations of the a-and b-molecules. So, using the rotational coordinates of the a and b molecules, V_Q is rewritten as

$$V_O=\frac{1}{4}eQ_{D_2}\frac{1}{R^5_{a,b1}}[3(X_{a,b1}\sin\theta_a\cos\varphi_a$$
$$+Y_{a,b1}\sin\theta_a\cos\varphi_a+Z_{a,b1}\cos\theta_a)^2-R^2_{a,b1}], \quad (2.8)$$

where

$$X_{a,b1}=R\sin\theta\cos\varphi+r\sin\theta_b\cos\varphi_b$$
$$Y_{a,b1}=R\sin\theta\sin\varphi+r\sin\theta_b\sin\varphi_b$$
$$Z_{a,b1}=R\cos\theta+r\cos\theta_b$$
$$R_{a,b1}=(X^2_{a,b1}+Y^2_{a,b1}+Z^2_{a,b1})^{1/2}$$

R, θ and φ denote the polar coordinates of the vector joining the centres of the two molecules and (θ_a, φ_a), (θ_b, φ_b) the polar and azimuthal angles of the molecular axes of the a-and b-molecules.

Thus the quadrupole interaction can be written

$$H_Q=H_Q(a, b1)+H_Q(a, b2) \qquad (2.9)$$

where for instance $H_Q(a, b1)$ represents the interaction between the quadrupole moment of nucleus 1 in the b-molecule and the electric field gradient at this molecules due to the a-molecule. Each term can be represented as follows:

$$H_Q(a, bi)=\sum_\mu Q_\mu(bi)\nabla E_{-\mu}(a, bi) \quad (i=1, 2) \quad (2.12)$$

where Q_μ is the nuclear quadrupole moment operator and consists of the following five components:

$$Q_0(b1)=\left[\frac{eQ_D}{2i(i-1)}\right][3i_{b1,z}^2-i(i+1)]$$

$$Q_{\pm1}(b1)=\mp\frac{\sqrt{6}}{2}\left[\frac{eQ_D}{2i(i-1)}\right][(i_{b1,X}\pm ii_{b1,Y})i_{b1,Z}$$

$$+i_{b1,Z}(i_{b1,X}\pm ii_{b1,Y})] \qquad (2.11)$$

$$Q_{\pm2}(b1)=\frac{\sqrt{6}}{2}\left[\frac{eQ_D}{2i(i-1)}\right](i_{b1,X}\pm ii_{b1,Y})^2$$

In these expressions Q_D is the nuclear quadrupole moment of D and i the nuclear spin vector ($i=1$), ∇E_μ is the electric field gradient and is a function of the rotational coordinates of molecules a and b, i.e.,

$$E_0=\frac{eQ_{D_2}}{8}(3A_0+6B_0-60C_0-15D_0)$$

$$E_{\pm1}=\mp\frac{\sqrt{6}}{24}eQ_{D_2}(-15A_{\pm1}+6B_{\pm1}$$

$$-30C_{\pm1}+105D_{\pm1}) \qquad (2.12)$$

$$E_{\pm2}=\frac{\sqrt{6}}{24}eQ_{D_2}(-15A_{\pm2}+6B_{\pm2}$$

$$-60C_{\pm2}+105D_{\pm2})$$

where

$$A_0=(R_{a,b1})^{-7}(R_{a,b1}^2-5Z_{a,b1}^2)$$

$$B_0=(R_{a,b1})^{-5}\cos^2\theta_a$$

$$C_0=(R_{a,b1})^{-7}(X_{a,b1}\sin\theta_a\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)Z_{a,b1}\cos\theta_a$$

$$D_0=(R_{a,b1})^{-9}(X_{a,b1}\sin\theta_a\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)^2(R_{a,b1}^2-7Z_{a,b1}^2)$$

$$A_{\pm1}=(R_{a,b1})^{-7}Z_{a,b1}(X_{a,b1}\pm iY_{a,b1})$$

$$B_{\pm1}=(R_{a,b1})^{-5}\cos\theta_a(\sin\theta_a\cos\varphi_a\pm i\sin\theta_a\sin\varphi_a)$$

$$C_{\pm1}=(R_{a,b1})^{-7}(X_{a,b1}\sin\theta_a\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)$$

$$\times[(X_{a,b1}\pm iY_{a,b1})\cos\theta_a+Z_{a,b1}(\sin\theta_a\cos\varphi_a\pm i\sin\theta_a\sin\varphi_a)]$$

$$D_{\pm1}=(R_{a,b1})^{-9}(X_{a,b1}\sin\theta\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)^2Z_{a,b1}(X_{a,b1}\pm iY_{a,b1})$$

$$A_{\pm2}=(R_{a,b1})^{-7}(X_{a,b1}\pm iY_{a,b1})^2$$

$$B_{\pm2}=(R_{a,b1})^{-5}(\sin\theta_a\cos\varphi_a\pm i\sin\theta_a\sin\varphi_a)^2$$

$$C_{\pm2}=(R_{a,b1})^{-7}(X_{a,b1}\pm iY_{a,b1})(X_{a,b1}\sin\theta_a\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)$$

$$\times(\sin\theta_a\cos\varphi_a\pm i\sin\theta_a\sin\varphi_a)$$

$$D_{\pm2}=(R_{a,b1})^{-9}(X_{a,b1}\pm iY_{a,b1})^2(X_{a,b1}\sin\theta_a\cos\varphi_a+Y_{a,b1}\sin\theta_a\sin\varphi_a+Z_{a,b1}\cos\theta_a)^2 \qquad (2.13)$$

We expand each of (2.13) in powers of r/R, where r is half the inter-nuclear distance in a D_2 molecule and R the distance between the centres of the two molecules; $r/R=10\ll1$ if we take for R the mean distance in the actual crystal.

Since H_Q is the sum of $H_Q(a,b1)$ and $H_Q(a,b2)$ and invariant against the inversion of molecule b with respect to its centre, and since the matrix elements of i_{b1} have opposite signs to those of i_{b2}, as seen from (A. 4), we have only to retain those terms of the expansion which change sign under the inversion of molecule b. The first terms of expansion can be discarded for this reason, the second terms adopted and the higher order terms will be neglected.

§ 3. Result and Discussion

We seek the matrix elements of H_d+H_Q (H_d: the dipolar interaction) between the state a=para and b=para and the state a=para and b=ortho. The details of the calculation of such matrix elements with respect to the rotational states and spin states will be given in Appendices. The change of energy of the rotational state of molecule b, which converts into ortho from para, must be balanced by an emission of phonons. If we denote by ψ_T and ψ_T' the wave functions of the initial and final vibrational states of the lattice, the para-ortho transition probability is proportional to

$$\frac{1}{81}\sum|\langle a=\text{para},\ b=\text{para},\ T|$$

$$H_d+H_Q|a=\text{para},\ b=\text{ortho},\ T'\rangle|^2. \qquad (3.1)$$

The summation in (3.1) runs over the initial 81 and final 54 states. After calculating the matrix elements with respect to the rotational and spin states, the term due to the dipole interaction can be expressed as

$$\frac{1}{81}\sum_{i=0}^{9}C_i|\langle T|f_i|T'\rangle|^2 \qquad (3.2)$$

where f_i's are functions of the relative coordinates of the centres of molecules a and b and are given by eq. (A. 4) of paper (I) and

C_i's are

$$\begin{aligned} C_0 &= 102\,\mu_D^4[1+(\mu_R/\mu_D)^2] \\ C_1+C_2 &= 378\,\mu_D^4[1+(\mu_R/\mu_D)^2] \\ C_3+C_4 &= 4110\,\mu_D^4[1+(\mu_R/\mu_D)^2] \\ C_5 &= 648\,\mu_D^4[1+(\mu_R/\mu_D)^2] \\ C_6+C_7 &= 675\,\mu_D^4[1+(\mu_R/\mu_D)^2] \\ C_8+C_9 &= 648\,\mu_D^4[1+(\mu_R/\mu_D)^2] \end{aligned} \tag{3.3}$$

The other term due to the quadrupole interaction can be expressed as

$$\frac{1}{81}\sum_{i,\pm} d_i^{\pm} |<T|g_i^{\pm}|T'>|^2 \tag{3.4}$$

where g_i's are given in (B. 3) and d_i's are

$$\begin{aligned} d_0 &= \frac{27\times 9}{4}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \\ d_1^+ + d_1^- &= \frac{27^2\times 43}{32}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \\ d_2^+ + d_2^- &= \frac{63^2\times 135}{16}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \\ d_3^+ + d_3^- &= \frac{63^2\times 15}{32}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \\ d_4^+ + d_4^- &= \frac{189^2\times 21}{16}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \\ d_5^+ + d_5^- &= \frac{189^2\times 3}{16}\left[\frac{e^2 Q_D Q_{D_2}}{2i(i-1)}\right]^2 \end{aligned} \tag{3.5}$$

We express f_i and $g_i^{\pm}$ in terms of the lattice vibration coordinates by the same methods as that described in Appendix *B* of paper (I) taking the Debye approximation. We calculate the transition probability due to two phonons emission processes. The lattice constant of solid D_2 is a little smaller than that of solid H_2. Assuming the same value for the lattice constant for D_2 as that of H_2, the Debye temperature is found to be 64.4°K ($1/\sqrt{2}$ times of H_2), while the energy difference between the rotational states $J=1$ and $J=0$ is found to be 86°K (half that of H_2). Therefore, the one phonon emission process is impossible. The processes involving more than two phonons might be much less important than the two phonons emission processes, as they were in paper (I), and will be neglected. Necessary data for the calculation of the two phonons emission processes are as follows:

Difference in rotational energy between $J=1$ and $J=0$ (in temperature scale): $E_r=86°\mathrm{K}$

Debye temperature: $\Theta_D=64.4°\mathrm{K}$

Sound velocity: $v=0.722\times 10^5$ cm/sec

Density: $\rho=0.179$ gr/cm^3

Internuclear distance: $2r=0.74$ Å

Deuteron magnetic moment:

$\mu_D=4.329\times 10^{-24}$ (erg/gauss)[2)]

Rotational magnetic moment:

$\mu_R=0.517\times\mu_D$ (erg/gauss)[2)]

Nuclear quadrupole moment of D:

$Q_D=2.738\times 10^{-27}$ cm^2 [2)]

Quadrupole moment of D_2 molecule:

$Q_{D_2}=0.232\times 10^{-16}$ cm^2 [3)]

We denote the transition probabilities due to the dipole and the quadrupole interactions by $W_d(2)$ and $W_Q(2)$, respectively. The theoreticel results for the respective conversion rates are:

$$\begin{aligned} 12\,W_d(2) &= 0.502\times 10^{-4} \text{ per hour} \\ 12\,W_Q(2) &= 0.622\times 10^{-4} \text{ per hour} \\ \text{total:} &\quad 1.124\times 10^{-4} \text{ per hour} \end{aligned} \tag{3.6}$$

Thus, in deuterium, magnetic dipole-dipole interaction and the quadrupole interaction contribute nearly equally to the conversion rate, when only the change of para-para pairs into para-ortho pairs is considered. The total conversion rate is about 0.01 % per hour which is very small compared with the corresponding value in solid H_2 (2 % per hour). This difference is mainly due to the following. The magnetic moment of deuteron is about one third of that of hydrogen. The magnetic dipole interaction between two molecules is proportional to the second power of this ratio, and the conversion rate due to the magnetic interactions is proportional to its fourth power, i.e. 10^{-2}.

Next we calculate the conversion rate due to the interaction between the para-molecules and the ortho-molecules with $I=2$. We have to seek the matrix elements of H_d between the states a=ortho b=para and a=ortho b=ortho with respect to the rotational and spin states. The result can be expressed by the same formula as eq. (3.2) except that C_i's are now replaced by

$$\begin{aligned} C_0 &= 270\,\mu_D^4 \\ C_1+C_2 &= 630\,\mu_D^4 \\ C_3+C_4 &= 6750\,\mu_D^4 \\ C_5 &= 1080\,\mu_D^4 \\ C_6+C_7 &= 1125\,\mu_D^4 \\ C_8+C_9 &= 1080\,\mu_D^4 \end{aligned}$$

We denote the corresponding transition probability by $W_d'(2)$. The conversion rate is found to be

$$12W_d'(2)=1.106\times10^{-4} \text{ per hour.} \tag{3.8}$$

The above calculations show that the para-concentration c changes with time according to the equation

$$\frac{dc}{dt}=-kc^2-k'c(1-c) \tag{3.9}$$

where, according to (3.6) and (3.8) $k=1.124\times10^{-4}$ per hour and $k'=1.106\times10^{-4}$ per hour. Since k and k' are nearly equal each other, we find that c is determined by

$$\frac{dc}{dt}=-kc\,, \qquad c=c_0e^{-kt}\,. \tag{3.10}$$

In all the above calculations, we neglected, as in paper (I), the interferences of the twelve interactions between one molecule and its twelve neighbours. This is, however, valid since the rotational substate of each molecule changes very frequently during the life time of a para D_2 molecule (ortho-molecule in the case of H_2), so that the phase of the rotational substate of any one molecule becomes uncorrelated with the phases of the rotational substates of other molecules.*

§ 4. Effect of Oxygen Molecules Dissolved in Solid Deuterium

The oxygen molecule has a magnetic moment of two Bohr magnetons in its ground state, so that the ortho-para conversion rate is greatly enhanced by oxygen molecules contaminated in the solid hydrogen. Already, in paper (I), this effect was treated assuming the oxygen spins to be at rest and self-diffusion of the hydrogen molecules to be negligible. In another paper[4)] the effect of self-diffusion was discussed. We obtained the result that the rate of conversion of a hydrogen molecule at a distance R from each oxygen molecule is $250\times(R_0/R)^{12}$ per hour, so that the ortho-molecules in the neighbourhood of each oxygen molecule change to para in a relatively short time. This initial increase of para-concentration reasonably explained experiments.

In D_2 molecule, a similar phenomenon will occur. The coupling between the nuclear quadrupole moments of D_2 and the total quadrupole moment of O_2 molecule may be negligible compared with the effect of the magnetic dipole-dipole interactions, as the quadrupole moment of O_2 may be of the same order of magnitude as that of D_2. The transition probability for a D_2 molecule at a distance R from an oxygen molecule is calculated by the same method as that used in paper (I). Here, instead of previous C_i's given by (4.1) in paper (I), the following C_i's appear:

$$\begin{aligned} C_0&=18\,\mu_D^2\mu_{0_2}^2\\ C_1+C_2&=36\,\mu_D^2\mu_{0_2}^2\\ C_3+C_4&=225\,\mu_D^2\mu_{0_2}^2\\ C_5&=54\,\mu_D^2\mu_{0_2}^2 \end{aligned} \tag{4.1}$$

The result of the calculation is:

$$W_{oxy.}(2)=35.9\times(R_0/R)^{12} \text{ per hour} \tag{4.2}$$

This value is 1/7 times that for H_2. Comparing this result with (3.6), we find that at $R=3.54R_0$ the effect of an oxygen molecule and the effect of the mutual interaction of D_2 molecules become comparable.

The writer would like to express her sincere thanks to Professor T. Nagamiya for encouragement and helpful discussions. She is also indebted to Mr J. Kanamori for valuable comments and to Miss H. Kobayashi of Tōhoku University for kind communications of her experimental results prior to publication.

Appendix A. The matrix elements of the dipole and quadrupole interactions with respect to the spin states.

(a) The matrix elements of the dipole interaction.

The non-vanishing matrix elements of the spin operators, of molecule b with respect to states $I=1$ and $I=0$ of molecule b are as follows:

$$\begin{aligned} &\langle 1,0|i_{b1,z}|0\rangle=-2/\sqrt{6}\\ &\langle 1,1|i_{b1,x}+ii_{b1,y}|0\rangle=2/\sqrt{3}\\ &\langle 1,-1|i_{b1,x}-ii_{b1,y}|0\rangle=2/\sqrt{3} \end{aligned} \tag{A.1}$$

The matrix elements with respect to states $I=1$ and $I=2$ are:

$$\begin{aligned} &\langle 1,\pm1|i_{b1,z}|2,\pm1\rangle=\mp1/2\\ &\langle 1,0|i_{b1,z}|2,0\rangle=-1/\sqrt{3}\\ &\langle 1,\pm1|i_{b1,x}\pm ii_{b1,y}|2,0\rangle=-1/\sqrt{6}\\ &\langle 1,0|i_{b1,x}\pm ii_{b1,y}|2,\mp1\rangle=\mp1/\sqrt{2}\\ &\langle 1,\mp1|i_{b1,x}\pm ii_{b1,y}|2,\mp2\rangle=1 \end{aligned} \tag{A.2}$$

The matrix elements of i_{b2} have opposite signs to those of i_{b1}.

---

* The writer is indebted to Dr. M. Bloom of the University of Vancouver for this interpretation.

The non-vanishing matrix elements of the spin operators of molecule a with respect to substates of $I=2$ and $I=1$, respectively, are as follows:

$$\begin{aligned}
&\langle 2, \pm 2 | i_{aj,z} | 2, \pm 2\rangle = \pm 1 \\
&\langle 2, 1 | i_{aj,z} | 2, \pm 1\rangle = \pm 1/2 \\
&\langle 2, \pm 2 | i_{aj,x} \pm i i_{aj,y} | 2, \pm 1\rangle = 1 \\
&\langle 2, \pm 1 | i_{aj,x} \pm i i_{aj,y} | 2, 0\rangle = 3/\sqrt{6} \\
&\langle 2, 0 | i_{aj,x} \pm i i_{aj,y} | 2, \mp 1\rangle = 3/\sqrt{6} \qquad \text{(A.3)} \\
&\langle 2, \mp 1 | i_{aj,x} \pm i i_{aj,y} | 2, \mp 2\rangle = 1 \\
&\langle 1, \pm 1 | i_{aj,z} | 1, \pm 1\rangle = \pm 1/2 \\
&\langle 1, \pm 1 | i_{aj,x} \pm i i_{aj,y} | 1, 0\rangle = \pm 1/\sqrt{2} \\
&\langle 1, 0 | i_{aj,x} \pm i i_{aj,y} | 1, \mp 1\rangle = \mp 1/\sqrt{2} \\
&\qquad\qquad\qquad\qquad (j=1,\ 2)
\end{aligned}$$

(b) The matrix elements of the quadrupole interaction.

This interaction has no matrix elements between states of $I=1$ and $I=0$. The non-vanishing matrix elements between $I=1$ and $I=2$ of b-molecule are as follows:

$$\begin{aligned}
&\langle 1, \pm 1 | 3 i_{b1,z}^2 - i(i+1) | 2, \pm 1\rangle = -3/2 \\
&\langle 1, \pm 1 | (i_{b1,x} \pm i i_{b1,y}) i_{b1,z} \\
&\quad + i_{b1z}(i_{b1,x} \pm i i_{b1,y}) | 2, 0\rangle = \mp \sqrt{3}/\sqrt{2} \\
&\langle 1, 0 | (i_{b1,x} \pm i i_{b1,y}) i_{b1,z} \\
&\quad + i_{b1,z}(i_{b1,x} \pm i i_{b1,y}) | 2, \mp 1\rangle = -1/\sqrt{2} \qquad \text{(A.4)} \\
&\langle 1, \mp 1 | (i_{b1,x} \pm i i_{b1,y}) i_{b1,z} \\
&\quad + i_{b1,z}(i_{b1,x} \pm i i_{b1,y}) | 2, \mp 2\rangle = \mp 1 \\
&\langle 1, \pm 1 | (i_{b1,x} \pm i i_{b1,y})^2 | 2, \mp 1\rangle = -1 \\
&\langle 1, 0 | (i_{b1,x} \pm i i_{b1,y})^2 | 2, \mp 2\rangle = \mp \sqrt{2}
\end{aligned}$$

The matrix elements of i_{b2} have opposite sign to those of i_{b1}.

Appendix B. The matrix elements of the dipole and the quadrupole interactions with respect to the rotational states.

The matrix elements of the dipole interaction was given in (A.2) and (A.3) of paper (I).

The non-vanishing matrix elements of the quadrupole interaction between the states $J=1$ and $J=0$ of the b-molecule: Expanding eq. (2.13) in powers of r/R, the second terms are the function of the rotational coordinates of the b-molecule and contain the terms $\cos\theta_b$, $\sin\theta_b \cos\varphi_b$ and $\sin\theta_b \sin\varphi_b$. The matrix elements of these functions are:

$$\begin{aligned}
&\langle 1, 0 | \cos\theta_b | 0\rangle = 1/\sqrt{3} \\
&\langle 1, \pm 1 | \sin\theta_b \cos\varphi_b | 0\rangle = \pm 1/\sqrt{6} \qquad \text{(B.1)} \\
&\langle 1, \pm 1 | \sin\theta_b \sin\varphi_b | 0\rangle = -i/\sqrt{6}
\end{aligned}$$

Using these relations the matrix elements of each of A, B, C and D in (2.13) with respect to the rotational states of the b-molecule can be calculated.

The non-vanishing matrix elements of the quadrupole interaction between the sub-states of $J=1$ of the a-molecule: The second terms of (2.13), expanded in power of r/R, contain the several types of the function of the rotational coordinates of the a-molecule. The non-vanishing matrix elements of these functions are:

$$\begin{aligned}
&\langle \pm 1 | \zeta_a^2 | \pm 1\rangle = \frac{1}{5} \\
&\langle 0 | \zeta_a^2 | 0\rangle = \frac{3}{5} \\
&\langle \pm 1 | \zeta_a(\xi_a \pm i\eta_a) | 0\rangle = \mp \frac{\sqrt{2}}{5} \\
&\langle 0 | \zeta_a(\xi_a \pm i\eta_a) | \mp 1\rangle = \pm \frac{\sqrt{2}}{5} \\
&\langle \pm 1 | (\xi_a \pm i\eta_a)^2 | \mp 1\rangle = -\frac{4}{5} \\
&\langle \pm 1 | \xi_a^2 + \eta_a^2 | \pm 1\rangle = \frac{4}{5} \\
&\langle 0 | \xi_a^2 + \eta_a^2 | 0\rangle = \frac{2}{5} \\
&\langle \pm 1 | \zeta_a(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \pm 1\rangle = \frac{1}{5}\zeta \\
&\langle \pm 1 | \zeta_a(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | 0\rangle = \mp \frac{1}{5\sqrt{2}}(\xi \mp i\eta) \\
&\langle 0 | \zeta_a(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \pm 1\rangle = \mp \frac{1}{5\sqrt{2}}(\xi \pm i\eta) \\
&\langle 0 | \zeta_a(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | 0\rangle = \frac{3}{5}\zeta \qquad \text{(B.2)} \\
&\langle \pm 1 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \pm 1\rangle \\
&\quad = \langle \mp 1 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \mp 1\rangle \\
&\quad = \frac{2}{5}(\xi \pm i\eta) \\
&\langle \pm 1 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | 0\rangle \\
&\quad = \langle 0 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \pm 1\rangle \\
&\quad = \mp \frac{\sqrt{2}}{5}\zeta \\
&\langle \pm 1 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | \mp 1\rangle \\
&\quad = -\frac{2}{5}(\xi \mp i\eta) \\
&\langle 0 | (\xi_a \pm i\eta_a)(\xi\xi_a + \eta\eta_a + \zeta\zeta_a) | 0\rangle = \frac{1}{5}(\xi \pm i\eta)
\end{aligned}$$

$$\langle \pm 1|(\xi\xi_a+\eta\eta_a+\zeta\zeta_a)^2|\pm 1\rangle=\frac{1}{5}(2-\zeta^2)$$

$$\langle \pm 1|(\xi\xi_a+\eta\eta_a+\zeta\zeta_a)^2|0\rangle=\mp\frac{\sqrt{2}}{5}\zeta(\xi\mp i\eta)$$

$$\langle \pm 1|(\xi\xi_a+\eta\eta_a+\zeta\zeta_a)^2|\mp 1=-\frac{1}{5}(\xi\mp i\eta)^2$$

$$\langle 0|(\xi\xi_a+\eta\eta_a+\zeta\zeta_a)^2|\pm 1\rangle=\pm\frac{\sqrt{2}}{5}\zeta(\xi\pm i\eta)$$

$$\langle 0|(\xi\xi_a+\eta\eta_a+\zeta\zeta_a)^2|0\rangle=\frac{1}{5}(1+2\zeta^2)$$

where $\zeta_a=\cos\theta_a$, $\xi_a=\sin\theta_a\cos\varphi_a$ and $\eta_a=\sin\theta_a\sin\varphi_a$.

Using (B.1) and (B.2), the matrix elements with respect to the rotational states of a and b molecules can be obtained. The results are functions of the relative coordinates X, Y, and Z of the centres of molecules a and b which we will not reproduce here. The functions g_i are given as follows:

$$\begin{aligned}
g_0&=Z(15R^4-70R^2Z^2+63Z^4)r/R^{11}\\
g_1^\pm&=(X\pm iY)(R^4-12R^2Z^2+21Z^4)r/R^{11}\\
g_2^\pm&=(X\pm iY)^2Z(R^2-3Z^2)r/R^{11}\\
g_3^\pm&=(X\pm iY)^3(R^2-9Z^2)r/R^{11}\\
g_4^\pm&=(X\pm iY)^4Zr/R^{11}\\
g_5^\pm&=(X\pm iY)^5r/R^{11}
\end{aligned}\qquad\text{(B.3)}$$

Electromagnetic Fields due to Current Flowing Parallel to Interface of Two Different Media

By Kazuo HORIUCHI

Department of Electrical Communication Engineering, School of Science and Engineering, Waseda University

(Received September 12, 1956)

The electromagnetic fields due to the line and surface current flowing in one direction parallel to an interface of two different media are theoretically investigated. Whole problems are dealt with by integral equations of Wiener-Hopf type, and described from a relatively general point of view. Particularly, illustrative cases of a plane wave incident upon a conducting half-plane and a uniform line-current parallel to its rim are studied in detail, and the solutions are given in integral forms. The results may be applied to practical problems.

§ 1. Introduction

Exact solutions in diffraction theory are seldom given, apart from the representation by an infinite series of suitable orthogonal functions. The most classical exact solution in closed form has been obtained by Sommerfeld[1] for diffraction from a half-plane sheet. His basic concept lay in a multi-valued solution of the wave equation, which was naturally adapted to the wedge problem where the physical discontinuities are in inclined planes, as formulated by MacDonald[2]; and its generalization has recently been completed by Nomura[3].

Since integral equations were introduced into the diffraction theory[4], they have formed the basis of many modern investigations. Exact solutions can be obtained from these integral equations only when they are susceptible to the method of Wiener-Hopf5). Copson6) published a solution for a half-plane problem based on this procedure for the first time, and its generality was appreciated by Schwinger7). He pointed out that any diffraction problem might be formulated in the form of inhomogeneous Wiener-Hopf integral equations, in case where waves are incident upon a structure of parallel conducting plates or cylinders. On the basis of his suggestion, Carlson and Heins8) solved the problem of scattering of waves by an infinite set of staggered semi-infinite plates, Heins9) solved a similar problem with a pair of semi-infinite parallel plates, and Levine10) solved the scalar problem of radiation from the open end of a circular cylinder. After that, Schwinger himself11) made an effort for the extention of the Levine's problem to the vector field, and Iijima12) gave independently a more detailed solution.

The series of these investigations also forms a generalization of Sommerfeld's problem, although it is different from MacDonald's work. It is the special feature of this system that the physical discontinuities are in parallel planes.

Moreover, there are several other similar but more complicated problems; namely, problems of reflection, refraction and diffraction which occur from a half-plane in the interface of two different media. They are important in the theoretical treatment of radio propagation over an inhomogeneous earth. Clemmow13) suggested that for this problem appeal will have to be made to the general theory of Wiener-Hopf, although he could not solve it exactly himself.* His idea was concerned only with the plane wave incidence, but in this paper we shall investigate these problems from the most general point of view. If we consider the case that a half-plane conductor or a current distribution lies parallel to the interface of two media, then the problem has the same property as those described at the beginning, and, therefore, is susceptible to Schwinger's method in its current form. In this case, however, it is necessary to extend the Sommerfeld's representation of the field due to a horizontal antenna over the earth15), for reasons of the inhomogeneity of medium. Under these circumstances the solutions are greatly complicated.

§ 2. Formulation of Problems

Let us first consider a uniform horizontal line current in the x-direction above the earth, at $y=y_0$, $z=h$ as shown in Fig. 1. Then the fields are represented by the following formulas by the Hertzian vectors in x-direction Π_x and Π_{xe} for the two media, respectively.

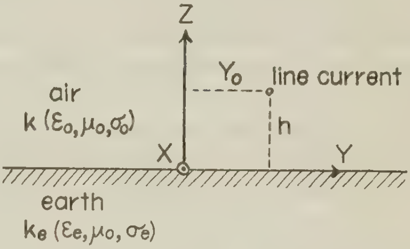

Fig. 1. A line current above the earth.

$$E_x=k^2\Pi_x\,,\qquad E_{xe}=k_e^2\Pi_{xe}\,,$$
$$H_y=\frac{k^2}{i\mu_0\omega}\frac{\partial\Pi_x}{\partial z}\,,\qquad H_{ye}=\frac{k_e^2}{i\mu_0\omega}\frac{\partial\Pi_{xe}}{\partial z}\,,\tag{1}$$

where

$$k^2=\mu_0\varepsilon_0\omega^2+i\omega\mu_0\sigma_0\,,\quad k_e^2=\mu_0\varepsilon_e\omega^2+i\omega\mu_0\sigma_e\,,$$

and it is assumed that the field-quantities have the harmonic time factor $\exp(-i\omega t)$ which is suppressed throughout. These Hertzian vectors are obtained by extending the Sommerfeld's solution for the horizontal antenna over the earth15), as follows:

$$\Pi_x(y,\,z;\,y_0,\,h)=\int_0^\infty\frac{d\lambda}{\mu}\cos\{\lambda(y-y_0)\}$$
$$\cdot\left\{e^{\mp(z-h)\mu}+\frac{\mu-\mu_e}{\mu+\mu_e}e^{-(z+h)\mu}\right\},\quad 0<z\gtrless h\tag{2}$$

$$\Pi_{xe}(y,\,z;\,y_0,\,h)$$
$$=\frac{2}{n^2}\int_0^\infty\frac{d\lambda}{\mu+\mu_e}e^{z\mu_e-h\mu}\cos\{\lambda(y-y_0)\}\,,\quad z<0\,,\tag{3}$$

where

---

*In reference 13) Clemmow gave relatively elegant solutions for the above series of problems by the method of the angular spectrum of plane waves, but only this problem he did not because of its complexity. Afterwards he investigated the same problem by his own method, but his theory is as yet incomplete in the sense that he excepted the difficult factorization of some important functions from his work14). Concerning this problem we will present a more complete theory in a separate paper.

$$\mu(\lambda)=\sqrt{\lambda^2-k^2}\,,\quad \mu_e(\lambda)=\sqrt{\lambda^2-k_e^2}$$

and

$$n=k_e/k\,.$$

The first term of Eq. (2) corresponds to the Hertzian vector for the line current located at $y=y_0$, $z=h$ in free space, and, therefore, may also be represented in the form of the zero order Hankel function:

$$(\pi i/2)H_0^{(1)}\{k\sqrt{(z-h)^2+(y-y_0)^2}\}\,.$$

If we use the above representations of the Hertzian vectors, the fields (1) automatically satisfy the boundary condition $E_x=E_{xe}$, $H_y=H_{ye}$ on the surface $z=0$.

When we wish to solve some problems of insertion of a third body into the system of two different media, *e.g.* air and earth, it is very convenient to consider an equivalent current distribution in place of the body. Particularly, if this current flows only in the x-direction, the aforementioned representations of the fields are very useful.

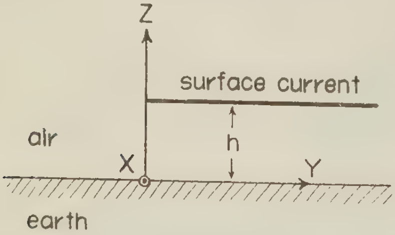

Fig. 2. A conducting half-plane above the earth.

Let us consider, as an illustrative case, a surface current flowing only in the x-direction, whose distribution is subject to a function $I(y)$ of the variable y, on the half-plane $z=h$, $y>0$, as in Fig. 2. Then, the fields due to such a current distribution are easily derived from the Hertzian vectors in the form:

$$\Pi_{\substack{x,\\xe}}(y,\,z)=\int_0^\infty I(y')\,\Pi_{\substack{x,\\xe}}(y,\,z;\,y',\,h)dy'\,, \quad (4)$$

where $\Pi_{\substack{x,\\xe}}$ under the integration are the same with the formulas of Eqs. (2) and (3). These fields also naturally satisfy the boundary conditions at $z=0$ and $z=h$, but the discontinuity of H_y occurs at the half-plane $z=h$, $y>0$ because of the surface current distribution in the x-direction. Since the density $J_x(y)$ of this surface current is measured by the discontinuity of H_y as follows

$$J_x(y)=\frac{2k^2}{i\mu_0\omega}\int_0^\infty dy'I(y')\int_0^\infty d\lambda\cos\{\lambda(y-y')\}\,, \quad (5)$$

$I(y)$ is related to the current density $J_x(y)$ by the formula

$$I(y)=\frac{i\mu_0\omega}{2\pi k^2}J_x(y)\,. \quad (6)$$

Such a current distribution is immeadiately and conveniently applied for the problem of plane wave incident upon a conducting half-plane on the earth, and for the problem of the similar conducting half-plane and a uniform line current parallel to its rim, and so on. We will investigate these problems in the following sections, in turn.

§3. A Plane Wave Incident upon A Conducting Half-Plane on the Earth

Let the half-plane $z=h$, $y>0$ on the earth be occupied by an infinitely thin, parfectly conducting sheet. Consider an incident plane wave E-polarized in which the electric field has only one component E_x^i in the x-direction given by

$$E_x^i=\exp\,[ikr\cos(\theta+\alpha)] \quad (7)$$

as in Fig. 3. Then on the conducting sheet a surface current in the x-direction is induced, which is subject to an unknown function $I(y)$. This conducting sheet, therefore, may be replaced by the surface current distribution as described in the preceding section.

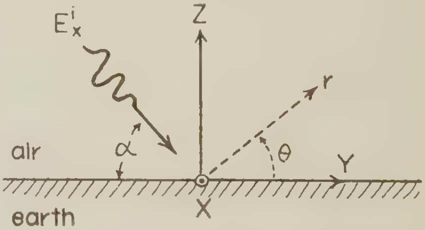

Fig. 3. An incident plane wave upon the earth.

In this case the fields consist of two parts. The first is the primary fields incident on, reflected from and transmitted through the boundary surface $z=0$, and always satisfies the boundary conditions at $z=0$. The second is the secondary fields produced by the surface current distribution on the conducting sheet. The latter also independently satisfies the condition of continuity at $z=0$ and $z=h$, provided the representations (4) are used. Thus, it is only necessary that the total electric field vanishes on the conducting sheet $z=h$, $y>0$. This condition leads to the next integral equation:

$$k^2\int_0^\infty dy'\, I(y')\int_0^\infty \frac{d\lambda}{\mu}\cos\{\lambda(y-y')\}$$
$$\cdot\left\{1+\frac{\mu-\mu_0}{\mu+\mu_e}e^{-2h\mu}\right\}+e^{iky\cos\alpha}$$
$$\cdot\{e^{-ikh\sin\alpha}-(1-T)e^{ikh\sin\alpha}\}=0 \qquad (8)$$

at $z=h$, $y>0$, where T is the transmission coefficient for the primary wave. Particularly, in the case $h=0$ the above equation is reduced to

$$k^2\int_0^\infty dy'\, I(y')\int_0^\infty \frac{2d\lambda}{\mu+\mu_e}\cos\{\lambda(y-y')\}$$
$$=-Te^{iky\cos\alpha}, \quad y>0. \qquad (9)$$

These equations are inhomogeneous integral equations of Wiener-Hopf type:

$$\int_0^\infty I(y')K(y-y')dy'=F(y), \quad y>0, \qquad (10)$$

and, therefore, our problems are converted into one of solving these integral equations with respect to the unknown function $I(y)$.

Now we confine ourselves to the case of $h=0$. Then the functions F and K in Eq. (10) have the following forms, respectively:

$$F(y)=-\frac{T}{k^2}e^{iky\cos\alpha},$$
$$K(y)=\int_0^\infty \frac{2d\lambda}{\mu+\mu_e}\cos(\lambda y), \qquad (11)$$

for $y>0$. If we define the following functions,

$$I(y)=\begin{cases} I(y), & y>0,\\ 0, & y<0;\end{cases}$$
$$F(y)=\begin{cases} F(y), & y>0,\\ 0, & y<0;\end{cases} \qquad (12)$$
$$G(y)=\begin{cases} 0, & y>0,\\ \int_0^\infty I(y')K(y-y')\,dy' & y<0;\end{cases}$$

then Eq. (10) is replaced by

$$\int_{-\infty}^\infty I(y')K(y-y')dy'=F(y)+G(y) \qquad (13)$$

for $-\infty<y<+\infty$. Let $\mathfrak{K}(\zeta)$, $\mathfrak{I}(\zeta)$, $\mathfrak{F}(\zeta)$ and $\mathfrak{G}(\zeta)$ be the Fourier transforms of $K(y)$, $I(y)$ $F(y)$ and $G(y)$, respectively. Then the Fourier transform of Eq. (13) formally becomes to

$$\mathfrak{I}(\zeta)\cdot\mathfrak{K}(\zeta)=\mathfrak{F}(\zeta)+\mathfrak{G}(\zeta). \qquad (14)$$

Now we easily find that

$$\mathfrak{K}(\zeta)=2\pi/\{\mu(\zeta)+\mu_e(\zeta)\} \qquad (15)$$

which is regular in the strip region

$$S:\quad |\mathscr{I}_m(\zeta)|<|\mathscr{I}_m(k)|, \qquad (16)$$

provided we assume

$$|\mathscr{I}_m(k)|\leq|\mathscr{I}_m(k_e)|,$$

and

$$\mathfrak{F}(\zeta)=\frac{T}{ik^2}\Big/(\zeta-k\cos\alpha) \qquad (17)$$

which is regular in the lower half-plane: $\mathscr{I}_m(\zeta)<\mathscr{I}_m(k\cos\alpha)$. The unknown function $\mathfrak{I}(\zeta)$ also is regular in the similar half-plane; *i.e.*, since we may assume for $I(y)$, a behavior like $\exp(i\kappa y)$ for large y, where $\mathscr{I}_m(\kappa)>0$, and then from the formula

$$\mathfrak{I}(\zeta)=\int_0^\infty I(y)e^{-i\zeta y}\,dy,$$

we find that $\mathfrak{I}(\zeta)$ will be regular in the lower half-plane $\mathscr{I}_m(\zeta)<\mathscr{I}_m(\kappa)$, which starts above the real axis in the ζ-plane. The other unknown function $\mathfrak{G}(\zeta)$, on the one hand, is regular in an upper half-plane starting below the real axis.

Next, let us consider a new function

$$\tau(\zeta)=\frac{2\mu(\zeta)}{\mu(\zeta)+\mu_e(\zeta)} \qquad (18)$$

which is regular in the strip S. Since $\tau(\zeta)\sim 1+O(1/\zeta)$ in S as $|\zeta|\to+\infty$, $\ln\tau(\zeta)\sim O(1/\zeta)$ in S as $|\zeta|\to+\infty$ on an appropriate branch of the ζ-plane. Thus $\ln\tau(\zeta)$ is regular in the whole strip-region S, and there we may apply the Cauchy's integral formula as follows

$$\ln\tau(\zeta)=\oint_C\frac{\ln\tau(t)}{t-\zeta}\,dt$$
$$=\int_{C_{(+)}}\frac{\ln\tau(t)}{t-\zeta}\,dt-\int_{C_{(-)}}\frac{\ln\tau(t)}{t-\zeta}\,dt, \qquad (19)$$

where ζ is an internal point of the contour C, and $C_{(+)}$, $C_{(-)}$ designate infinite straight

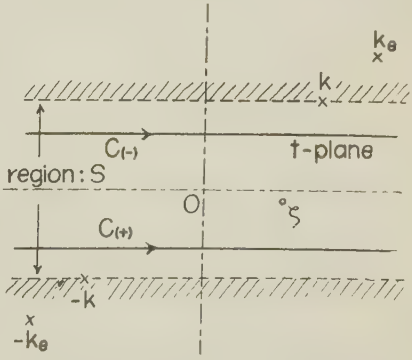

Fig. 4. Integration paths of Eq. (19).

line contours in the strip S as in Fig. 4. Let $\chi_{(+)}(\zeta)$, $\chi_{(-)}(\zeta)$ be the first and second integrals of Eq. (19), respectively, then $\exp\{\chi_{(+)}(\zeta)\}$, $\exp\{\chi_{(-)}(\zeta)\}$ may be analytically continued over the all ζ-plane, and the former is regular and different from zero in the upper half-plane of ζ above the line $C_{(+)}$ and the latter in the lower half-plane below $C_{(-)}$. Thus, we can represent $\mathfrak{K}(\zeta)$ as a quotient of functions $\mathfrak{K}_{(+)}(\zeta)$ and $\mathfrak{K}_{(-)}(\zeta)$, which are regular and not zero in the upper and lower half-planes, respectively:

$$\mathfrak{K}(\zeta)=\mathfrak{K}_{(+)}(\zeta)/\mathfrak{K}_{(-)}(\zeta)\,, \tag{20}$$

$$\left.\begin{aligned} \mathfrak{K}_{(+)}(\zeta)&=\pi^{1/2}\exp\{\chi_{(+)}(\zeta)\}\cdot/\sqrt{\zeta+k}\,,\\ \mathfrak{K}_{(-)}(\zeta)&=\pi^{-1/2}\exp\{\chi_{(-)}(\zeta)\}\cdot\sqrt{\zeta-k}\,. \end{aligned}\right\} \tag{21}$$

It is easily shown that these new functions behave in the following manner.

$$\begin{aligned} &\mathfrak{K}_{(+)}(\zeta)\sim O(\zeta^{-1/2}) \text{ as } |\zeta|\to+\infty,\\ &\qquad\qquad \mathscr{Im}(\zeta)>\mathscr{Im}(-k)\\ &\mathfrak{K}_{(-)}(\zeta)\sim O(\zeta^{1/2}) \text{ as } |\zeta|\to+\infty,\\ &\qquad\qquad \mathscr{Im}(\zeta)<\mathscr{Im}(k). \end{aligned}, \tag{22}$$

If Eq. (20) is inserted in Eq. (14) and suitable manipulations are applied, it follows that

$$\frac{\mathfrak{G}(\zeta)}{\mathfrak{K}_{(+)}(\zeta)}+\frac{(iT/k^2)}{\zeta-k\cos\alpha}\left\{\frac{1}{\mathfrak{K}_{(+)}(\zeta)}-\frac{1}{\mathfrak{K}_{(+)}(k\cos\alpha)}\right\}$$
$$=\frac{\mathfrak{J}(\zeta)}{\mathfrak{K}_{(-)}(\zeta)}-\frac{iT}{k^2}\cdot\frac{1}{(\zeta-k\cos\alpha)\cdot\mathfrak{K}_{(+)}(k\cos\alpha)}\,. \tag{23}$$

The left-hand side of Eq. (23) is regular in the upper half-plane and the right-hand side in the lower half-plane. Since these half-planes overlap each other, both sides may be considered as analytic continuations of each other and together they define an integral function throughout the ζ-plane. For absolute convergence of $I(y)$ and $G(y)$ in the interval including the point $y=0$, one may assume that

$$\begin{aligned} &\mathfrak{J}(\zeta)\sim O(\zeta^{\alpha-1})\,,\quad \alpha<1\,,\\ &\qquad\qquad \mathscr{Im}(\zeta)<\mathscr{Im}(k)\,,\\ &\mathfrak{G}(\zeta)\sim O(\zeta^{\beta-1})\,,\quad \beta<1\,,\\ &\qquad\qquad \mathscr{Im}(\zeta)>-\mathscr{Im}(-k)\,, \end{aligned} \tag{24}$$

as $|\zeta|\to+\infty$. Thus it turns out that both sides have algebraic behavior of negative fractional degree at infinity, and the integral function above defined is zero by a modification of *Liouville*'s theorem. Hence the left- and right-hand sides of Eq. (23) are identically zero, and this determines $\mathfrak{J}(\zeta)$ and $\mathfrak{G}(\zeta)$ simultaneously; for instance

$$\mathfrak{J}(\zeta)=\frac{iT}{k^2}\cdot\frac{\mathfrak{K}_{(-)}(\zeta)}{\mathfrak{K}_{(+)}(k\cos\alpha)}\cdot\frac{1}{\zeta-k\cos\alpha}\,, \tag{25}$$

and, moreover, by the inverse transformation,

$$I(y)=-\frac{T}{2\pi ik^2}\int_{i\eta-\infty}^{i\eta+\infty}\frac{\mathfrak{K}_{(-)}(\zeta)}{\mathfrak{K}_{(+)}(k\cos\alpha)}\cdot\frac{e^{i\zeta y}}{\zeta-k\cos\alpha}d\zeta\,, \tag{26}$$

where $\eta<\mathscr{Im}(k)$. It is easy to obtain formally the secondary fields produced by this current distribution $I(y)$ from these formulas.

In addition, since the function $\mathfrak{J}(\zeta)$ vanishes to the order $\zeta^{-1/2}$ as $|\zeta|\to+\infty$, it is to be noted that the density of the surface current behaves in the vicinity of its rim as follows

$$J_x(y)\sim O(y^{-1/2})\,,\ \text{as } y\to+0\,. \tag{27}$$

§ 4. A Conducting Half-Plane in Interface of Two Different Media and A Uniform Line-Current Parallel to Its Rim

In this section we consider the case that a uniform line-current parallel to the x-axis is located at $y=y_0$, $z=h$ and the half-plane $z=0$, $y>0$ is occupied by a conducting sheet, as in Fig. 5. In this case, too, the fields are represented by the primary fields due to the line-current and the secondary fields due to an unknown surface current $I(y)$ in the x-direction on the conducting sheet, just as in the preceding section.

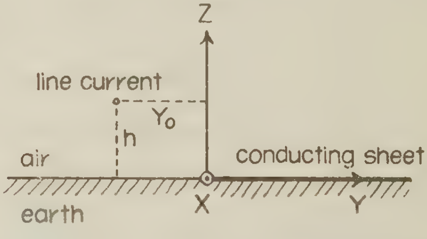

Fig. 5. A line current and a conducting half-plane on the earth.

Applying the representations in § 2, we can obtain the function $I(y)$ from the next equation

$$\int_0^\infty dy'\,I(y')\int_0^\infty\frac{2d\lambda}{\mu+\mu_e}\cos\{\lambda(y-y')\}$$
$$+\int_0^\infty\frac{2d\lambda}{\mu+\mu_e}e^{-h\mu}\cos\{\lambda(y-y_0)\}=0,\ y>0; \tag{28}$$

which follows from the boundary condition at the conducting surface $z=0$, $y>0$. Let $K(y)$ be the same as in Eq. (11) and $F(y)$ be

$$F(y)=-\int_0^\infty \frac{2d\lambda}{\mu+\mu_e} e^{-h\mu}\cos\{\lambda(y-y_0)\}, \tag{29}$$

then it is found that the above equation (28) has the same form as Eq. (10), which is the integral equation of Wiener-Hopf. If we consider that $I(y)$ vanishes for $y<0$, whereas $F(y)$ has the bounded values throughout $-\infty<y<+\infty$, and if we define a new function

$$G(y)=\begin{cases}\int_0^\infty I(y')K(y-y')dy'-F(y), & y<0,\\ 0, & y>0,\end{cases} \tag{30}$$

then the integral equation above described is rewritten into the same form as Eq. (13). Therefore, its Fourier transform becomes equal to Eq. (14), provided the same notations are adopted. In this case, $\mathfrak{K}(\zeta)$ is given by Eq. (15) and has the same behavior as in the preceding section, but

$$\mathfrak{F}(\zeta)=-\frac{2\pi}{\mu(\zeta)+\mu_e(\zeta)}e^{-i\zeta y_0-h\mu(\zeta)} \tag{31}$$

is regular in the strip region S as same as $\mathfrak{K}(\zeta)$. On the other hand, we may assume

$$\begin{aligned} I(y) &\sim \frac{1}{\sqrt{y}}e^{iky}, \quad \text{as} \quad y\to+\infty,\\ G(y) &\sim \frac{1}{\sqrt{-y}}e^{-iky}, \quad \text{as} \quad y\to-\infty; \end{aligned} \tag{32}$$

hence it is easily shown that $\mathfrak{J}(\zeta)$ and $\mathfrak{G}(\zeta)$ are regular in the lower half-plane $\mathscr{I}_m(\zeta)<\mathscr{I}_m(k)$ and the upper half-plane $\mathscr{I}_m(\zeta)>-\mathscr{I}_m(k)$, respectively.

Since $\mathfrak{K}(\zeta)$ is now factorized in the form of Eq. (20), we have, from Eq. (14),

$$\frac{1}{\mathfrak{K}_{(-)}(\zeta)}\exp[-i\zeta y_0-h\mu]=\frac{\mathfrak{G}(\zeta)}{\mathfrak{K}_{(+)}(\zeta)}-\frac{\mathfrak{J}(\zeta)}{\mathfrak{K}_{(-)}(\zeta)}, \tag{33}$$

an equation whose left-hand side is regular in the strip S, while the first and second terms of the right-hand side are regular in upper and lower half-planes, respectively. For absolute convergence of $I(y)$ and $G(y)$ in the interval including the vicinity of $y=0$, we may assume the same behavior of $\mathfrak{J}(\zeta)$ and $\mathfrak{G}(\zeta)$ at infinity as Eq. (24); hence the right-hand side of Eq. (33) has algebraic behavior of negative fractional degree at infinity. Thus, from transform theory, the inverse of the first term of the right-hand side of Eq. (33) vanishes for $y>0$, and the inverse of the second term vanishes for $y<0$. The inverse transform of the left-hand side exists over all y. Consequently, the inverse transform of the whole Eq. (33) becomes to

$$\int_{-\infty}^{+\infty}\frac{e^{-i\zeta y0-h\mu}}{\mathfrak{K}_{(-)}(\zeta)}\cdot e^{i\zeta y}d\zeta=j(y)+g(y), \qquad -\infty<y<+\infty, \tag{34}$$

where

$$\begin{aligned} j(y)&=0, \text{ for } y<0; =\int_{-\infty}^{+\infty}\frac{\mathfrak{J}(\zeta)}{\mathfrak{K}_{(-)}(\zeta)}e^{i\zeta y}d\zeta, \quad y>0;\\ g(y)&=\int_{-\infty}^{+\infty}\frac{\mathfrak{G}(\zeta)}{\mathfrak{K}_{(+)}(\zeta)}e^{i\zeta y}d\zeta, \text{ for } y<0;\\ &=0, \quad \text{for } y>0. \end{aligned} \tag{35}$$

Multiplying Eq. (34) by e^{-izy} and integrating over positive values of y, we have

$$\frac{\mathfrak{J}(z)}{\mathfrak{K}_{(-)}(z)}=\frac{1}{2\pi i}\int_{-\infty}^{+\infty}\frac{e^{-i\zeta y_0-h\mu(\zeta)}}{(\zeta-z)\cdot\mathfrak{K}_{(-)}(\zeta)}d\zeta, \tag{36}$$

which is regular in the lower half-plane $\mathscr{I}_m(\zeta)>\mathscr{I}_m(z)$. Hence the current distribution $I(y)$ is calculated from this formula by the inverse transformation as follows

$$I(y)=\frac{1}{2\pi}\int_{-\infty}^{+\infty}dz\,e^{izy}\cdot\frac{\mathfrak{K}_{(-)}(z)}{2\pi i}\int_{-\infty}^{+\infty}d\zeta \cdot\frac{e^{-i\zeta y_0-h\mu(\zeta)}}{(\zeta-z)\cdot\mathfrak{K}_{(-)}(\zeta)}, \tag{37}$$

where

$$|\mathscr{I}_m(\zeta)|<|\mathscr{I}_m(k)|, \ \mathscr{I}_m(\zeta)>\mathscr{I}_m(z), \ y>0.$$

It is the final expression for the current distribution.

§ 5. Final Representations of Fields

In our cases, the secondary fields are formulated in the form

$$f(y,z)=\int_0^{+\infty}dy'I(y')\int_0^{+\infty}d\lambda g\{\lambda;z\}\cos\{\lambda(y-y')\}, \tag{38}$$

where $g\{\lambda;z\}$ is always an even function with respect to λ, as shown in § 2, $I(y)$ is the inverse transform of $\mathfrak{J}(\zeta)$ and also the integration

$$G(y,z)=\int_0^{+\infty}d\lambda\, g\{\lambda;z\}\cos(\lambda y) \tag{39}$$

is the inverse transform of $g\{\lambda;z\}$ multiplied by π. Hence we easily find, by the *convolution* theorem of Fourier transforms, that

$$\begin{aligned} f(y,z)&=\int_0^{+\infty}dy'I(y')G(y-y';z)\\ &=\frac{1}{2}\int_{-\infty}^{+\infty}d\lambda\,\mathfrak{J}(\lambda)\cdot g\{\lambda;z\}e^{i\lambda y}. \end{aligned} \tag{40}$$

Thus, we can directly obtain the secondary fields from the transform $\mathfrak{J}(\zeta)$ of $I(y)$ rather than from $I(y)$ itself, calculating the integrals as Eq. (40).

§ 6. Conclusion

We have rigorously investigated, in this paper, the problems of the line and surface current flowing in one direction parallel to an interface of two different media. Whole problems have been dealt with by the integral equations of Wiener-Hopf type, and described from the relatively general point of view.

They are problems having a theoretical interest, but the results here obtained may be applied to several practical problems: wave propagations over the inhomogeneous earth, effects of snow in microwave transmission systems and diffraction of waves by a mountain-chain which divides the atmosphere into two parts whose meteorological properties are different, and so on. It is necessary, however, to give more detailed or rather numerical solutions, which we shall investigate in other paper.

Particularly, the solution of § 3 is important because it leads to the analysis of the problems of reflection, refraction and diffraction due to a screen which lies in an interface of of two different media.

In conclusion, it is a pleasure for the author to express his sincere gratitude to Professor T. Hirota and Assistant Professor T. Soejima who have given kind encouragements and helpful advices.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 2, FEBRUARY, 1957

On the Hypersonic Viscous Flow past a Flat Plate with Suction or Injection

By Michiru YASUHARA

Institute of Science and Technology, University of Tokyo

(Received June 28, 1956)

The hypersonic viscous flow past a flat plate with suction or injection is dealt with by Kármán-Pohlhausen's method in special cases when suction or injection velocity proportional to $p_B^{1/2}$ or $x^{-1/4}$, especially for the region of strong interaction between the shock wave and the boundary layer, were p_B is the pressure on the plate and x is the distance measured along the plate from its leading edge.

Several numerical examples are given, which shows similar effects of injection to those in the case of incompressible flow that the injection makes all the height of the shock wave, the thickness of the boundary layer and the pressure on the plate larger than those in the case of no injection. On the contrary, in the case of suction no remarkable change both in the height of the shock wave and the pressure on the plate can be seen and only the velocity profile in the boundary layer is affected by the suction.

§ 1. Introduction

Recently various investigations have been made on the hypersonic viscous flow over slender bodies, and the results have led us to expect that the thickness of the boundary layer becomes larger and larger with increasing Mach number and at the same time the temperature on the body becomes higher and higher. Therefore it may be expected that strong suction will be necessary to keep the thickness of the boundary layer within a small amount, while the surface cooling or injection will be required to avoid the extremely high temperature on the body.

The purpose of the present paper is to estimate the effects of suction or injection on the region of strong interaction between the shock wave and the boundary layer. Either suction or injection may be used for the boundary-layer control and the surface cooling etc. in high-speed flights.

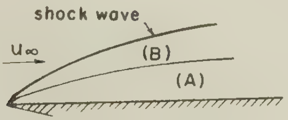

Fig. 1. Flow model on a flat plate.

As a preliminary, we first consider the hypersonic viscous flow past a plate without suction as shown in Fig. 1. As suggested by various previous writers, a shock wave emanates from the leading edge of the plate and the boundary layer is also formed on the plate. In this case, the flow field between the shock wave and the plate can be divided into two regions: In region (A) extending from the plate part of the way to the shock wave, viscous effects are important but the pressure change across it is so small that boundary layer theory may be used to describe the flow within it. Between the shock wave and the region (A), which is nothing but the boundary layer, there is a region (B) in which the effects of viscosity are small, but large entropy gradients occur near the junction with the region (A). This region (B) is called the "inviscid layer."

A region far behind the leading edge of the plate was investigated by Lees and Probstein$^{1)}$. Shen, Li and Nagamatsu$^{2)}$ investigated a region in which the interaction between the shock wave and the boundary layer is strong, assuming that the shock wave coincides with the outer edge of the region (A), and they found that there exists a similar solution throughout the region (A). Recently, Stewartson$^{3)}$ also discussed the problem more accurately by considering the existence of the region (B) and showed that there exists a similar solution in the region (B), too, which may be joined up to that in the region (A) without inconsistency.

Similar argument may be assumed to be valid also in cases when there is suction or injection on the plate, provided that the suction or injection is of moderate strength not to violate the boundary-layer approximation, and the object of the present paper is to discuss the effects of such a suction or injection on the height of the shock wave, the thickness of the boundary layer and the pressure on the plate.

§2. Equations of Motion and their Solutions

2.1 General Equations of Motion

Taking a flat plate occupying the positive half of the x-axis, we assume that the fluid flows along it with uniform velocity u_∞ at infinity and that a shock wave emanates from the leading edge of the plate (Fig. 2).

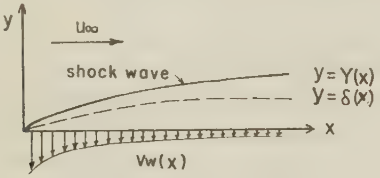

Fig. 2. Flow model on a flat plate with suction.

We denote by p the pressure, ρ the density, μ the coefficient of viscosity, T the temperature, y the distance normal to the plate, u, v the components of the fluid velocity in the x, y directions, respectively, and c_p the specific heat at constant pressure of the fluid. Also, let the equation of the shock wave be

$$Y=Y(x)\,, \tag{1}$$

where Y is for the present unknown.

Throughout this paper, subscripts ∞, s, and w represent quantities at infinity, those just behind the shock wave, and those on the wall, respectively.

We now assume that the flow behind the shock wave either inviscid or of the boundary-layer type in which the pressure is a function of x only, and then we consider the following system of equations:

$$\frac{\partial(\rho u)}{\partial x}+\frac{\partial(\rho v)}{\partial y}=0\,, \tag{2}$$

$$\rho u\frac{\partial u}{\partial x}+\rho v\frac{\partial u}{\partial y}=-\frac{\partial p}{\partial x}+\frac{\partial}{\partial y}\left(\mu\frac{\partial u}{\partial y}\right), \tag{3}$$

$$\rho u\frac{\partial v}{\partial x}+\rho v\frac{\partial v}{\partial y}=-\frac{\partial p}{\partial y}\,, \tag{4}$$

$$\rho u\frac{\partial(C_pT)}{\partial x}+\rho v\frac{\partial(C_pT)}{\partial y}-u\frac{\partial p}{\partial x}-v\frac{\partial p}{\partial y}=\mu\left(\frac{\partial u}{\partial y}\right)^2+\frac{\partial}{\partial y}\left\{\frac{\mu}{P_r}\frac{\partial(C_pT)}{\partial y}\right\}, \tag{5}$$

$$p/p_\infty=\rho T/\rho_\infty T_\infty\,, \tag{6}$$

where P_r is the Prandtl number. Equation (2) is the equation of continuity valid everywhere. Equation (3) is from the x-component of the momentum equation valid in the boundary layer regime and in the inviscid regime. Equation (4) is from the y-component of the momentum equation valid in the inviscid layer. In the boundary layer its effect on p must be negligible. Equation (5) is the energy equation valid in both regions, and Equation (6) is the equation of state valid everywhere. There are many terms neglected in these equations, but as shown by Stewartson, their effect is negligible if $Y\ll x$, and u can be replaced by u_∞ in the inviscid layer[3)].

Throughout this paper it is assumed that the fluid possesses the properties

$$P_r=1\,,\qquad \mu/\mu_\infty=CT/T_\infty\,, \tag{7}$$

where

$$C=\left(\frac{T_w}{T_\infty}\right)^{1/2}\frac{(T_\infty+S)}{(T_w+S)}\,,$$

and S denotes Sutherland's constant.

Now, on the plate $y=0$, $x>0$,

$$u=0,\quad v=v_w,\quad \partial T/\partial y=0,$$

taking it to be thermally insulated and with suction or injection velocity on the plate, where $v_w{}^2\ll u_\infty{}^2$. Then, the equations of motion have a simple integral

$$\frac{T}{T_\infty}=1+\frac{\gamma-1}{2a^2_\infty}(u^2_\infty-u^2-v^2)\,, \tag{8}$$

where a_∞ represents the velocity of sound in the undisturbed flow, and v is neglected in comparison with u_∞ in the boundary layer.

2.2 Inviscid Layer

Under above fundamentals, Stewarton discussed the solution in the inviscid layer using a stream function ψ defined by

$$\left.\begin{aligned}\rho_\infty\frac{\partial\psi}{\partial y}&=\rho u\,,\\ \rho_\infty\frac{\partial\psi}{\partial x}&=-\rho v\,.\end{aligned}\right\} \tag{9}$$

The results are as follows. If the equation of the shock wave is assumed to be

$$Y=\vartheta x^{3/4}(1+\alpha x^{1/2}+\cdots\cdot), \tag{10}$$

where the reason that $x^{3/4}$ is chosen as the leading term will be discussed in 2.3, and, if the following expressions are used,

$$\begin{aligned}
\eta&=\psi/u_\infty Y\ ,\\
v&=\{2u_\infty/(\gamma+1)\}(dY/dx)\,V(\eta,x)\ ,\\
p/p_\infty&=\{2\gamma M^2_\infty/(\gamma+1)\}(dY/dx)^2\,P(\eta,x)\ ,\\
V&=V_0(\eta)-x^{1/2}[4\alpha V_1(\eta)/3\\
&\qquad+16V_2(\eta)/9M^2_\infty\vartheta^2]+\cdots\ ,\\
P&=P_0(\eta)-x^{1/2}[4\alpha P_1(\eta)/3\\
&\qquad+16P_2(\eta)/9M^2_\infty\vartheta^2]+\cdots\ ,
\end{aligned} \tag{11}$$

the ordinary differential equations for P_0, V_0, P_1, V_1, $\cdots$ are obtained, which were integrated by Stewarton numerically, and it was found at $\eta=0$ that

$$\left.\begin{aligned}P_0&=0.599\ , & P_1&=-1.64\ , & P_2&=1.285\ ,\\ V_0&=0.711\ , & V_1&=-2.04\ , & V_2&=2.49\ ,\end{aligned}\right\} \tag{12}$$

taking $\gamma=1.4$ for air. Since ψ is a measure of the mass of fluid confined between the shock wave and the plate, almost mass of fluid is contained between $\eta=1$ and $\eta=0$, that is, in the inviscid layer. Lastly, it is convenient to give the value of y instead of v at the end of the inviscid layer. From the definition of ψ in Eq. (9), we find

$$v_E\equiv v_{\eta=0}=\left\{u\left(\frac{\partial y}{\partial x}\right)_\psi\right\}_{\eta=0}=u_\infty\frac{dy_E}{dx}\ ,$$

and therefore

$$y_E=\int_0^\infty\frac{v_B}{u_E}\,dx\ , \tag{13}$$

where suffix E denotes quantities at $\eta=0$ in the inviscid layer. As v at $\eta=0$ is obtained from Eqs. (11) and (12) when $\gamma=1.4$, y_E can be calculated by using Eq. (13), and the result is given by

$$y_E=\frac{2Y(x)}{\gamma+1}\left[V_0(0)-\frac{3}{5}\left\{\frac{4}{3}\alpha V_1(0)+\frac{16}{9M^2_\infty\vartheta^2}V_0(0)\right\}x^{1/2}+\cdots\cdot\right]. \tag{14}$$

2.3 *Boundary Layer*

The dominant equations of motion in the boundary layer are Eqs. (2) and (3), with boundary conditions $u=0$, $v=v_w$ at $y=0$ and $u=u_B$ outside the boundary layer, and Eq. (4) is reduced to $\partial p/\partial y=0$, that is, $p=p(x)$, where suffix B represents quantities outside the boundary layer. This boundary condition can be replaced by $u\to u_\infty$ as $y\to y_B$, where y_B is the thickness of the boundary layer and corresponds to y at $\eta=0$ in the inviscid layer. The adoptability of the latter condition is shown as follows.

$\eta=0$ corresponds to a stream line $\psi=0$ of the inviscid layer as seen from Eq. (11). While from Eqs. (2), (3) and (9) with the aid of Eq. (8) in which v must be neglected in this layer, the value of v at the boundary layer is reduced to

$$\begin{aligned}
v_B&=\left[u\frac{\partial}{\partial x}\int_{\psi_w}^{\psi}\frac{\rho_\infty}{\rho u}\,d\psi\right]_B\\
&=\left[u\frac{\partial}{\partial x}\int_{\psi_w}^{\psi}\frac{p_\infty}{pu}\left\{1+\frac{\gamma-1}{2a^2_\infty}(u^2_\infty-u^2)\right\}d\psi\right]_B,
\end{aligned}$$

where ψ_w respresents the value of ψ at the wall and is a function of x. The term unity in the bracket of the above equation can be neglected, since in the boundary layer

$$1\ll\{(\gamma-1)/2a^2_\infty\}(u^2_\infty-u^2)\ .$$

Futher, the upper limit of the integration can be replaced by ∞, since when ψ is large on the scale of the boundary layer, $u-u_\infty$ is exponentially small as shown by Stewartson. At the edge of the boundary layer therefore

$$v_B=\frac{\gamma-1}{2}M^2_\infty u_\infty\frac{d}{dx}\left\{\frac{p_\infty}{p_B}\int_{\psi_w}^\infty\left(\frac{u_\infty}{u}-\frac{u}{u_\infty}\right)d\psi\right\}, \tag{15}$$

since $p=p(x)=p_w=p_B$ and $u=u_\infty$ there. In the boundary layer, the pressure will be represented by p_B. In the same way, from Eq. (9), y_B is reduced to

$$y_B=y_{\psi\to\infty}=\frac{\gamma-1}{2}M^2_\infty\frac{p_\infty}{p_B}\int_{\psi_w}^\infty\left(\frac{u_\infty}{u}-\frac{u}{u_\infty}\right)d\psi.$$

Comparing the above equation with Eq. (15), the following relation is deduced:

$$v_B=u_\infty\frac{dy_B}{dx}\ , \tag{16}$$

which shows that the outer edge of the boundary layer also corresponds to a stream line. From Eqs. (13) and (16), if a match of v between the inviscid solution at $\psi=0$ and the boundary-layer solution for $\psi=\infty$ is effected, the value of y between both layers is done smoothly.

In the present paper, Kármán-Pohlhausen's approximation is used to discuss the boundary layer. Integrating Eqs. (2) and (3) over the boundary layer, and combining these, the following momentum integral relation is obtained:

$$\frac{\tau_w}{\rho_\infty u^2_\infty} \equiv \frac{(\mu \partial u/\partial y)_w}{\rho_\infty u^2_\infty}$$
$$= \frac{2}{(\gamma-1)M^2_\infty} \frac{d}{dx} \left\{ \frac{p_B}{p_\infty} \int_0^\delta \frac{u/u_\infty}{1+(u/u_\infty)} dy \right\}$$
$$- \frac{\delta}{\gamma M^2_\infty} \frac{d}{dx} \left(\frac{p_B}{p_\infty} \right) - \frac{\rho_w v_w}{\rho_\infty u_\infty} , \tag{17}$$

where δ corresponds to y_B approximated in Kármán-Pohlhausen's sense. The above relation have been used by Shen, Li and Nagamatsu[2)] in their treatment of the hypersonic Shock wave boundary layer interaction problems in case when $v_w=0$.

As in the case of incompressible boundary layer, we now put

$$u/u_\infty = f(\xi) , \quad \xi = y/\delta , \tag{18}$$

where $f(\xi)$ is a polynomial of ξ of any degree. It is well known that in the case of imcompressible boundary layer, the quartic form of $f(\xi)$, i.e. a polynomial of degree four, gives plausible results and that no more accuracy can be gained by considering a polynomial of higher degree. However, it is not certain whether the situation is similar in the present problem or not.

In the present paper, the quadratic form of $f(\xi)$, i.e. a polynomial of degree two, is used for reason described later on. Thus,

$$f(\xi) = \xi + \frac{\Lambda}{2} \xi (1-\xi) . \tag{19}$$

Then, Eq. (2) is reduced to

$$\rho_w v_w u_\infty \delta \left(1 + \frac{\Lambda}{2} \right) = - \delta^2 \frac{dp_B}{dx} - \mu_w u_\infty \Lambda , \tag{20}$$

at the wall, taking the plate to be thermally insulated, i.e. $(\partial T/\partial y)_w = 0$.

Further, if we introduce a function $F(\Lambda)$ defined by

$$F(\Lambda) \equiv \int_0^1 \frac{d\xi}{1+f(\xi)} , \tag{21}$$

Eq. (17) is reduced to

$$\frac{\mu_w \left(1 + \frac{\Lambda}{2} \right)}{\rho_\infty u_\infty} = \frac{2\delta}{(\gamma-1)M^2_\infty} \frac{d}{dx} \left[\frac{p_B}{p_w} \delta \{ 1 - F(\Lambda) \} \right]$$
$$- \frac{\delta^2}{\gamma M^2_\infty} \frac{d}{dx} \left(\frac{p_B}{p_\infty} \right) - \frac{\rho_w v_w}{\rho_\infty u_\infty} \cdot \delta , \tag{22}$$

Now, we shall here confirm that the form of the shock wave as assumed in Eq. (10) is consistent. If $Y \sim x^n$, we have from Eqs. (11) and (14) $p_B \sim x^{2(n-1)}$ and $y_B \sim x^n$ when x is small, since V_0 and P_0 are functions of η only. While we see from Eqs. (20) and (22) that if $p_B \sim x^{2(n-1)}$

$$\delta \sim 1/\sqrt{\ } dp_B/dx \sim x^{3/2-n} ,$$

in order to make the expanded form of Λ in power series of x begin with a constant term, when $v_w=0$. Therefore for consistency of y_B and δ, we must have $n=3/2-n$, whence $n=3/4$. The existence of such n in the boundary layer was first demonstrated by Li, Nagamatsu, and Stewartson showed that such n also exists in the inviscid layer. Referring to Eqs. (20) and (22), it is easily known that if $\rho_w v_w \sim x^{-3/4}$, the similar solution exists also in case when $v_w \not\fallingdotseq 0$.

Next, the evaluation of the term $\rho_w v_w$ will be discussed. From Eq. (8) we have on the wall

$$\frac{\rho_w}{\rho_\infty} \doteq \frac{2}{(\gamma-1)M^2_\infty} \frac{p_B}{p_\infty} \sim x^{-1/2} ,$$

and therefore if $v_w \sim x^m$, then $\rho_w v_w \sim x^{-1/2+m}$ and the similar solution exists when $-1/2+m = -3/4$ or $m=-1/4$. Whence $v_w \sim {}^{-1/4} \sim p_B{}^{1/2}$ garantees the existence of the similar solution. Recently, porous wall methods have been used as a transonic wind tunnel technique with great interest, which suggest that the flow velocity v_w passing through the wall is proportional to $(p_w - p_a)$ near the transonic range where p_a represents the pressure in the plenum chamber, and $v_w \sim (p_w - p_a)^{1/1.3}$ at slightly higher Mach number range. Though these experimental relations have not yet been investigated in the high supersonic range, it seems to be plausible to consider the case when the power is equal to 1/2 as a model. This model just corresponds to $v_w \sim p_B{}^{1/2}$.

Based upon the above discussions, it is assumed that there exists the following relation:

$$\frac{\rho_w v_w}{\rho_\infty u_\infty} = \frac{2}{(\gamma-1)M^2_\infty} \frac{p_B}{p_\infty} \alpha \left(\frac{p_B}{p_\infty} \right)^{1/2}$$
$$= \frac{2}{(\gamma-1)M^2_\infty} \left(\frac{p_B}{p_\infty} \right)^{3/2} , \tag{23}$$

where α denotes a proportionality factor. In the case of suction $\alpha < 0$.

In the case of injection $(\alpha > 0)$ we assume also that the injection velocity along the wall is proportional to $p_w{}^{1/2}$, or more directly to $x^{-1/4}$. Although its physical meaning is not clear, yet numerical calculations for this case have also been carried out for the purpose of estimating the injection effect.

2.4 Matching Procedure

Now, a match between the inviscid solution at $\psi=0$ and the boundary layer solution for $\psi\to\infty$ will be effected. For the discussion about such conditions reference should be made to Stewarton's paper. It was shown in 2.2 that if the equation of the shock wave is given by Eq. (10), p_E/p_∞ and y_E at the inner edge of the inviscid layer are obtained by setting $\eta=0$ in Eqs. (11) and (14). On the other hand, p_B/p_∞ and δ must be satisfied by Eqs. (20) and (22), and therefore solutions matching at the boundary of both layers can be obtained by making $p_E/p_\infty=p_B/p_\infty$ and $y_E=\delta$. By introducing the following relations

$$\delta \doteq y_B = \frac{2}{(\gamma+1)} V_0(0)\,\vartheta\, x^{3/4}+\cdots ,$$

$$\frac{p_B}{p_\infty}=\frac{p_E}{p_\infty}=\frac{9\gamma M^2_\infty}{8(\gamma+1)}P_0(0)\vartheta^2 x^{-1/2}+\cdots , \tag{24}$$

into Eqs. (20) and (22), equations for determining ϑ and Λ can be obtained. From these equations together with Eqs. (19) and (21), Λ and ϑ are determined, where ϑ is of the form

$$\vartheta=\theta\left(\frac{M^2_\infty C\mu_\infty}{\rho_\infty u_\infty}\right)^{1/4}\equiv\theta L^{1/4}, \tag{25}$$

and Y, δ, v_B/u_∞, P_B/P_∞ and $\tau_w/\rho_\infty u^2_\infty$ are obtained as follows:

$$Y=\theta\left(\frac{L}{x}\right)^{1/4}x+0\,(x^{5/4})\equiv R_S\left(\frac{L}{x}\right)^{1/4}x+\cdots ,$$

$$\delta=\frac{2V_0(0)\theta}{(\gamma+1)}\cdot\left(\frac{L}{x}\right)^{1/4}x+0(x^{5/4})\equiv\Lambda\cdot\left(\frac{L}{x}\right)^{1/4}x+\cdots ,$$

$$\frac{v_B}{u_\infty}=\frac{3V_0(0)\theta}{2(\gamma+1)}\left(\frac{L}{x}\right)^{1/4}+0(x^{1/4})\equiv V_B\left(\frac{L}{x}\right)^{1/4}x+\cdots ,$$

$$\frac{p_w}{p_\infty}=\frac{p_B}{p_\infty}=\frac{9\gamma P_0(0)\theta^2}{8(\gamma+1)}\left(\frac{LM^4_\infty}{x}\right)^{1/2}+0(1)$$
$$\equiv P_w\left(\frac{LM^2_\infty}{x}\right)^{1/2}+\cdots .$$

$$\frac{\tau_w}{\rho_\infty u^2_\infty}=\frac{(\gamma^2-1)\left(1+\frac{\Lambda}{2}\right)}{2V_0(0)\,\theta}\left(\frac{L}{x}\right)^{3/4}+0(x^{-1/4})$$
$$\equiv S_w\left(\frac{L}{x}\right)^{3/4}+\cdots . \tag{26}$$

It is required to determine the region of validity of Eqs. (2) to (6) and of the division of the flow field into a boundary layer and an inviscid layer. Stewartson found that the region of validity is restricted by the condition $(Y/x)^2\ll 1$, and further that the flow field may be divided into inviscid and viscous fields if, in terms of ψ, the thickness of the viscous layer is much thinner than that of inviscid field. The situation is the same in the present problem, too. For the detail of the reduction procedure, the reader may be referred to Stewartson's paper. Combining above results and the condition of convergency of the power series, it is known that the results of the present paper should be taken to be valid in the range

$$\frac{M^2_\infty C\mu_\infty}{\rho_\infty u_\infty}\ll x\ll\frac{M^2_\infty C\mu_\infty}{\rho_\infty u_\infty},$$
$$\alpha=0\,(1/M^2_\infty)\ , \tag{27}$$

The lower bound is also the lower bound for the validity of the assumption of a continuum. Further, errors caused by Kármán-Pohlhausen's approximation should be estimated, these are not discussed exactly in the present paper, but concerning the values of Y, δ, and p_B/p_∞ when $\alpha=0$, comparison with Stewartson's results as shown in Table I may be of use for the present purpose.

Table I. Comparison of numerical values for the flat plate without suction

	R_S	Λ	P_w
Stewartson's result	1.188	0.704	0.555
Kármán-Pohlhausen's approximation			
Quadratic	1.245	0.738	0.602
Quartic	1.387	0.822	0.756
Sextic	1.505	0.892	0.890

§ 3. Numerical Results and Discussions

Numerical values for the present problem are compared with Stewartson's ones in Table I in case when $v_w=0$. From the table, it will be seen that polynomials of lower degree give more plausible values than polynomials of higher degree. Thus, our calculations have been confined only to the quadratic form of $f(\xi)$.

It is known from Eq. (26) that effects of suction or injection can be characterized by the term θ and Λ which are functions of γ and αM^2_∞. Fig. 3 shows the values of $z\equiv\theta/\theta_{\alpha=0}$ and z^2 for several values of αM^2_∞ when $\gamma=1.4$. Y, δ, and v_B are proportional to z, and p_B is proportional to z^2. Fig. 4 shows the coefficient S_w of the shear stress.

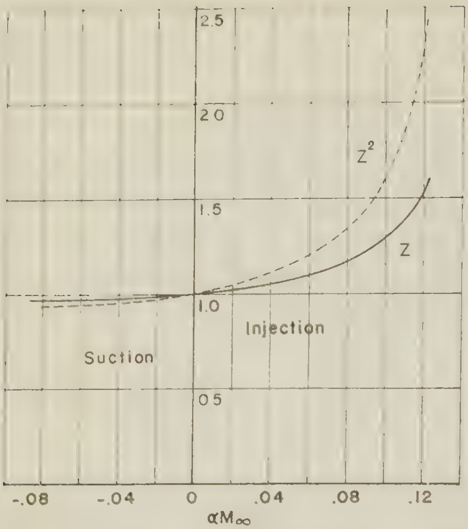

Fig. 3. Relation between αM_∞ and z or z^2.

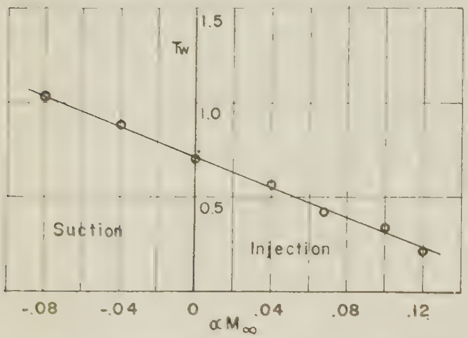

Fig. 4. Relation between αM_∞ and S_w.

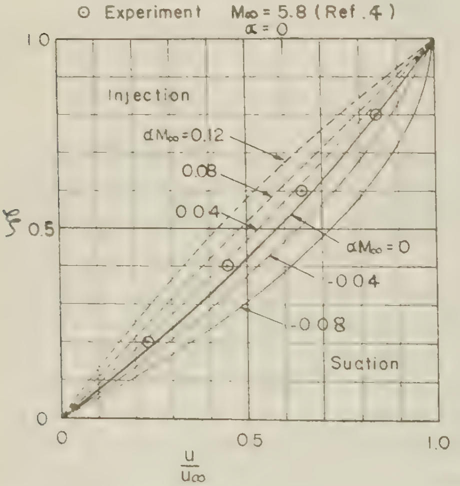

Fig. 5. Velocity profiles in the boundary layer.

Fig. 5 shows the velocity profiles for several values of αM^2_∞. Fig. 3 shows that z does not diminish sensibly with increasing $-\alpha M^2_\infty$, the suction parameter, and therefore also Y, δ, v_B, and $p_w = p_B$ are not affected sensibly by the suction in contrast to the ordinary boundary-layer theory, while visible effects can be seen in the velocity profile and the shear stress as shown in Figs. 4 and 5. On the contrary, z increases with increasing αM^2_∞, the injection parameter, and therefore Y, δ, v_B and p_B are also increased, while the shear stress decreased as expected from the ordinary boundary-layer theory. It should be remarked, however that these results are concerned with the leading term of each quantity, and further that our results are only valid in cases when $v_w \sim p_B^{1/2} \sim x^{-1/4}$.

§ 4. Conclusion

The hypersonic viscous flow past a flat plate with suction or injection is dealt with by Kármán-Pohlhausen's method in special cases when suction or injection velocity is proportional to $p_B^{1/2}$ or $x^{-1/4}$, especially for the region of strong interaction between the shock wave and the boundary layer, where p_B is the pressure on the plate and x is the distance measured along the plate from its leading edge. Several numerical examples are given, which show similar effects of injection to those in the case of incompressible flow that the injection makes all the height of the shock wave, the thickness of the boundary layer and the pressure on the plate larger than those in the case of no injection. On the contrary, in the case of suction no remarkable changes both in the shock wave and the pressure on the plate can be seen, and only the velocity profile in the boundary layer is affected by the suction. These results are deduced by calculating only the leading term of each quantity. In addition, the results of the present paper are restricted by assumptions that the plate is thermally insulated, $P_r = 1$, and $C_p = \text{const}$.

In conclusion, the author would like to express his gratitude to Prof. S. Uchida for his kind suggestion and valuable discussions during the course of the present investigation.

Experimental Studies on Laminar Sub-layer in Turbulent Boundary Layer involving Separation

By Yutaka SHIGEMITSU

Transportation Technical Research Institute, Tokyo

(Received July 30, 1956)

Observations were made on the mean and fluctuational velocities of the flow near a wall in turbulent boundary layer with non-zero pressure gradient. The edge of the sub-layer was defined as the maximum-point of the u-distribution curve. Important results obtained are as follows (suffixes 1 and 0 denoting here the values at the edge of the sub-layer and just outside the boundary layer): (i) In the field with constant pressure the curves of $\overline{U}/\overline{U}_1$ versus y/δ_1 are similar to those in the field with a fixed value of $\overline{U}_1\delta_1/\nu$ equal to about 165, indicating that the well-known relation between $\overline{U}/U_\tau$ and yU_τ/ν holds near the wall, U_τ being the frictional velocity; (ii) The curve of $\overline{U}/\overline{U}_1$ varies in such a manner that $\partial^2(\overline{U}/\overline{U}_1)/\partial(y/\delta_1)^2$ increases with dP_0/dx near the wall; (iii) The laminar sub-layer persists until the boundary layer separates and the separation of the sub-layer seems to be equivalent to turbulent separation phenomenon.

§ 1. Introduction

One of the important purposes of the investigation of turbulent boundary layer is to search for either theoretically or experimentally, the relation between the mean velocity distribution across the layer and the effect of pressure gradient of main stream. As is well known, the logarithmic law describes the mean velocity distribution approximately in the case of no pressure gradient. Observation of the mean velocity distribution in many cases in which there exists pressure gradient shows that the effect of pressure gradient seems to be conspicuous in the flow remote from a wall. As pointed out by Ludieg and Tillmann,[1] however, the effect of a wall is large in its vicinity and the logarithmic law can well be applied there even in the case of non-zero pressure gradient.

On the other hand, since the pioneer work by T. E. Stanton[2] it has been widely believed that in the immediate vicinity of a wall in turbulent boundary layer there exists a region where the effect of molecular viscosity is very strong, and such a region has been called generally laminar sub-layer. The above descriptions are concerned with the turbulent region of the turbulent boundary layer above the laminar sub-layer. It is known that in the laminar sub-layer with constant pressure, the velocity distribution is linear and the logarithmic law in turbulent region cannot be extended either logically or experimentally into the laminar sub-layer. As for the mechanism of this sub-layer, K. Suyehiro[3] proposed an important suggestion, based upon the conception of stability of Couette flow, that the Reynolds number at the edge of sub-layer $\overline{U}_1\delta_1/\nu$ is constant (suffix 1 denoting the value at the edge of the laminar sub-layer). Althouth this characteristic feature has been ascertained experimentally, yet it leads to a troublesome result that the logarithmic and linear velocity distributions in the two regions develop independently, and therefore the whole velocity distribution in the boundary layer has no similarity character even in the case of constant pressure. We consider that this is a significant character which should not be overlooked when we study the turbulent boundary layer in general case. To search for the similarity character in turbulent region in the case of flow with non-zero pressure gradient, F. H. Clauser[4] has made an important investigation. However, the mechanism of flow in the laminar sublayer is different from that in turbulent region, and it is quite questionable whether the linear velocity distribution in the laminar sub-layer may not be affected by pressure gradient as in the case of flow just above the sub-layer, or whether there may be another similarity law prescribing its effect apart from that in turbulent region.

In connexion with this problem the writer has attempted[5], a few years ago, to develop Suyehiro's supposition into the general case of turbulent boundary layer with non-zero pressure gradient and to formulate it mathematically. According to these interpretations the laminar sub-layer is one type of viscous flow under its lower critical condition of stability being affected by the Reynolds stress outside the layer, and to characterize the effect of pressure gradient in the laminar sub-layer we have introduced such a parameter $\lambda=\frac{-1}{\rho\nu}\frac{dP_0}{dx}\frac{\delta_1^2}{\bar{U}_1}$ where suffix 0 means the value in the main flow. Important results obtained from this formulation are enumerated as follows: (i) In the case of constant pressure the mean velocity distribution in the sub-layer has approximately a similar curve of $\bar{U}/\bar{U}_1$ plotted against y/δ_1 for a constant Reynolds number $\bar{U}_1\delta_1/\nu$; (ii) In case when there exists non-zero pressure gradient both the value of $\bar{U}_1\delta_1/\nu$ and the functional form of $(\bar{U}/\bar{U}_1)(y/\delta_1\}$ vary as the parameter λ; (iii) The function $(\bar{U}/\bar{U}_1)(y/\delta_1)$ has such a character that $\partial^2(\bar{U}/\bar{U}_1)/\partial(y/\delta_1)^2$ has negative, zero or positive value near $y/\delta_1=0$ according as the value of λ is positive, zero or negative; (iv) There is a negative critical value λ_c at which the value of $\partial\bar{U}/\partial y$ vanishes at the wall. Based upon these interpretations we can also develop[6] the decaying similarity law of isotropic turbulence or of turbulent wake into non-decaying form in turbulent boundary layer.

In order to assert the validity of these results, however, more experimental verifications are needed. So far, there have been only few measurements on the laminar sub-layer, especially for the case of pressure gradient. As will be mentioned later, the thickness δ_1 of the sub-layer becomes too small for usual Reynolds numbers, and the previous observations concerning the turbulent boundary layer have been carried out for such cases. Unless the undisturbed velocity is sufficiently low it becomes very difficult to survey the state of flow in the laminar sub-layer. From this point of view, we have carried out observations on the mean and fluctuational velocities in the laminar sub-layer with non-zero pressure gradient, by making δ_1 to be about 0.4~1.0 mm for undisturbed velocities of 3~12 m/sec. In this paper, some observed results will be presented for the purpose of understanding the fundamental character of the laminar sub-layer in general case and checking, at the same time, the above-mentioned theoretical results.

§ 2. Preliminary Measurements

The experiment was conducted in a small-scale low-turbulence wind tunnel with the test section of 20 cm × 30 cm × 200 cm in our laboratory. Turbulence level $u_0/\bar{U}_0$ in the main flow is 0.01~0.05 per cent according as the mean speed $\bar{U}_0=1\sim30$ m/sec. A lacquered iron plate was placed horizontally near the floor, and a tripping wire of diameter of about 1 mm was stretched on the plate 30 cm downstream the leading edge so as to produce fully developed turbulent flow in the boundary layer. Measurements were made along the centre line of the plate. If necessary, pressure gradient was given along the plate by placing a curved wall on the ceiling, and in order to make the boundary layer separate steadily, a curved bluff body was placed at the end of the plate. The pressure distribution was measured by a small static-tube of diameter of about 1.5 mm which was slided on the plate. An example of the arrangements is shown in Fig. 1.

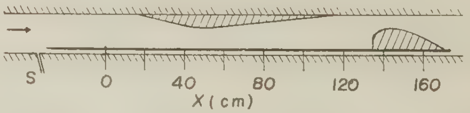

Fig. 1. Schematic diagram of arrangement of the equipments. S is a slit which serves to draw out the boundary layer upstream of the plate.

Measurements of the mean speed $\bar{U}$ and fluctuational velocity u near the plate in turbulent boundary layer were made by a hot-wire anemometer for various undisturbed velocities as well as for various pressure gradients. In the measurements of velocity distribution, the constant-temperature method was employed. The moved distance of the position of the hot-wire was found by the micro-screw reading, and the absolute value of its nearest location to the plate was measured by an optical height gauge which determined the distance between the tip of the hot-wire prong and its image on the lacquered plate.

It is well known that when a hot-wire anemometer is used near a solid wall, the heat loss at a given speed is probably affected by the presence of the wall. To avoid this effect as far as possible, the hot-wire temperature used was made not so high. In still air the said effect became perceptible at a distance of about 0.5 mm from the plate, but in moving air it became very small. At positions near the plate where the mean velocity was larger than 1 m/sec, the conspicuous effect was not found in the measurements, and any correction has not been made to the determination of the mean and fluctuational velocity distributions. Near the separation-point, however, this become remarkable owing to low mean speed, but these uncorrected values were rejected from the data. As an example of these measurements, that for the laminar boundary layer, the velocity distribution of which is known theoretically, is shown in Fig. 2.

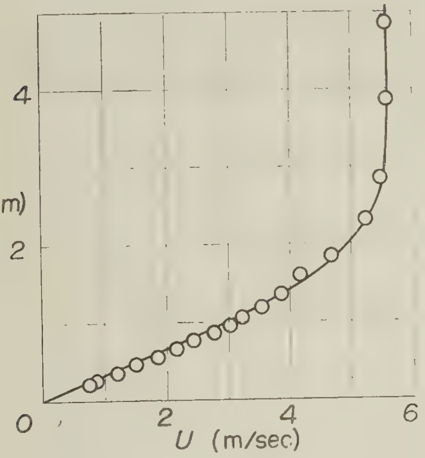

Fig. 2. Comparison of observed velocity distribution in the laminar boundary layer along a flat plate with the Blasius curve. The data were obtained upstream of the tripping wire in the case of no pressure gradient.

§ 3. Similarity Character in the Case of Flow along a Flat Plate

For the purpose of surveying general aspects of flow near a wall in turbulent boundary layer, a field of zero pressure gradient was first made along the plate by taking away curved obstacles from the test section. Fig. 3 shows an example of observed distributions of $\bar{U}$ and u near the plate. They both tend smoothly to zero at the wall. But, was widely observed in turbulent boundary layer flow or in turbulent pipe flow (non-decaying turbulence) it is significant that the fluctuational velocity u tends to zero rapidly through the maximum point very near the wall, while the mean velocity becomes zero gradually. Such a character has never been found in turbulent wake or free jet (decaying turbulence). We consider this maximum-point as an evidence of the appearance of the edge of the laminar sub-layer, where the stability of viscous flow begins to break down and small vortices are produced incessantly. Thus, it is supposed that the region of flow outside this point (near the mark D in Fig. 3) has a feature of complicated vortex chaos motion caused by these vortices. In the laminar sub-layer, however, the fluctuational velocity does not indicate vortex chaos motion, being only affected by vortex motions outside the sub-layer. The principal character of the sub-layer is determined by molecular viscosity even if effects of fluctuational velocity cannot be neglected near the edge. Fig. 4 shows variations of the fluctuational velocity u outside and inside the same laminar sub-layer as shown in Fig. 3. High-frequency harmonics outside the sub-layer tend to vanish in the layer by molecular viscosity, and the fluctuation becomes like

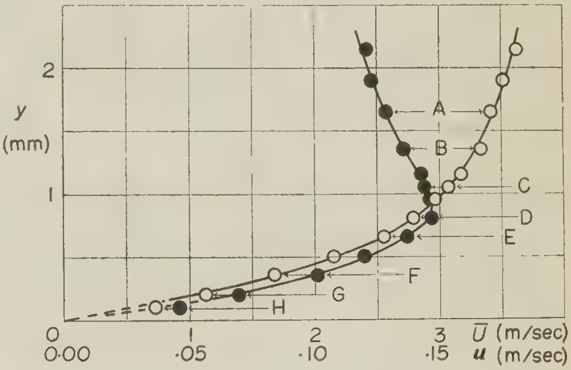

Fig. 3. Distributions of the mean velocity $\bar{U}$ indicated by the mark ○ and the fluctuational velocity u indicated by the mark ● near the flat plate in case when the main-stream velocity $\bar{U}_0$ is 5.30 m/sec.

the laminar-boundary-layer oscillation in case when the main flow has a moderate degree of turbulence. According to the above discussions, the thickness of the sub-layer can be defined as the distance of the maximum-point of **u**-distribution curve from the wall, and therefore other outer boundary conditions are easily surveyed experimentally.

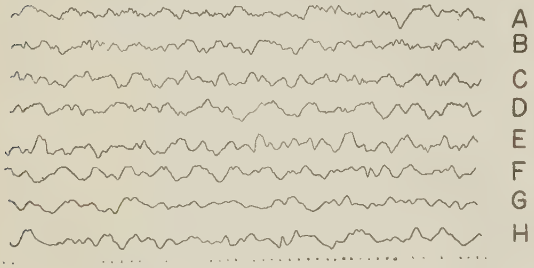

Fig. 4. Oscillograph records of u-fluctuation near the plate. States of flow are the same as in Fig. 3, marks A, B, $\cdots$ indicating the corresponding positions of hot-wire and time-marks being 0.01 second apart.

As mentioned in §1, $\overline{U}_1\delta_1/\nu$ is considered to be constant in the case of zero pressure gradient under consideration. Through several series of measurements for various undisturbed velocities ranging from 3 to 12 m/sec, this constant value was ascertained to be about 165, and no systematic variation of the value due to Reynolds number could be detected. These values are indicated in Fig. 5 with corresponding values of δ_1. As another boundary condition prescribing the effect of Reynolds shearing stress outside the sub-layer,

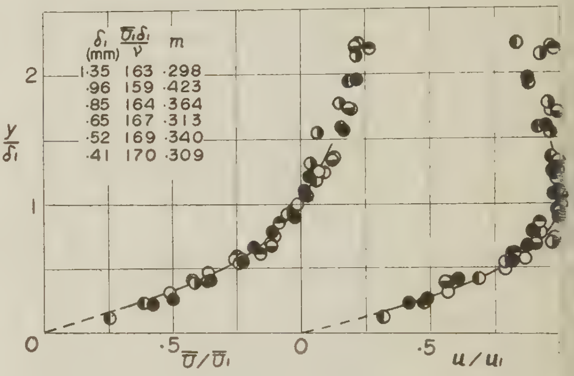

Fig. 5. Constancy of the Reynolds number $\overline{U}_1\delta_1/\nu$ at the edge of the laminar sub-layer and similarity character in $\overline{U}$- and **u**-distributions in the case of flow along a flat slate. Marks ●, ○, ◕, ◑, ⊖ and ◓ show respectively the observed values in cases when the thickness δ_1 of the sub-layer was 1.35, 0.96, 0.85, 0.65, 0.52 and 0.41mm respectively.

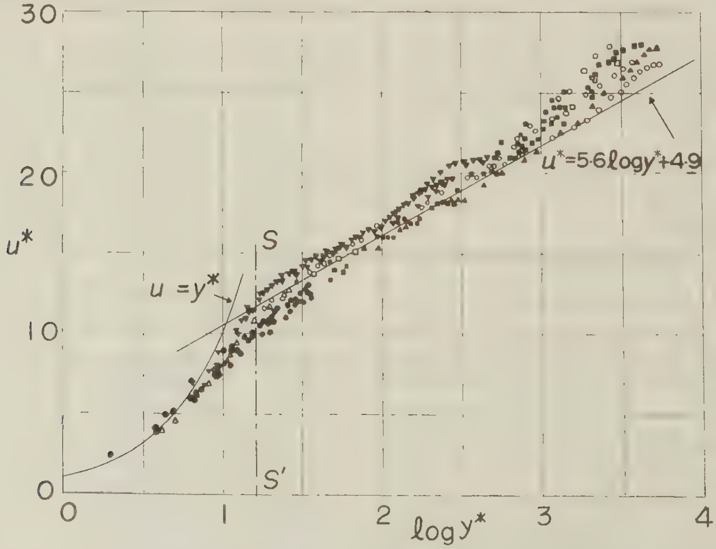

Fig. 6. Universal velocity distribution in turbulent boundary layer along a flat plate. The mark ● shows evaluated values from the data in Fig. 5. Other marks correspond to the observed values by several investigators:

variation of the value of the quantity $(\partial\overline{U}/\partial y)_1(\delta_1/\overline{U}_1)(=m)$ is important. Some of the observed values of this quantity are shown in Fig. 5. Theoretical estimation of the value of this quantity seems to be very difficult.

As mentioned in § 1, the laminar sub-layer in the present case of zero pressure gradient is considered to have a similarity character approximately. To survey it experimentally, the values of $\overline{U}/\overline{U}_1$ and $\boldsymbol{u}/\boldsymbol{u}_1$ were plotted against y/δ_1 in Fig. 5. It will be seen from this figure that no deviation from the similitude in $\overline{U}$- and $\boldsymbol{u}$-distributions can be detected experimentally. It is well known that when u^* and y^* are taken respectively as $\overline{U}/U_\tau$ and yU_τ/ν where $U_\tau=\sqrt{\nu(\partial\overline{U}/\partial y)_{y=0}}$, there exists a universal relation between them in the turbulent boundary layer with a constant pressure. In our notations they can be written as:

$$u^*=\sqrt{\frac{c}{\alpha}}\frac{\overline{U}}{\overline{U}_1}\,,\qquad y^*=\sqrt{c\alpha}\,\frac{y}{\delta_1}\,,\qquad (3.1)$$

where $c=\overline{U}_1\delta_1/\nu$ and $\alpha=(\partial\overline{U}/\partial y)_{y=0}(\delta_1/\overline{U}_1)$. Then, the similarity character of the curve of $\overline{U}/\overline{U}_1$ versus y/δ_1 subject to $\overline{U}_1\delta_1/\nu=c$ gives rise to the universal velocity distribution $u^*(y^*)$ in the laminar sub-layer. In our data the values of U_τ are estimated by tangents at the wall in $\overline{U}$-distribution curves, and these representations are shown in Fig. 6 compared with other observed values in the laminar sub-layer and in the turbulent region.

§ 4. Variation of Similitude with a Pressure Gradient

It is important that in the case of constant pressure, the observed similarity character of the curve $\overline{U}/\overline{U}_1$ versus y/δ_1 subject to $\overline{U}_1\delta_1/\nu=c$ gives rise to the universal $u^*\sim y^*$ relation in the laminar sub-layer and at the same time it belongs to the special case of $\lambda=0$ in our similarity character mentioned in § 1 (ii). In the case of non-zero pressure gradient the interrelation between dP_0/dx and the form of $u^*(y^*)$-curve has not been clarified in the whole turbulent region, besides the fact that just outside the sub-layer the logarithmic law is not affected by dP_0/dx. Then, in the laminar sub-layer the effects of dP_0/dx will be surveyed experimentally in the extended form of our similarity character, by which the form of $\overline{U}/\overline{U}_1$ versus y/δ_1 and the value of $\overline{U}_1\delta_1/\nu$ are determined uniquely by the parameter λ.

Experimental equipments to produce non-zero pressure gradient along the plate are as mentioned in § 2. Two sets of curved walls on the ceiling were used under several undisturbed velocities. For instance, when the

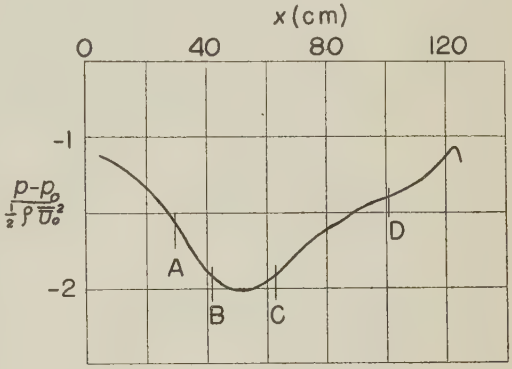

Fig. 7. Pressure distribution along the centre line on the flat plate in the same arrangement of equipments as shown in Fig. 1, with undisturbed velocity $\overline{U}_0=11.51$ m/sec upstream of the slit S. The values of abscissa are the same as in Fig. 1.

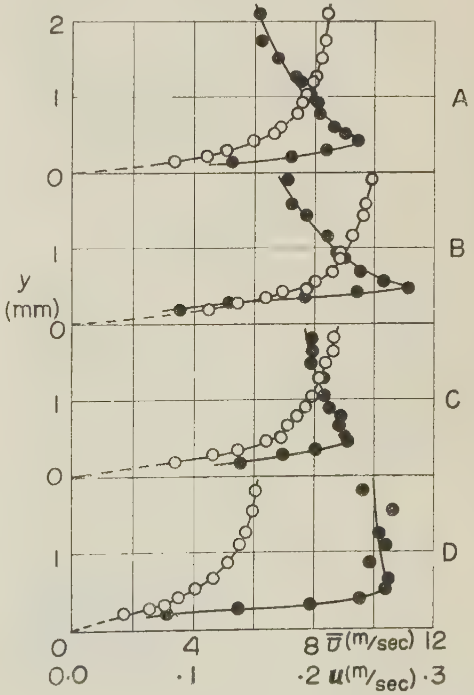

Fig. 8. Distributions of the mean velocity indicated by the mark ○ and the fluctuational velocity $\boldsymbol{u}$ indicated by the mark ● near the plate for various pressure gradients. The states of flow and positions of observation are the same as shown in Fig. 7.

velocity $\overline{U}_0$ was made to be 11.51 m/sec in the arrangement as shown in Fig. 1, the pressure distribution became as shown in Fig. 7. To get a general view of the effect of pressure gradient on the state of the sub-layer, $\overline{U}$- and u-distributions were observed at four sections A, B, C, D. They are shown in Fig. 8. It is seen that the curvature at the maximum-point of the u-distribution curve increases or decreases respectively according as the pressure gradient is negative or positive. Such a tendency has been partly observed previously[7]. This character is considered to be an evidence of the accumulation or diffusion of vortices, which are produced at the up-stream edge of laminar sub-layer and are carried respectively with approaching or detaching mean direction of the flow to the wall. At any rate, the thickness δ_1 of the layer can be determined by the measured u-distribution.

Since it is difficult to realize experimentally a pressure gradient with constant λ along the x-direction, the state of the sub-layer was surveyed with local values of λ under several undisturbed velocities and pressure gradients. Fig. 9 shows the distributions of observed values of $\overline{U}_1\delta_1/\nu$ and m plotted against λ. The observed points are fairly scattered because of the difficulty of experimental measurement, but general view of these empirical results may be understood. The scattering of the observed points of m may be caused to some extent by the character that it cannot be expressed essentially by the single parameter λ.

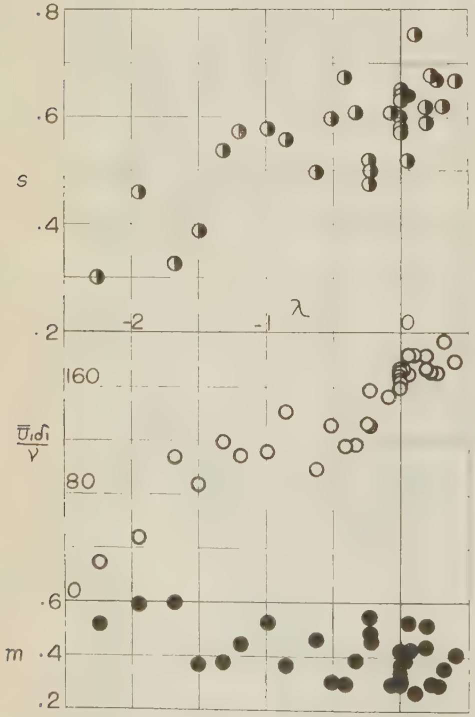

Fig. 9. Empirical results of the distributions of $\overline{U}_1\delta_1/\nu$ and $(\partial\overline{U}/\partial y)_1(\delta_1/\overline{U}_1)$ $(=m)$ plotted against the parameter λ, and an appearance of the effect of pressure gradient on the mean velocity distribution in the laminar sub-layer expressed in the parameter in (4.1).

Concerning the mean velocity distribution in the laminar sub-layer, any conspicuous variation did not appear as in the case of the u-distribution curve. But, observed precisely, the variation of the form of the curve of $\overline{U}/\overline{U}_1$ versus y/δ_1 with a pressure gradient was found. As a method to examine this effect quantitatively, a parameter s defined as:

$$s=\overline{U}(y')/\overline{U}_1\,,\qquad y'/\delta_1=0.4 \tag{4.1}$$

was introduced. Experimentally evaluated values of s are plotted against λ in Fig. 9. These data are still scattered, but a tendency that s decreases with a negative value of λ can be ascertained. In the immediate vicinity of the wall, the inertia force and Reynolds stress may be neglected, and the essential feature of the equations of motion is written as:

$$-\lambda \doteqdot \partial^2(\overline{U}/\overline{U}_1)/\partial(y/\delta_1)^2\,. \tag{4.2}$$

The above-observed character is important as the effect of pressure gradient in the laminar sub-layer subject to the theoretical relation (4.2). But, by the above measurements it cannot be proved whether the similarity character of the curve of $\overline{U}/\overline{U}_1$ versus y/δ_1 under a constant $\overline{U}_1\delta_1/\nu$ may exist in the case of constant λ, as observed in the case of constant pressure.

§ 5. States of Flow near the Turbulent Separation-point

It is important to investigate the mechanism of turbulent separation phenomena experimentally, but because of experimental difficulties many observed results have not been presented. In the arrangement of equipments as shown in Fig. 1, we can make the flow separate from the wall stationarily by keeping the vortex motion produced after the separation fixed in the corner of the plate and the bluff body. The picture in Fig. 10 shows an example of the flow pattern near the turbulent separation-point, where the pressure distribution along the centre line of the plate is also indicated. It is well recognized by these observations that the boundary layer separated clearly at a certain line on the plate. But, near this separation-line, it was very difficult to retain two-dimentionality of the mean flow because of the small scale of the test section, and the data are not necessarily reliable to be compared quantitatively with the two-dimentional theoretical results concerning the sub-layer.

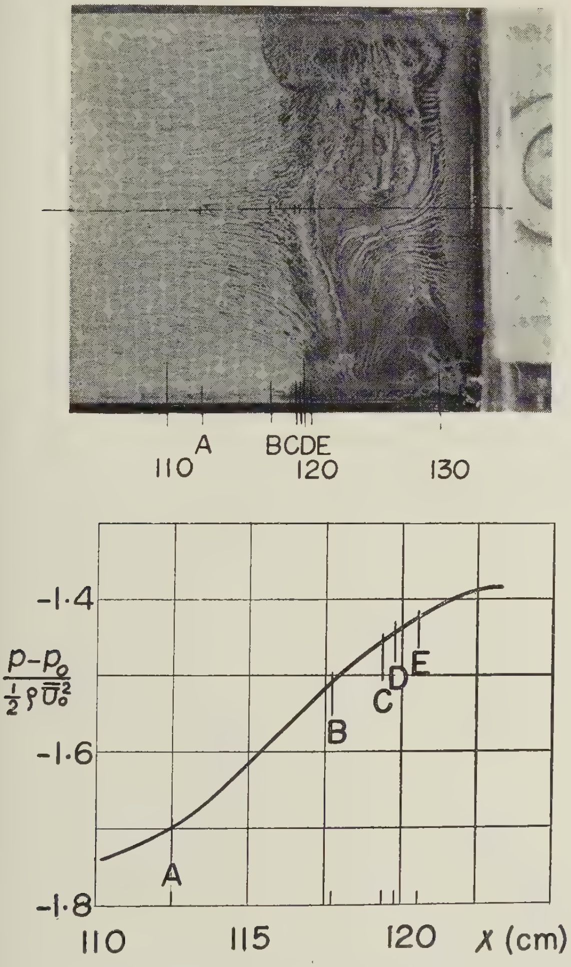

Fig. 10. States of flow near the turbulent separation-point. The flow pattern was obtained by kerosene-lampblack method in the flow with $\overline{U}_0=7.35$ m/sec upstream of the slit S, using an arrangement of equipments other than that is shown in Fig. 1. The pressure-distribution curve was measured in this state of flow where the abscissa x is measured in cm from the tripping wire.

Distributions of the mean and fluctuational velocities are shown in Fig. 11, which shows that the flow separates near the position D and the distributions at E are those of the back flow. From $\boldsymbol{u}$- and $\overline{U}$-distribution curves near the wall at A, B, C, it may be said that the laminar sub-layer exists until the boundary layer separates and the separation of the laminar sub-layer itself tells turbulent separation phenomenon. It is an important qualitative result of the present observations, but owing to the lack of two-dimentionality we could not determine the critical value λ_c at which the laminar sub-layer separates from the wall.

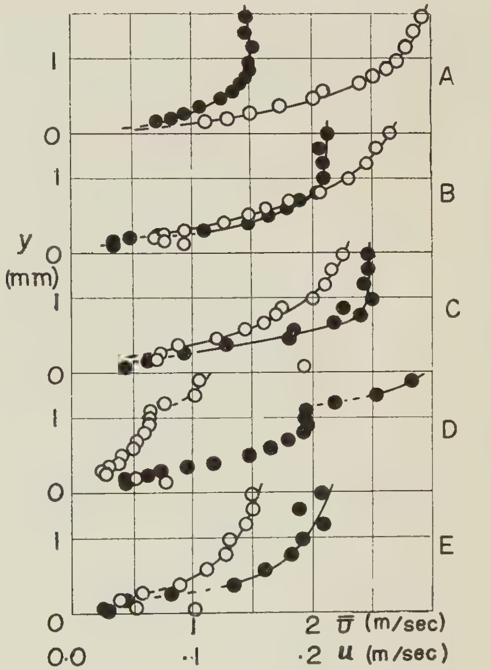

Fig. 11. Distributions of the mean velocity indicated by the mark ○ and the fluctuational velocity $\boldsymbol{u}$ indicated by the mark ● near the separation-line. The states of flow and positions of observation are the same as shown in Fig. 10. In this case the effect of heat loss by the wall appears clearly owing to the very low mean speed. Data in the cases D and E are not inserted in Fig. 9.

In conclusion, the author wishes to express

his sincere gratitude to Professor I. Tani for his valuable advice and also to members of the Turbulence Research Group in Japan for helpful discussions.

Diffraction of Electromagnetic Waves by Ribbon and Slit. I

By Yûkichi NOMURA and Shigetoshi KATSURA
Department of Applied Science, Tôhoku University

(Received September 26, 1956)

Rigorous solutions are presented of the problem of diffraction of plane electromagnetic waves by an infinitely thin, perfectly conducting infinitely long ribbon and by an infinitely long slit in a plane conducting screen, where the plane of incidence is perpendicular to the edge of the ribbon or slit but arbitrary angle of incidence and polarization. The unique solution satisfying the edge condition is obtained from the electric and magnetic type Hertz vectors, each of which has one scalar component, by the method of expansion in the hypergeometric polynomial. The expressions of the scattering coefficient, transmission coefficient, electric current on the ribbon, electric field in the slit, electric field at the distant place are obtained as a function of $ka=2\pi a/\lambda$.

§ 1. Introduction

The diffraction of electromagnetic waves by an infinitely long ribbon and slit are solved by Mathieu functions by McLachlan[1], and by integral equation method by Bouwkamp[2], Hönl and others[14),15)] Müller and Westpfahl[16] and de Hoop[17]. Most of their results, however, are restricted to normal incidence, and still far from numerical computation. Here we want to solve this problem in case where the plane of incidence is perpendicular to the edge of the ribbon or slit but arbitrary angle of incidence and polarization, by the expansion in hypergeometric polynomial. This method succeeds in many cases for problems of potential, vibration, and of wave propagation[3)–13)]. Particularly the former papers "Acoustic field by a vibrating source arbitrarily distributed on a plane circular disk[10]" and "Diffraction of electromagnetic waves by circular plate and circular hole[13]" are referred to I and II respectively.

In case of diffraction of electromagnetic field by circular plate and hole, the field is assumed to be derived by the electric type Hertz vector Π which has two scalar components Π_x and Π_y. In the present case the field is assumed to be derived by two Hertz vectors Π and Π^*, of electric type and magnetic type, each of which has one scalar component. Then the diffracted field is described in terms of Weber-Schafheitlin integrals with unknown coefficients, which are determined with the aid of hypergeometric polynomial expansion. In this method the expression of scattering cross section, transmission coefficient, electric current on the ribbon, electric field in the slit, electric field at the distant place are obtained. The numerical results and discussions will be reported in the subsequent papre.

In case of normal incidence our results agree to the work of Bouwkamp[2] and others[16],[17]. Our method, however, has advantage to be able to solve other kind of problems which cannot be solved by other method[3]-[9].

The theory of ribbon and slit corresponds each other by Babinet principle, so the formula for a ribbon and a slit are listed in the left and right side respectively.

§ 2. General Solutions

We consider an infinitesimally thin perfectly conducting ribbon or infinitesimally thin perfectly conducting screen of infinite extent with a slit. A rectangular coordinate system is chosen so that the ribbon or screen lies in the xy-plane and their edge is given by $y=\pm a$. We consider a plane wave incident from the negative half space, with its plane of incidence yz plane, angle of incidence α. The electromagnetic field of the incident wave (i) and the reflected wave (r) is described by

Case of ribbon

$$E^{(i)}=(E_2,\ -E_1\cos\alpha,\ E_1\sin\alpha)\times\exp(-ikz\cos\alpha-iky\sin\alpha)\ ,$$

$$H^{(i)}=\frac{k}{\mu\omega}(E_1,\ E_2\cos\alpha,\ -E_2\sin\alpha)\times\exp(-ikz\cos\alpha-iky\sin\alpha)\ ,$$

for all space.

Case of slit

$$\left.\begin{aligned}E^{(i)}&=(E_1,\ -E_2\cos\alpha,\ E_2\sin\alpha)\times\exp(-ikz\cos\alpha-iky\sin\alpha)\ ,\\ H^{(i)}&=\frac{k}{\mu\omega}(E_2,\ E_1\cos\alpha,\ -E_1\sin\alpha)\times\exp(-ikz\cos\alpha-iky\sin\alpha)\ ,\\ E^{(r)}&=(-E_1,\ E_2\cos\alpha,\ E_2\sin\alpha)\times\exp(ikz\cos\alpha-iky\sin\alpha)\ ,\\ H^{(r)}&=\frac{k}{\mu\omega}(E_2,\ E_1\cos\alpha,\ E_1\sin\alpha)\times\exp(ikz\cos\alpha-iky\sin\alpha)\ .\end{aligned}\right\}\quad(2.1)$$

for negative half space.

Here $k=2\pi/\lambda$ is the wave number, the harmonic time dependence $\exp i\omega t$ being omitted throughout. The electromagnetic field is assumed to be derived in terms of the electric type Hertz vector and magnetic type Hertz vector both of which has only x-component.

$$E=\text{rot rot}\ \Pi-i\mu\omega\ \text{rot}\ \Pi^*\ ,\qquad H=i\varepsilon\omega\ \text{rot}\ \Pi+\text{rot rot}\ \Pi^*\ ,$$

$$\left.\begin{aligned}E&=-i\mu\omega\ \text{rot}\ \Pi+\text{rot rot}\ \Pi^*\ ,\\ H&=\text{rot rot}\ \Pi+i\varepsilon\omega\ \text{rot}\ \Pi^*\ ,\end{aligned}\right\}\quad(2.2)$$

$$\Pi=(f^{(i)}+f,\ 0,\ 0)\ ,\qquad \Pi^*=\sqrt{\varepsilon/\mu}\,(f^{*(i)}\mp f^*,\ 0,\ 0)\ .$$

where the upper and lower sign refers to positive and negative z respectively.

$$\left.\begin{aligned}\Pi&=\sqrt{\varepsilon/\mu}\,(-f,\ 0,\ 0) && (z>0)\\ &=\sqrt{\varepsilon/\mu}\,(f^{(i)}+f^{(r)}+f,\ 0,\ 0) && (z<0)\ ,\\ \Pi^*&=(f^*,\ 0,\ 0) && (z>0)\\ &=(f^{*(i)}+f^{*(r)}+f^*,\ 0,\ 0) && (z<0)\ .\end{aligned}\right\}\quad(2.3)$$

The Hertz vectors of the incident and reflected waves are given by

$$f^{(i)}=\frac{E_2}{k^2}e^{-ikz\cos\alpha-iky\sin\alpha}\ ,\qquad f^{*(i)}=\frac{E_1}{k^2}e^{-ikz\cos\alpha-iky\sin\alpha}\ .$$

$$\left.\begin{aligned}f^{(i)}&=\frac{E_2}{k^2}e^{-ikz\cos\alpha-iky\sin\alpha}\ ,\\ f^{*(r)}&=\frac{E_2}{k^2}e^{ikz\cos\alpha-iky\sin\alpha}\ ,\\ f^{*(i)}&=\frac{E_1}{k^2}e^{-ikz\cos\alpha-iky\sin\alpha}\ ,\\ f^{*(r)}&=-\frac{E_1}{k^2}e^{ikz\cos\alpha-iky\sin\alpha}\ ,\end{aligned}\right\}\quad(2.4)$$

The Hertz vector of the diffracted field is assumed to be given by

$$\left.\begin{aligned} f&=\frac{E_2}{k^2}\left(\sum_{n=0}^{\infty}A_nS_n^{-1/2}(y,z)+\sum_{n=0}^{\infty}B_nS_n^{1/2}(y,z)\right)\cdot\\ f^*&=\frac{E_1}{k^2}\cos\alpha\left(\sum_{n=0}^{\infty}A_n^*S_n^{*-1/2}(y,z)+\sum_{n=0}^{\infty}B_n^*S_n^{*1/2}(y,z)\right),\end{aligned}\right\}\tag{2.5}$$

where

$$\left.\begin{aligned} S_n^{m}(y,z)&=\sqrt{\frac{y}{a}}\int_0^{\infty}\frac{\sqrt{\xi}\,J_m(y\xi/a)\,J_{2n+m+1/2}(\xi)}{\sqrt{\xi^2-\gamma^2}}\exp\left(\mp(\xi^2-\gamma^2)^{1/2}\frac{z}{a}\right)d\xi\,,\\ S_n^{*m}(y,z)&=\sqrt{\frac{y}{a}}\int_0^{\infty}\frac{J_m(y\xi/a)\,J_{2n+m+3/2}(\xi)}{\sqrt{\xi}}\exp\left(\mp(\xi^2-\gamma^2)^{1/2}\frac{z}{a}\right)d\xi\,,\end{aligned}\right\}\tag{2.6}$$

where

$$\gamma=ka\,,\qquad m=\pm\tfrac{1}{2}\,.$$

Here each of $S_n^{\pm1/2}(y,z)$ and $S_n^{*\pm1/2}(y,z)$ is a solution of the two-dimensional wave equation $\partial^2\phi/\partial y^2+\partial^2\phi/\partial z^2+k^2\phi=0$. The solution with superscript $m=-\frac{1}{2}$ is an even solution and that with $m=\frac{1}{2}$ is an odd solution of y respectively. $\mp$ sign in the exponential corresponds to $z\gtrless0$ respectively.

Let z derivative of f and f^* be $\mp g$ and $\mp g^*$, then

$$\left.\begin{aligned} g&=\frac{E_2}{k^2a}\left(\sum_{n=0}^{\infty}A_nT_n^{-1/2}(y,z)+\sum_{n=0}^{\infty}B_nT_n^{1/2}(y,z)\right),\\ g^*&=\frac{E_1\cos\alpha}{k^2a}\left(\sum_{n=0}^{\infty}A_n^*T_n^{*-1/2}(y,z)+\sum_{n=0}^{\infty}B_n^*T_n^{*1/2}(y,z)\right),\end{aligned}\right\}\tag{2.7}$$

where

$$\left.\begin{aligned} T_n^{m}(y,z)&=\sqrt{\frac{y}{a}}\int_0^{\infty}\sqrt{\xi}\,J_m(y\xi/a)\,J_{2n+m+1/2}(\xi)\exp\left(\mp(\xi^2-\gamma^2)^{1/2}\frac{z}{a}\right)d\xi\,,\\ T_n^{*m}(y,z)&=\sqrt{\frac{y}{a}}\int_0^{\infty}\frac{\sqrt{\xi^2-\gamma^2}\,J_m(y\xi/a)\,J_{2n+m+3/2}(\xi)}{\sqrt{\xi}}\exp\left(\mp(\xi^2-\gamma^2)^{1/2}\frac{z}{a}\right)d\xi\,.\end{aligned}\right\}\tag{2.8}$$

$S_n^{*\mp1/2}(y,0)$ and $T_n^{\pm1/2}(y,0)$ are Weber-Schafheitlin's integrals, and have the property to become zero for $y\geq a$. By the use of this property several problems of potentials, vibrations, and wave equations have been solved[3)–13)]. Then it is found that on the plane $z=0$:

the electric and magnetic field of the diffracted wave for $y>a$, are continuous	the tangential component of the resultant electric field and the normal component of the resultant magnetic field are zero for $y>a$ (perfectly conducting screen). The tangential component of the resultant electric field and the normal component of the resultant magnetic field are continuous for $y<a$.
The condition for the conducting plate, that the resultant tangential component of electric field and the resultant normal component of the magnetic field are zero for $y<a$, is expressed by	The other condition for the slit, that the tangential component of the resultant magnetic field and the normal component of the resultant electric field† are continuous for $y<a$ is expressed by

$$f+f^{(i)}=0\tag{2.9}$$

---

† p. 287 in II, the second and the fourth lines from the bottom in the right hand side part, electric should be read magnetic, and magnetic should be read electric.

and

$$g^*+\partial f^{*(i)}/\partial z=0 \tag{2.10}$$

for $y<a$, $z=0$. (2.9) and (2.10) are rewritten by

$$\left.\begin{aligned} &\sum_{n=0}^{\infty} A_n S_n^{-1/2}(y,\,0)=-\cos(ky\sin\alpha)\,, \\ &\sum_{n=0}^{\infty} B_n S_n^{1/2}(y,\,0)=i\sin(ky\sin\alpha) \end{aligned}\right\} \tag{2.11}$$

and

$$\left.\begin{aligned} &\sum_{n=0}^{\infty} A_n^* T_n^{*-1/2}(y,\,0)=ika\cos(ky\sin\alpha)\,, \\ &\sum_{n=0}^{\infty} B_n^* T_n^{*1/2}(y,\,0)=ka\sin(ky\sin\alpha)\,. \end{aligned}\right\} \tag{2.12}$$

Now we expand the both hand sides of (2.11) and (2.12) by the hypergeometric polynomials. By Appendix in II and by similar calculations,

$$J_m(p\sqrt{x})=x^{m/2}\sum_{\nu=0}^{\infty}(2m+4\nu+1)\frac{J_{m+2\nu+1/2}(p)}{\sqrt{p}}u_\nu{}^m(x) \tag{2.13}$$

$$=x^{m/2}\sum_{\nu=0}^{\infty}(2m+4\nu+3)\frac{J_{m+2\nu+3/2}(p)}{p^{3/2}}v_\nu{}^m(x)\,, \tag{2.14}$$

where

$$u_\nu{}^m(x)=x^{-m/2}\int_0^\infty\frac{J_m(\sqrt{x}\,\xi)J_{m+2\nu+1/2}(\xi)}{\sqrt{\xi}}d\xi$$

$$=\frac{\Gamma(m+\nu+\frac{1}{2})}{\sqrt{2}\,\nu!\,\Gamma(\nu+m+1)}x^{-m}(1-x)^{1/2}\frac{d^\nu}{dx^\nu}\{x^{m+\nu}(1-x)^{\nu-1/2}\} \tag{2.15}$$

and

$$v_\nu{}^m(x)=x^{-m/2}\int_0^\infty\sqrt{\xi}\,J_m(\sqrt{x}\,\xi)J_{m+2\nu+3/2}(\xi)d\xi$$

$$=\frac{\sqrt{2}\,\Gamma(m+\nu+3/2)}{\nu!\,\Gamma(m+\nu+1)}x^{-m}(1-x)^{-1/2}\frac{d^\nu}{dx^\nu}\{x^{m+\nu}(1-x)^{\nu+1/2}\} \tag{2.16}$$

and $x=(y/a)^2$. Thus the right hand sides of (2.11) and (2.12) are expanded.

Let

$$S_n^m(y,\,0)=\sum_{\nu=0}^{\infty}(2m+4\nu+1)G_{n\nu}^m u_\nu^m(x) \tag{2.17}$$

and

$$T_n^{*m}(y,\,0)=\sum_{\nu=0}^{\infty}(2m+4\nu+3)\,G_{n\nu}^{*m}v_\nu^m(x)\,, \tag{2.18}$$

then

$$G_{n\nu}^m=\int_\gamma^\infty\frac{J_{2n+m+1/2}(\xi)J_{2\nu+m+1/2}(\xi)}{(\xi^2-\gamma^2)^{1/2}}d\xi$$

$$-i\int_0^\gamma\frac{J_{2n+m+1/2}(\xi)J_{2\nu+m+1/2}(\xi)}{(\gamma^2-\xi^2)^{1/2}}d\xi\,, \tag{2.19}$$

$$G_{n\nu}^{*m}=\int_\gamma^\infty\frac{(\xi^2-\gamma^2)^{1/2}J_{2n+m+3/2}(\xi)J_{2\nu+m+3/2}(\xi)}{\xi^2}d\xi$$

$$+i\int_0^\gamma\frac{(\gamma^2-\xi^2)^{1/2}J_{2n+m+3/2}(\xi)J_{2\nu+m+3/2}(\xi)}{\xi^2}d\xi\,. \tag{2.20}$$

Substitution of (2.13) (2.14) (2.17) (2.18) with (2.19) and (2.20) into (2.11) and (2.12) gives

$$\left.\begin{aligned} A_n &= -\sqrt{\pi/2}\sum_{\nu=0}^{\infty} X_{n\nu} J_{2\nu}(\gamma\sin\alpha)\,, \\ B_n &= i\sqrt{\pi/2}\sum_{\nu=0}^{\infty} Y_{n\nu} J_{2\nu+1}(\gamma\sin\alpha)\,, \\ A_n^* &= i\gamma\sqrt{\pi/2}\sum_{\nu=0}^{\infty} X_{n\nu}^* \frac{J_{2\nu+1}(\gamma\sin\alpha)}{\gamma\sin\alpha}\,, \\ B_n^* &= \gamma\sqrt{\pi/2}\sum_{\nu=0}^{\infty} Y_{n\nu}^* \frac{J_{2\nu+2}(\gamma\sin\alpha)}{\gamma\sin\alpha}\,. \end{aligned}\right\} \tag{2.21}$$

where $X_{n\nu}$, $Y_{n\nu}$, $X_{n\nu}^*$ and $Y_{n\nu}^*$ are inverse matrices of $G_{n\nu}^{-1/2}$, $G_{n\nu}^{1/2}$, $G_{n\nu}^{-*1/2}$ and $G_{n\nu}^{*1/2}$ respectively, that is

$$\left.\begin{aligned} &\sum_{\nu=0}^{\infty} G_{\nu n}^{-1/2} X_{\nu s} = \delta_{sn}\,, && \sum_{\nu=0}^{\infty} G_{\nu n}^{1/2} Y_{\nu s} = \delta_{sn}\,, \\ &\sum_{\nu=0}^{\infty} G_{\nu n}^{*-1/2} X_{\nu s}^* = \delta_{sn}\,, && \sum_{\nu=0}^{\infty} G_{\nu n}^{*1/2} Y_{\nu s}^* = \delta_{sn}\,. \end{aligned}\right\} \tag{2.22}$$

where δ_{sn} is Kronecker's symbol.

In case of normal incidence,

$$\left.\begin{aligned} A_n &= -\sqrt{\pi/2}\,X_{n0}\,, & B_n &= 0\,, \\ A_n^* &= \frac{i\gamma}{2}\sqrt{\pi/2}\,X_{n0}^*\,, & B_n^* &= 0\,. \end{aligned}\right\} \tag{2.23}$$

The solutions (2.5) with coefficients (2.21) by (2.22) thus determined, satisfies the edge condition (Cf. § 5).

§ 3. Calculation of $G_{n\nu}^m$ and $G_{n\nu}^{*m}$

Imaginary part of $G_{n\nu}^m$ and $G_{n\nu}^{*m}$ are given by I (15) and II (32). Results for the real part of $G_{n\nu}^m$ in the former papers are not valid for half integer of m. Here we calculate the real part of $G_{n\nu}^{\mp 1/2}$.

Write $2\nu+m+\frac{1}{2}=\alpha$, $2n+m+\frac{1}{2}=\beta$. The integral representation of the product of the Bessel functions is substituted and the integral representation by Γ-function is used, then

$$\mathscr{R}\,G_{n\nu}^m = \int_\gamma^\infty \frac{J_\alpha(\xi)J_\beta(\xi)}{(\xi^2-\gamma^2)^{1/2}}\,d\xi \tag{3.1}$$

$$= \frac{2}{\pi}\int_0^{\pi/2} d\theta\,\cos(\alpha-\beta)\theta\,\frac{1}{2\pi i}\int_{-1/3-i\infty}^{-1/3+i\infty} ds\,\frac{\Gamma(-s)\cos^{\alpha+\beta+2s}\theta}{\Gamma(\alpha+\beta+s+1)}\int_\gamma^\infty d\xi\,\frac{\xi^{\alpha+\beta+2s}}{(\xi^2-\gamma^2)^{1/2}}\,. \tag{3.2}$$

The contour in s plane is shifted to the straightline from $-(\alpha+\beta)/2-1/3-i\infty$ to $-(\alpha+\beta)/2-1/3+i\infty$, and the integration over ξ and θ are carried out, then

$$= \sqrt{\pi/2}\,\frac{1}{2\pi i}\int_C \frac{\Gamma(-s)\Gamma(\alpha+\beta+2s+1)\Gamma(-(\alpha+\beta)/2-s)(\gamma/2)^{\alpha+\beta+2s}ds}{\Gamma(\alpha+\beta+s+1)\Gamma(\alpha+s+1)\Gamma(\beta+s+1)\Gamma(-(\alpha+\beta)/2-s+\frac{1}{2})}\,, \tag{3.3}$$

where C is the contour consisted of the circumference in the right half plane and the straight line parallel to the imaginary axis at $s=-(\alpha+\beta)/2-1/3$ in the clock-wise direction. The poles of the integrand are simple poles at $s=-(\alpha+\beta)/2$, $-(\alpha+\beta)/2+1$, $\cdots$ -2, -1, and double poles at $s=0, 1, 2, \cdots$ The sum of the residues of the former is denoted by I_1, and the latter by I_2 respectively. As the residue of $\Gamma(-s)$ at $s=n$ is $-(-)^n/n!$ we have

$$I_1 = \frac{\sqrt{\pi}}{2}\sum_{\mu=0}^{(\alpha+\beta)/2-1}\frac{(-)^\mu}{\mu!}\,\frac{\Gamma((\alpha+\beta)/2-\mu)\Gamma(2\mu+1)(\gamma/2)^{2\mu}}{\Gamma((\alpha+\beta)/2+\mu+1)\Gamma((\alpha-\beta)/2+\mu+1)\Gamma((\beta-\alpha)/2+\mu+1)\Gamma(\frac{1}{2}-\mu)}\,, \tag{3.4}$$

$$I_2=\frac{\sqrt{\pi}}{2}\frac{1}{2\pi i}\int_C\frac{\pi}{\sin\pi s}\frac{\pi}{\sin\pi((\alpha+\beta)/2+s)}$$

$$\times\frac{\Gamma(\alpha+\beta+2s+1)(\gamma/2)^{\alpha+\beta+2s}}{\Gamma(1+s)\Gamma((\alpha+\beta)/2+s+1)\Gamma(\alpha+\beta+s+1)\Gamma(\alpha+\beta+1)\Gamma(\beta+s+1)\Gamma(-(\alpha+\beta)/2-s+\frac{1}{2})}$$

$$=(-)^{(\alpha+\beta)/2+1}\frac{\sqrt{\pi}}{2}\sum_{\mu=0}^{\infty}\left[\frac{d}{ds}\right.$$

$$\left.\times\frac{\Gamma(\alpha+\beta+2s+1)(\gamma/2)^{\alpha+\beta+2s}}{\Gamma(1+s)\Gamma((\alpha+\beta)/2+s+1)\Gamma(\alpha+\beta+s+1)\Gamma(\alpha+s+1)\Gamma(\beta+s+1)\Gamma(-(\alpha+\beta)/2-s+\frac{1}{2})}\right]_{s=\mu}$$

$$=(-)^{(\alpha+\beta)/2+1}\frac{\sqrt{\pi}}{2}\sum_{\mu=0}^{\infty}$$

$$\times\frac{\Gamma(\alpha+\beta+2\mu+1)(\gamma/2)^{\alpha+\beta+2\mu}}{\Gamma(1+\mu)\Gamma((\alpha+\beta)/2+\mu+1)\Gamma(\alpha+\beta+\mu+1)\Gamma(\alpha+\mu+1)\Gamma(\beta+\mu+1)\Gamma(-(\alpha+\beta)/2-\mu+\frac{1}{2})}$$

$$\times\left\{2\log\frac{\gamma}{2}+2\psi(\alpha+\beta+2\mu+1)-\psi(1+\mu)-\psi\left(\frac{\alpha+\beta}{2}+\mu+1\right)-\psi(\alpha+\beta+\mu+1)\right.$$

$$\left.-\psi(\alpha+\mu+1)-\psi(\beta+\mu+1)+\psi\left(-\frac{\alpha+\beta}{2}-\mu+\frac{1}{2}\right)\right\}. \tag{3.5}$$

where $\psi(z)=d\log\Gamma(z)/dz$.

Real part of $G_{n\nu}^{*m}$ can be calculated similary and the result is $(2\nu+m+3/2=\alpha,\ 2n+m+3/2=\beta)$

$$\mathscr{R}G_{n\nu}^{*m}=\int_{\gamma}^{\infty}\frac{(\xi^2-\gamma^2)^{1/2}J_\alpha(\xi)J_\beta(\xi)}{\xi^2}d\xi=I_1{}^*+I_2{}^*, \tag{3.6}$$

$$I_1{}^*=\frac{\sqrt{\pi}}{4}\sum_{\mu=0}^{(\alpha+\beta)/2-1}\frac{(-)^\mu}{\mu!}\frac{\Gamma((\alpha+\beta)/2-\mu)\Gamma(2\mu+1)(\gamma/2)^{2\mu}}{\Gamma(\mu+1+(\alpha-\beta)/2)\Gamma(\mu+1+(\beta-\alpha)/2)\Gamma(\mu+1+(\alpha+\beta)/2)\Gamma(-\mu+3/2)}, \tag{3.7}$$

$$I_2{}^*=(-)^{(\alpha+\beta)/2+1}\frac{\sqrt{\pi}}{4}\sum_{\mu=0}^{\infty}$$

$$\times\frac{\Gamma(\alpha+\beta+2\mu+1)(\gamma/2)^{\alpha+\beta+2\mu}}{\Gamma(\mu+1)\Gamma((\alpha+\beta)/2+\mu+1)\Gamma(\alpha+\mu+1)\Gamma(\beta+\mu+1)\Gamma(\alpha+\beta+\mu+1)\Gamma(-(\alpha+\beta)/2-\mu+3/2)}$$

$$\times\left\{2\log\frac{\gamma}{2}+2\psi(\alpha+\beta+2\mu+1)-\psi(\mu+1)-\psi\left(\frac{\alpha+\beta}{2}+\mu+1\right)\right.$$

$$\left.-\psi(\alpha+\mu+1)-\psi(\beta+\mu+1)-\psi(\alpha+\beta+\mu+1)+\psi\left(-\frac{\alpha+\beta}{2}-\mu+\frac{3}{2}\right)\right\}. \tag{3.8}$$

The first a few terms of $G_{n\nu}^{-1/2}$ and $G_{n\nu}^{*-1/2}$ are shown as follows.

$$G_{00}^{-1/2}=-\frac{1}{2}\left\{2\log\frac{\gamma}{2}-3\psi(1)+\psi\left(\frac{1}{2}\right)\right\}+\frac{1}{2}\left(\frac{\gamma}{2}\right)^2\left\{2\log\frac{\gamma}{2}+2\psi(3)-5\psi(2)+\psi\left(-\frac{1}{2}\right)\right\}$$

$$-\frac{9}{32}\left(\frac{\gamma}{2}\right)^4\left\{2\log\frac{\gamma}{2}+2\psi(5)-5\psi(3)+\psi\left(-\frac{3}{2}\right)\right\}+\cdots$$

$$-i\frac{\pi}{2}\left[1-4\left(\frac{\gamma}{2}\right)^2+9\left(\frac{\gamma}{2}\right)^4+\cdots\right],$$

$$G_{10}^{-1/2}=G_{01}^{-1/2}=-\frac{1}{8}\left(\frac{\gamma}{2}\right)^2\left\{2\log\frac{\gamma}{2}-2\psi(1)-\psi(2)+\psi\left(-\frac{1}{2}\right)\right\}$$

$$+\frac{1}{8}\left(\frac{\gamma}{2}\right)^4\left\{2\log\frac{\gamma}{2}+2\psi(5)-2\psi(4)-\psi(3)-2\psi(2)+\psi\left(-\frac{3}{2}\right)\right\}+\cdots$$

$$-i\frac{\pi}{2}\left[\frac{1}{4}\left(\frac{\gamma}{2}\right)^2-\frac{1}{4}\left(\frac{\gamma}{2}\right)^4+\cdots\right],$$

$$G_{11}^{-1/2}=\frac{1}{4}+\frac{1}{12}\left(\frac{\gamma}{2}\right)^2$$
$$-\frac{3}{64}\left(\frac{\gamma}{2}\right)^4\left\{2\log\frac{\gamma}{2}+\psi(5)-\psi(1)-3\psi(3)+\psi\left(-\frac{3}{2}\right)\right\}+\cdots$$
$$-i\frac{\pi}{2}\left[\frac{3}{32}\left(\frac{\gamma}{2}\right)^4+\cdots\right. \tag{3.9}$$

$$G_{00}^{*-1/2}=\frac{1}{2}+\frac{1}{4}\left(\frac{\gamma}{2}\right)^2\left\{2\log\frac{\gamma}{2}+\psi(3)-3\psi(2)+\psi\left(\frac{1}{2}\right)-\psi(1)\right\}$$
$$-\frac{1}{16}\left(\frac{\gamma}{2}\right)^4\left\{2\log\frac{\gamma}{2}+2\psi(5)-\psi(4)-3\psi(3)+\psi\left(-\frac{1}{2}\right)-\psi(2)\right\}+\cdots$$
$$+i\frac{\pi}{2}\left[\frac{1}{2}\left(\frac{\gamma}{2}\right)^2-\frac{1}{24}\left(\frac{\gamma}{2}\right)^4+\cdots\right],$$

$$G_{10}^{*-1/2}=G_{01}^{*-1/2}=-\frac{1}{24}\left(\frac{\gamma}{2}\right)^2$$
$$+\frac{1}{96}\left(\frac{\gamma}{2}\right)^4\left\{2\log\frac{\gamma}{2}+\psi(5)-\psi(4)-\psi(2)+\psi\left(-\frac{1}{2}\right)-\psi(1)-\psi(3)\right\}+\cdots$$
$$+i\frac{\pi}{2}\left[\frac{1}{48}\left(\frac{\gamma}{2}\right)^4+\cdots\right],$$

$$G_{11}^{*-1/2}=\frac{1}{6}-\frac{1}{48}\left(\frac{\gamma}{2}\right)^2-\frac{1}{320}\left(\frac{\gamma}{2}\right)^4+O(\gamma^6,\log\gamma)+iO(\gamma^6)\,. \tag{3.10}$$

The inversion of $G_{n\nu}^{-1/2}$ and $G_{n\nu}^{*-1/2}$ gives the series representation of $X_{n\nu}$, and $X_{n\nu}^*$. The first a few terms are given by

$$X_{00}=\frac{2}{-2\log\gamma/2-a_1-\pi i}+\cdots,$$
$$a_1=-3\psi(1)+\psi(1/2)=2C-2\log 2=-0.23188\,. \tag{3.11}$$

$$X_{00}^*=2-\left(\frac{\gamma}{2}\right)^2\left(2\log\frac{\gamma}{2}+a_2+\pi i\right)+\left(\frac{\gamma}{2}\right)^4\left[\frac{19}{240}+\frac{a_3}{4}+\frac{\pi^2}{2}+\frac{1}{2}\log\frac{\gamma}{2}\right.$$
$$\left.+\frac{1}{2}\left(2\log\frac{\gamma}{2}+a_2\right)^2+i\left\{\frac{\pi}{4}+2\pi\log\frac{\gamma}{2}+\pi a_2\right\}\right]+O(\gamma^6)\,,$$
$$X_{01}^*=X_{10}^*=\frac{1}{2}\left(\frac{\gamma}{2}\right)^2-\left(\frac{\gamma}{2}\right)^4\left\{\frac{3}{8}\log\frac{\gamma}{2}+\frac{a_4}{8}-\frac{1}{16}+\frac{a_2}{4}+\frac{3\pi i}{8}\right\}+O(\gamma^6)\,,$$
$$a_2=\psi(3)-3\psi(2)+\psi(1/2)-\psi(1)=2C-3/2-2\log 2=-1.73186\,,$$
$$a_3=2\psi(5)-\psi(4)-3\psi(3)+\psi(-1/2)-\psi(2)\,,$$
$$a_4=\psi(5)-\psi(4)-\psi(2)+\psi(-1/2)-\psi(1)-\psi(3)\,. \tag{3.12}$$

§ 4. Diffracted Field at Large Distances from the Ribbon

Each of Π and Π^* determined in § 2 satisfies the two-dimensional wave equation. We express Π and Π^* at a distant point by Green's function in two dimensions and values of Π and $\partial\Pi/\partial z$ on the ribbon,

$$\Pi=-\frac{i}{4}\int\left\{H_0^{(2)}(kR')\frac{\partial\Pi}{\partial n}-\Pi\frac{\partial}{\partial n}H_0^{(2)}(kR')\right\}dS'\,. \tag{4.1}$$

The same equation holds for Π^*. Here R' is the distance between the point $Q(y)$ on the ribbon and P at the distant point. The integration dS' is carried out on both sides of the ribbon, S_+ and S_-. Evidently

$$(\Pi)_{S_+}=(\Pi)_{S_-}=f\ , \qquad \left(\frac{\partial \Pi}{\partial n}\right)_{S_+}=\left(\frac{\partial \Pi}{\partial n}\right)_{S_-}=-g\ ,$$

$$\frac{\partial}{\partial n}H_0^{(2)}(kR')=-k\cos\theta H_1^{(2)}(kR')\ ,$$

hence

$$\Pi=-\frac{i}{2}\int_{-a}^{a}\frac{\partial \Pi}{\partial n}H_0^{(2)}(kR')dy\ , \tag{4.2}$$

$$\Pi^*=-\frac{ik}{2}\cos\theta\int_{-a}^{a}\Pi^* H_1^{(2)}(kR')dy\ , \tag{4.3}$$

where θ is the angle between z axis and the semi-straight line joining the origin and P. When $PQ=R$ is large enough,

$$\Pi=e^{3\pi i/4}\sqrt{\frac{2}{\pi}}\frac{E_2}{k^2a}\frac{e^{-ikR}}{\sqrt{kR}}\int_0^a e^{iky\sin\theta}\left\{\sum_{n=0}^{\infty}A_nT_n^{-1/2}(y,0)+\sum_{n=0}^{\infty}B_nT_n^{1/2}(y,\,0)\right\}dy\ . \tag{4.4}$$

Integration of y yields[†]

$$=e^{-\pi i/4}\sqrt{\frac{\pi}{2}}\frac{E_2}{k^2}\frac{e^{-ikR}}{\sqrt{kR}}A(\alpha,\,\theta)\ ,$$

where $A(\alpha,\,\theta)$ is a scattering amplitude of incident direction α and observation direction θ, and is given by

$$A(\alpha,\,\theta)=\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}\{X_{n\nu}J_{2\nu}(\gamma\sin\alpha)J_{2n}(\gamma\sin\theta)+Y_{n\nu}J_{2\nu+1}(\gamma\sin\alpha)J_{2n+1}(\gamma\sin\theta)\}\ . \tag{4.5}$$

Similarly for Π^*,

$$\left.\begin{aligned}&-(\Pi^*)_{S_+}=(\Pi^*)_{S_-}=\sqrt{\varepsilon/\mu}\,f^*\ , \qquad \left(\frac{\partial \Pi^*}{\partial n}\right)_{S_+}=-\left(\frac{\partial \Pi^*}{\partial n}\right)_{S_-}\ ,\\ &\Pi^*=\sqrt{\frac{\varepsilon}{\mu}}e^{-\pi i/4}\sqrt{\frac{\pi}{2}}\frac{E_1}{k^2}\frac{e^{-ikR}}{\sqrt{kR}}A^*(\alpha,\,\theta)\ ,\end{aligned}\right\} \tag{4.6}$$

where

$$\begin{aligned}A^*(\alpha,\,\theta)=\gamma\cos\alpha\cdot\gamma\cos\theta\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}\Bigg\{&X^*_{n\nu}\frac{J_{2\nu+1}(\gamma\sin\alpha)}{\gamma\sin\alpha}\frac{J_{2n+1}(\gamma\sin\theta)}{\gamma\sin\theta}\\ &+Y^*_{n\nu}\frac{J_{2\nu+2}(\gamma\sin\alpha)}{\gamma\sin\alpha}\frac{J_{2n+2}(\gamma\sin\theta)}{\gamma\sin\theta}\Bigg\}\ .\end{aligned} \tag{4.7}$$

When we neglect the smaller term, the electromagnetic field of the diffracted wave at distant point is given by

$$\left.\begin{aligned}&E_x=k^2\Pi_x\ , \qquad E_\theta=-k^2\sqrt{\mu/\varepsilon}\,\Pi_x^*\ , \qquad E_R=0\ ,\\ &H_x=k^2\Pi_x^*\ , \qquad H_\theta=k^2\sqrt{\varepsilon/\mu}\,\Pi_x\ , \qquad H_R=0\ ,\end{aligned}\right\} \tag{4.8}$$

[†] $\int_0^1 d\rho\int_0^\infty d\xi\cos(\rho\gamma\sin\alpha)\sqrt{\rho}\,\xi^{-1/2}J_{-1/2}(\xi)J_{2n+1}(\xi)=\sqrt{\frac{2}{\pi}}\frac{J_{2n+1}(\gamma\sin\alpha)}{\gamma\sin\alpha}$,

$\int_0^1 d\rho\int_0^\infty d\xi\cos(\rho\gamma\sin\alpha)\sqrt{\rho}\,\xi^{1/2}J_{-1/2}(\xi)J_{2n}(\xi)=\sqrt{\frac{2}{\pi}}J_{2n}(\gamma\sin\alpha)$,

$\int_0^1 d\rho\int_0^\infty d\xi\sin(\rho\gamma\sin\alpha)\sqrt{\rho}\,\xi^{-1/2}J_{1/2}(\xi)J_{2n+2}(\xi)=\sqrt{\frac{2}{\pi}}\frac{J_{2n+2}(\gamma\sin\alpha)}{\gamma\sin\alpha}$,

$\int_0^1 d\rho\int_0^\infty d\xi\sin(\rho\gamma\sin\alpha)\sqrt{\rho}\,\xi^{1/2}J_{1/2}(\xi)J_{2n+1}(\xi)=\sqrt{\frac{2}{\pi}}J_{2n+1}(\gamma\sin\alpha)$.

$|A(\alpha, \theta)|$ and $|A^*(\alpha, \theta)|$ give the relative field intensity at the distant point.

The energy flow from the surface of semi-cylinder of radius R is

$$W=\frac{\pi}{4}\sqrt{\frac{\varepsilon}{\mu}}\frac{1}{k}\mathscr{R}\{E_2^2|A(\alpha, \theta)|^2+E_1^2|A^*(\alpha, \theta)|^2\}\,. \tag{4.9}$$

The half of the scattering coefficient σ of the ribbon, which is equal to the transmission coefficient t of the slit, is given by

$$t=\frac{\sigma}{2}=\frac{\pi}{2}\frac{1}{\gamma\cos\alpha}\int_0^{\pi/2}\{\sin^2\psi|A(\alpha, \theta)|^2+\cos^2\psi|A^*(\alpha, \theta)|^2\}d\theta\,, \tag{4.10}$$

where $E_2=E\sin\psi$, $E_1=E\cos\psi$.

In case of electric type normal incidence ($\psi=\pi/2$, $\alpha=\pi/2$),

$$\begin{aligned}\frac{\sigma_2}{2}=t_2=\frac{\pi^2}{2\gamma}\Big[&\frac{1}{2}|X_{00}|^2+\Big\{-\frac{1}{2}|X_{00}|^2+\frac{1}{4}|X_{00}X_{10}|\Big\}\Big(\frac{\gamma}{2}\Big)^2\\&+3\Big\{\frac{1}{32}|X_{00}|^2-\frac{1}{12}|X_{00}X_{10}|+\frac{1}{192}|X_{00}X_{20}|+\frac{1}{64}|X_{20}|^2\Big\}\Big(\frac{\gamma}{2}\Big)^4+O(\gamma^6)\Big]\end{aligned} \tag{4.11}$$

$$=\frac{\pi^2}{\gamma}\frac{1}{(2\log(\gamma/2)+a_1)^2+\pi^2}+\cdots\,, \tag{4.12}$$

It is noted that t_2 tend to infinity when γ tend to zero.

In case of magnetic type normal incidence ($\psi=0$, $\alpha=\pi/2$),

$$\begin{aligned}\frac{\sigma_1}{2}=t_1=\frac{\pi^2\gamma^3}{32}\Big[&\frac{1}{4}|X_{00}^*|^2+\Big\{-\frac{1}{16}|X_{00}^*|^2+\frac{1}{48}|X_{00}^*X_{10}^*|\Big\}\Big(\frac{\gamma}{2}\Big)^2\\&+\Big\{\frac{5}{384}|X_{00}^*|^2-\frac{1}{96}|X_{00}^*X_{10}^*|+\frac{1}{1920}|X_{00}^*X_{20}^*|+\frac{1}{1152}|X_{10}^*|^2\Big\}\Big(\frac{\gamma}{2}\Big)^4+O(\gamma^6)\Big]\end{aligned} \tag{4.13}$$

$$=\frac{\pi^2\gamma^3}{32}\Big[1+\Big(\frac{\gamma}{2}\Big)^2\Big(-2\log\frac{\gamma}{2}-a_2-\frac{1}{4}\Big)+O(\gamma^4)\Big], \tag{4.14}$$

(4.14) is qualitatively similar to the transmission coefficient of circular plate or hole. (4.14) agrees with those obtained by Bouwkamp2) and others16)-17).

§ 5. Electromagnetic Field on the Ribbon and Slit

The electromagnetic field caused by the diffracted field on the ribbon and slit is given by

$$\left.\begin{array}{l|l}
E_x=k^2\Pi_x\,, & E_x=k^2\Pi_x^*\,,\\
E_y=-ik\sqrt{\dfrac{\mu}{\varepsilon}}\dfrac{\partial\Pi_x^*}{\partial z}\,, & E_y=-ik\sqrt{\dfrac{\mu}{\varepsilon}}\dfrac{\partial\Pi_x}{\partial z}\,,\\
E_z=ik\sqrt{\dfrac{\mu}{\varepsilon}}\dfrac{\partial\Pi_x^*}{\partial y}\,, & E_z=ik\sqrt{\dfrac{\mu}{\varepsilon}}\dfrac{\partial\Pi_x}{\partial y}\,,\\
H_x=\pm J_y=k^2\Pi_x^*\,, & H_x=k^2\Pi_x\,,\\
H_y=\mp J_z=ik\sqrt{\dfrac{\varepsilon}{\mu}}\dfrac{\partial\Pi_x}{\partial z}\,, & H_y=ik\sqrt{\dfrac{\varepsilon}{\mu}}\dfrac{\partial\Pi_x^*}{\partial z}\,,\\
H_z=-ik\sqrt{\dfrac{\varepsilon}{\mu}}\dfrac{\partial\Pi_x}{\partial y}\,. & H_z=-ik\sqrt{\dfrac{\varepsilon}{\mu}}\dfrac{\partial\Pi_x^*}{\partial y}\,.
\end{array}\right\} \tag{5.1}$$

Here the terms $\partial^2\Pi/\partial y^2$ and $\partial^2\Pi/\partial y\partial z$ do not appear and hence it is evident that the edge conditions are satisfied.

The surface current density due to the diffracted field and the incident field is

$$J_y=\sqrt{\frac{\varepsilon}{\mu}}E_1\Bigg[\mp e^{-iky\sin\alpha}-\sqrt{\frac{\pi}{2}}\cos\alpha$$
$$\times\left\{i\gamma\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}X_{n\nu}^{*}\frac{J_{2\nu+1}(\gamma\sin\alpha)}{\gamma\sin\alpha}S_n^{*-1/2}(y,0)\right.$$
$$\left.+\gamma\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}Y_{n\nu}^{*}\frac{J_{2\nu+2}(\gamma\sin\alpha)}{\gamma\sin\alpha}S_n^{*1/2}(y,0)\right\}\Bigg],$$

$$J_x=\sqrt{\frac{\varepsilon}{\mu}}E_2\Bigg[\mp\cos\alpha\, e^{-iky\sin\alpha}+\frac{i}{\gamma}\sqrt{\frac{\pi}{2}}$$
$$\times\left\{-\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}X_{n\nu}J_{2\nu}(\gamma\sin\alpha)T_n^{-1/2}(y,0)\right.$$
$$\left.+i\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}Y_{n\nu}J_{2\nu+1}(\gamma\sin\alpha)T_n^{1/2}(y,0)\right\}\Bigg],$$

Here the upper sign indicates the current density of the back surface of the ribbon and the lower sign indicates that of the front surface.

The electric field in the slit is

$$\left.\begin{aligned}
E_x&=E_1\cos\alpha\sqrt{\frac{\pi}{2}}\\
&\quad\times\left\{i\gamma\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}X_{n\nu}^{*}\frac{J_{2\nu+1}(\gamma\sin\alpha)}{\gamma\sin\alpha}S_n^{*-1/2}(y,0)\right.\\
&\quad\left.+\gamma\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}Y_{n\nu}^{*}\frac{I_{2\nu+2}(\gamma\sin\alpha)}{\gamma\sin\alpha}S_n^{*1/2}(y,0)\right\},\\
E_y&=-E_2\frac{i}{\gamma}\sqrt{\frac{\pi}{2}}\\
&\quad\times\left\{-\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}X_{n\nu}J_{2\nu}(\gamma\sin\alpha)T_n^{-1/2}(y,0)\right.\\
&\quad\left.+i\sum_{n=0}^{\infty}\sum_{\nu=0}^{\infty}Y_{n\nu}J_{2\nu+1}(\gamma\sin\alpha)T_n^{1/2}(y,0)\right\},
\end{aligned}\right\}\tag{5.2}$$

where

$$\left.\begin{aligned}
S_n^{*-1/2}(y,0)&=\sqrt{\frac{2}{\pi}}\frac{1}{(2n+1)}(1-\rho^2)^{1/2}F\left(-n,\,n+1;\,\frac{1}{2};\,\rho^2\right),\\
S_n^{*1/2}(y,0)&=\sqrt{\frac{2}{\pi}}\rho(1-\rho^2)^{1/2}F\left(-n,\,n+2;\,\frac{3}{2};\,\rho^2\right),\\
T_n^{-1/2}(y,0)&=\sqrt{\frac{2}{\pi}}(1-\rho^2)^{-1/2}F\left(-n,\,n;\,\frac{1}{2};\,\rho^2\right),\\
T_n^{1/2}(y,0)&=\sqrt{\frac{2}{\pi}}(2n+1)\rho(1-\rho^2)^{-1/2}F\left(-n,\,n+1;\,\frac{3}{2};\,\rho^2\right)\qquad \rho=y/a\,.
\end{aligned}\right\}\tag{5.3}$$

When the incident electric wave is parallel to the ribbon, $J_y=0$ and $J_x\propto(1-\rho^2)^{-1/2}f_1(\rho)$ and when it is perpendicular to it, $J_x=0$ and $J_y\propto(1-\rho^2)^{1/2}f_2(\rho)$,

When the incident electric wave is perpendicular to the slit, $E_x=0$ and $E_y\propto(1-\rho^2)^{-1/2}f_1(\rho)$ and when it is parallel to it, $E_y=0$ and $E_x\propto(1-\rho^2)^{1/2}f_2(\rho)$,

where $f_1(\rho)$ and $f_2(\rho)$ are regular function of ρ in $-1\leqq\rho\leqq1$.

The total amount of the diffracted energy flow on the upper surface of the slit is equal to the scattered energy for $z>0$.

$$\begin{aligned}
S_z&=\frac{1}{2}\mathscr{R}(E_x\tilde{H}_y-E_y\tilde{H}_x)\\
&=\frac{1}{2}\mathscr{R}\Bigg[\Bigg\{E_1^2\cos^2\alpha\left(\sum_{n=0}^{\infty}A_n^{*}S_n^{*-1/2}(y,0)+\sum_{n=0}^{\infty}B_n^{*}S_n^{*1/2}(y,0)\right)\\
&\quad+i\frac{E_2^2}{\gamma}\left(\sum_{n=0}^{\infty}A_nT_n^{-1/2}(y,0)+\sum_{n=0}^{\infty}B_nT_n^{1/2}(y,0)\right)\Bigg\}e^{-iky\sin\alpha}\Bigg],
\end{aligned}$$

where ~ denotes the complex conjugate quantity. The transmission coefficient is

$$t=\frac{\pi}{2\gamma\cos\alpha}\mathscr{I}\{\sin^2\psi A(\alpha,\alpha)-\cos^2\psi A^*(\alpha,\alpha)\}\,.\tag{5.4†}$$

---

† de Hoop's scattering amplitude $A_2(\theta,\theta_0)$ refers to f (not to Π). Hence

$$2\pi\tilde{A}(\alpha,\theta)=A_2(\theta,\theta_0)\,,\qquad -2\pi\tilde{A}^*(\alpha,\theta)=A_1(\theta,\theta_0)\,.$$

In case of normal incidence, the current density, field intensity, and the transmission coefficient are given by

$$\left.\begin{array}{ll} J_x=\sqrt{\dfrac{\varepsilon}{\mu}}E_2\Big[\mp 1-\dfrac{i}{\gamma}\sum\limits_{n=0}^{\infty}X_{n0}(1-\rho^2)^{-1/2} & E_y=E_2\dfrac{i}{\gamma}\sum\limits_{n=0}^{\infty}X_{n0}(1-\rho^2)^{-1/2} \\ \qquad\times F\left(-n,n;\dfrac{1}{2};\rho^2\right)\Big], & \qquad\times F\left(-n,n;\dfrac{1}{2};\rho^2\right), \\ J_y=\sqrt{\dfrac{\varepsilon}{\mu}}E_1\Big[\mp 1-\dfrac{i\gamma}{2}\sum\limits_{n=0}^{\infty}X_{n0}^*\dfrac{1}{(2n+1)} & E_x=E_1\dfrac{i\gamma}{2}\sum\limits_{n=0}^{\infty}X_{n0}^*\dfrac{1}{2n+1}(1-\rho^2)^{1/2} \\ \qquad\times(1-\rho^2)^{1/2}F\left(-n,n+1;\dfrac{1}{2};\rho^2\right)\Big]. & \qquad\times F\left(-n,n+1;\dfrac{1}{2};\rho^2\right). \end{array}\right\} \tag{5.5}$$

$|J_x|$ and $|J_y|$ in (5.5) are qualitatively similar to Fig. 6 and Fig. 7 in II respectively. $|E_y|$ and $|E_x|$ are qualitatively similar to Fig. 8 and Fig. 9 in II respectively. [r/a in Fig. 6, 7, 8 and 9 in II should be read $(r/a)^2$.]

$$t=\frac{\pi}{2}\mathscr{I}\left\{\sin^2\psi\frac{X_{00}}{\gamma}-\cos^2\psi\frac{\gamma X_{00}^*}{4}\right\}. \tag{5.6}$$

Substitution of series representation of X_{00} and X_{00}^* into (5.6) gives the same results with (4.12) and (4.13).

The numerical calculation of the results and discussions will be published in the subsequent paper.

§ 6. Summary

The authors have solved the problem of the diffraction of electromagnetic waves by an infinitely long ribbon or slit in case where the plane of incidence is perpendicular to the edge of the ribbon or slit and the angle of incidence and polarizations are arbitrary. The diffracted field is assumed to be derived by electric type and magnetic type Hertz vectors, both of which have only one scalar component and which are expressed in terms of Weber-Schafheitlin's integrals with unknown coefficients. These coefficients are determined by hypergeometric polynomial expansion. The expressions for scattering cross section, transmission coefficients, electric current density of the ribbon, electric field intensity in the slit, electric field intensity at the distant point are obtained. Numerical results and discussions will be reported in the subsequent paper.

Application of Variational Method to the Thomas-Fermi Equation

By Teruo IKEBE and Tosio KATO

Department of Physics, Faculty of Science, University of Tokyo

(Received October 22, 1956)

Variational method is applied to derive two inequalities giving rigorous upper and lower bounds for the initial slope $B_0=-\varphi'(0)$ of the ordinary Thomas-Fermi function $\varphi(x)$, the solution of the non-linear equation

$$\varphi''=x^{-1/2}\varphi^{3/2}$$

with the boundary conditions

$$\varphi(0)=1\,,\qquad \varphi(\infty)=0\,.$$

Application of these formulas using simple trial functions leads to the estimate

$$1.5865\leq B_0\leq 1.5883\,.$$

§1. Introduction

In the Thomas-Fermi statistical model of a free neutral atom, we are to solve the following non-linear differential equation of second order[2] over the interval $(0, \infty)$

$$\varphi''=x^{-1/2}\varphi^{3/2} \tag{1.1}$$

with the boundary conditions

$$\varphi(0)=1\,,\qquad \varphi(\infty)=0\,. \tag{1.2}$$

The unique solution of the above problem, the so-called ordinary Thomas-Fermi function, can be shown to exist[5]. Practically, however, as has been done by a number of authors, it can be solved with the aid of numerical integration method. Since the behavior of a solution of (1.1) subject to the condition $\varphi(0)=1$ alone depends very sensitively upon the initial value of its derivative, it is important in numerical solution to determine the initial slope $B_0=-\varphi'(0)$ as precisely as possible.

It is noted that solution of (1.1) and (1.2) could be reduced to the variational problem of minimizing the functional

$$J[u]=\int_0^\infty\left(u'^2+\frac{4}{5}\,x^{-1/2}u^{5/2}\right)dx\,, \tag{1.3}$$

where the trial function $u(x)$ is positive and subject to the same conditions as (1.2). Eq. (1.1) is nothing but the Euler's equation of $J[u]$. On the other hand, the initial slope can be written in the following form:

$$B_0=-\varphi'(0)=\int_0^\infty(\varphi'^2+x^{-1/2}\varphi^{5/2})dx\,, \tag{1.4}$$

for

$$\int_0^\infty\varphi'^2dx=\varphi\varphi'\Big|_0^\infty-\int_0^\infty\varphi\varphi''dx=-\varphi'(0)$$
$$-\int_0^\infty x^{-1/2}\varphi^{5/2}dx$$

using (1.1) and (1.2). In case of linear differential equations, such quantities B_0 as required above often turn out to be the extremal values themselves of the corresponding functionals $J[u]$, but in our case it cannot be expected on account of non-linearity.

By variational observation, however, we shall derive in §2 the relation

$$\frac{6}{7}\,B_0=J[\varphi]\,, \tag{1.5}$$

which E. A. Milne deduced by partial integration already in 1927[4].

In order to carry out the estimation of B_0, we shall transform the functional $J[u]$ into its reciprocal form

$$I[v]=-2v(0)-\int_0^\infty\left(v^2+\frac{6}{5}\,x^{1/3}v'^{5/3}\right)dx \tag{1.6}$$

by means of the Friedrichs transformation[1], and make use of the relation $I[v]\leq J[u]$ (see §2). Then with (1.5) we are led to the inequalities

$$\frac{7}{6}\,I[v]\leq B_0\leq\frac{7}{6}\,J[u]\,, \tag{1.7}$$

estimating the initial slope.

§2. Derivation of the Inequalities

We shall denote by $\varphi(x)$ the ordinary Thomas-Fermi function, which is also the extremal function of $J[u]$, and consider an admissible trial function defined by $\varphi_\lambda(x)=\varphi(\lambda x)$ with λ sufficiently near to 1. Then the stationary value of

$$J[\varphi_\lambda]=\int_0^\infty\left[\lambda^2\varphi'(\lambda x)^2+\frac{4}{5}\,x^{-1/2}\varphi(\lambda x)^{5/2}\right]dx$$
$$=\int_0^\infty\left[\lambda\varphi'(x')^2+\frac{4}{5}\,\lambda^{-1/2}x'^{-1/2}\varphi(x')^{5/2}\right]dx'$$
$$(\lambda x=x')$$

should be attained at $\lambda=1$; in other words $(\partial J[\varphi_\lambda]/\partial\lambda)_{\lambda=1}=0$. This immediately leads to

$$5\int_0^\infty \varphi'^2 dx = 2\int_0^\infty x^{-1/2}\varphi^{5/2}dx \,.$$

In view of (1.4), therefore, we have the result (1.5).

Now we shall perform the Friedrichs or involutory transformation[1)] on the functional $J[u]$ as follows: Put

$$F(x,\, u,\, u') = u'^2 + \frac{4}{5}\,x^{-1/2}u^{5/2}\,, \tag{2.1}$$

x, u, u' being independent variables, and

$$F_{u'} = 2v\,, \qquad F_u = 2v'\,, \tag{2.2}$$

$$2vu' + 2v'u - F(x,\, u,\, u') = \Phi(x,\, v,\, v')\,, \tag{2.3}$$

where u, u' solved from Eqs. (2.2) as functions of x, v, v' should be substituted in (2.1) and (2.3). This is known as the Legendre transformation in the theory of differential equations. The condition that this transformation could be carried out is

$$\frac{\partial(F_u,\, F_{u'})}{\partial(u,\, u')} = F_{uu}F_{u'u'} - F_{uu'}{}^2 \neq 0\,, \tag{2.4}$$

which in our case can be easily proved to hold, for

$$F_{uu}F_{u'u'} - F_{uu'}{}^2 = 6x^{-1/2}u^{1/2} > 0\,. \tag{2.5}$$

Thus we arrive at the following reciprocal functional form to $J[u]$:

$$\begin{aligned} I[v] &= 2v(\infty)u(\infty) - 2v(0)u(0) - \int_0^\infty \Phi(x,\, v,\, v')dx \\ &= -2v(0) - \int_0^\infty \left(v^2 + \frac{6}{5}\,x^{1/3}v'^{5/3}\right)dx \end{aligned} \tag{2.6}$$

with

$$v' = \frac{dv}{dx}\,,$$

where no boundary conditions are assumed on $v(x)$. A sufficient condition that

$$I[v] \leq J[u] \tag{2.7}$$

is[1)]

$$F_{uu}F_{u'u'} - F_{uu'}{}^2 > 0\,, \qquad F_{u'u'} > 0\,,$$

which is seen to be satisfied by (2.5) and $F_{u'u'}=2$. The equality sign in (2.7) holds for $u=\varphi$ and $v=\psi=\varphi'$, so that we have

$$I[v] \leq J[\varphi] = I[\psi] \leq J[u]\,.$$

This is noting but the inequalities (1.7) except for a numerical factor.

In order to simplify further calculation we shall carry out some transformations on (1.3) and (2.6). First in (1.3) let us replace the integration variable x by μx, and find the optimum value of μ, which minimizes $J[u]$ for the given $u(x)$. Then we obtain

$$J[u] = 3\left(\frac{2}{5}\right)^{2/3}\left(\int_0^\infty u'^2dx\right)^{1/3}\left(\int_0^\infty x^{-1/2}u^{5/2}dx\right)^{2/3}.$$

If we want to remove the condition $u(0)=1$, $u(x)$ should be replaced by $u(x)/u(0)$, which results in multiplying the factor $u(0)^{-7/3}$ on the above expression. A similar procedure can be applied to (2.6) with another transformation which replaces $v(x)$ by $\nu v(\mu x)$. The result is

$$I[v] = \frac{15}{7}\left(\frac{2}{7}\right)^{4/3}(-v(0))^{7/3} \times\left(\int_0^\infty v^2dx\right)^{-1/3}\left(\int_0^\infty x^{1/3}v'^{5/3}dx\right)^{-1}.$$

By use of the above expressions and (1.5), we now obtain for B_0 the following inequalities:

$$\begin{aligned} &\frac{5}{2}\left(\frac{2}{7}\right)^{4/3}(-v(0))^{7/3} \\ &\qquad\times\left(\int_0^\infty v^2dx\right)^{-1/3}\left(\int_0^\infty x^{1/3}v'^{5/3}dx\right)^{-1} \leq B_0 \\ &\leq \frac{7}{2}\left(\frac{2}{5}\right)^{2/3}u(0)^{-7/3} \\ &\qquad\times\left(\int_0^\infty u'^2dx\right)^{1/3}\left(\int_0^\infty x^{-1/2}u^{5/2}dx\right)^{2/3}, \end{aligned} \tag{2.8}$$

where u, v are any smooth functions such that $u(x)\geq 0$, $v'(x)\geq 0$.

§ 3. Numerical Results

Let us compute the bounds of B_0 using some simple functions for u and v. Before entering into calculation, however, we remark that linear trial functions containing some variational parameters will not do so well in our case as in linear problems, for the calculation will be, in general, more complicated than in linear cases. Therefore we shall choose our trial functions so that the desired integrals in (2.8) may be obtained analytically, and that, if possible, $u(x)$ and $v(x)$ may approximate $\varphi(x)$ respectively $\psi(x)=\varphi'(x)$ fairly well.

If we adopt for $u(x)$ the function

$$u(x) = (1+x^{1/\alpha})^{-\beta} \qquad (0<x<\infty)\,,$$

where α, β are variational parameters to be determined, then both the integrals $\int_0^\infty u'^2dx$

and $\int_0^\infty x^{-1/2}u^{5/2}dx$ can be expressed in terms of beta functions and we have

$$\frac{7}{6}J[u]=\frac{7}{2}\left(\frac{2}{5}\right)^{2/3}\alpha^{1/3}\beta^{2/3}$$
$$\times B(2-\alpha,\ 2\beta+\alpha)^{1/3}B\left(\frac{\alpha}{2},\ \frac{5\beta-\alpha}{2}\right)^{2/3}.$$

Thus any pair of positive numbers α, β furnishes us with an upper bound of B_0. The pair of suitable values of α, β are determined from the simultaneous equations

$$\frac{\partial J[u]}{\partial\alpha}=0 \quad\text{and}\quad \frac{\partial J[u]}{\partial\beta}=0\,.$$

But these values and also the corresponding value of the functional $J[u]$ have been computed by K. Umeda and S. Kobayashi as follows:⁶⁾

$$\alpha=1.08252\,,\quad \beta=2.0892\,,\quad J[u]=1.3614\,.$$

So we have

$$B_0\leq 1.5883\,.$$

Next let us take for $v(x)$ the function

$$v(x)=\begin{cases}-(1-x^{1/\alpha})^{\beta} & (0<x\leq 1)\\ 0 & (1<x<\infty)\end{cases}$$

(α, β: variational parameters).

The integrals $\int_0^\infty v^2dx$ and $\int_0^\infty x^{1/3}v'^{5/3}dx$ are again obtained in terms of beta functions;

$$\frac{7}{6}I[v]=\frac{5}{2}\left(\frac{2}{7}\right)^{4/3}\alpha^{1/3}\beta^{-5/3}$$
$$\times B(\alpha,\ 2\beta+1)^{-1/3}B\left(\frac{5-\alpha}{3},\ \frac{5\beta-2}{3}\right)^{-1}.$$

Again, any pair of positive numbers α, β substituted in the expression gives a lower bound of B_0. Determining α, β from the equations

$$\frac{\partial I[v]}{\partial\alpha}=0 \quad\text{and}\quad \frac{\partial I[v]}{\partial\beta}=0\,,$$

we find $\alpha=1.831$ and $\beta=18$. With these values we obtain for a lower bound of B_0

$$B_0\geq 1.5865\,.$$

Thus we have estimated the initial slope B_0 as

$$1.5865\leq B_0\leq 1.5883 \qquad (3.1)$$

with an error less than 0.1 percent.

Though (3.1) is a rigorous estimate of B_0, it is not sharp enough compared with the values obtained by other authors, especially those by Umeda and his collaborators³⁾. However, it should be remarked that a more detailed calculation by use of existing tables of the ordinary Thomas-Fermi function²⁾,³⁾ will lead to a much sharper and still rigorous estimate of B_0.

A New Method of Electro-Machining of Hard Metals

By Tasaburô YAMAGUTI

Physical Institute, College of Arts and Sciences, Chiba University

(Received October 18, 1955)

In the customary method of electro-machining of hard metals, it is necessary to initiate some condenced discharges or quenched sparks between the metal to the machined and the tool by incomplete contracts or repeated contacts, where the tool must be kept as the cathode in the circuit of direct current.

In the present method, an ordinary alternating current is used, superposed with some adequate high frequency electric oscillations. The metal and the tool are dipped in water and they are adjusted to keep a certain small separation. Thus, we can initiate favorable quenched discharges in every half cycle, in which the metal is in positive potential.

A merit of the present method is that the developments of any cracks in the machined surface are perfectly prevented even for hard metals, such as tungsten. The time required for drilling a tungsten plate of 3 mm in thickness by a tungsten rod, 1.54 mm in dia., is 4 minutes resulting a hole 1.75 mm in diameter. Screw cutting through a quenched steel plate is proved successful by choosing a brass external thread as a tooling electrode. The mechanism of electro-mechanical machining due to quenched discharges is explained qualitatively; the drilling effect being ascribed to electric attraction working on the melt of the plate, and the consumption of the electrode to a bluster effect of positive ions.

§ 1. Introduction

In the usual electro-machining method, a plate to be machined and the tool are connected to a direct current circuit with a condencer parallel to it[1]. The drilling performed by condenced discharge or quenched spark maintained by incomplete contacts or by repeated contacts of the plate and the electrode. There are, however, some difficulties in this usual method. Deformation of the electrode often caused by machanical contacts with the plate and by stickings of the molten metal drops reduces the accuracy of the machining. Further, when the electrode is drawn back from the contact, very minute cracks are apt to be formed on the surface which was liquified and softened by heating action of large current flowing through the contact point. Furthermore, as the repeated contacts of the electrode are required in this method, feed and rotation of the electrode necessary for the cutting of screw threads cannot be done with simple mechanisms.

The objects of the present experiment are to avoid these difficulties and to perform the machining with the supply from commercial alternating current source. Discharges between the tool and the plate connected in the alternating current circuit are initiated by superposition of high frequency oscillations. The superposition, however, is limited to every half cycle, when the plate is in positive potential[2]. To get a quenched discharge, a condenser connected with a helical wire of small inductance in series is inserted parallel to the electrodes.

§ 2. Experimental Method and Apparatus

The electric circuit of the experimental arrangement is shown in Fig. 1, where E is a

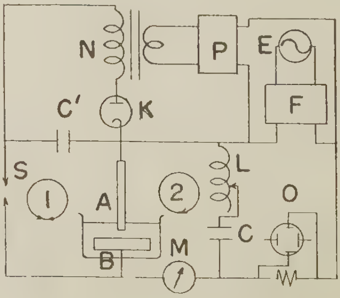

Fig. 1. Electrical circuit of the apparatus.

110 vlot, 50 cycle, single phase alternating current source. The electrode A and the plate B to be drilled are immersed in water and are connected to E through a wave filter F. A condenser C and an inductance L made of herical copper wire, arranged in series, are connected to A and B. Drilling of B is done by quenched discharges of C. One of the secondary terminals of a neon-transformer N is connected to the electrode A passing through a kenotron K, and another to the plate B through a park gap S. A condenser C' 2000 pF in capacity is inserted between one terminal of spark gap and the filament of K. By the rectifying action of K, C' is charged up in every other half cycle and is discharged through the gap, causing high frequency oscillations in the circuit 1. These oscillations initiate quenched discharges of the condenser C in the space between A and B, when these are brought approach. The number of the initiations can be counted by the use of a cathode ray oscillograph inserted in the position O. Furthermore, the initiation of quenched discharges is limited only when the plate is in positive potential by adjustment of a phase shifter P inserted in the primary circuit of the neon-transformer N. The spark gap is made of two tungsten discs about 10 mm in diameter facing each other at a distance 0.25 mm. The secondary potential of N is about 2.3 kv. Capacities of C are varied by several different combinations of condensers of 8 μF. Inductance L of the helical wire is also variable from 0 to 5 μH. Inductance of the lead wire in the circuit 2, excluding the helical wire, is about 2 μH, and this inductance increases with the capacity in the present experiment. M is a dc ammeter to measure discharge current.

In the present experiment, time needed for drilling, loss of the electrode A and diameter of holes drilled in B are measured for several values of C and L, and thus favourable optimum conditions for the drilling are obtained. Thicknesss of the tungsten plates is from 2.82 to 2.97 mm and the diameter of the tool of tungsten rod is 1.54 mm.

Preliminary experiments on the electromechanical cutting of internal screw threads in steel and tungsten carbide plate are carried out. A brass screw, 8 mm in diameter and 1.25 mm in pitch, is used as the cathode and is made to approach to the plate to be drilled guided by a screw of the same pitch.

§ 3. Experimental Results

The observed time interval to finish the drilling and loss of the rod are reduced to values for 3 mm plate for the sake of comparison of the results. The values are shown in Figs. 2 a and b, where the absissa is capacity of condenser C and the ordinate is the reduced time t for drilling. The marks given in the figure represent values of inductance L inserted in the circuit 2. The time t excluding the case for large C decreases with increase of C. The relation between t and C is discussed in the later section. When the capacity is kept constant, the time varies with L having a minimum at a certain value of L as can be seen from the distribution of the marks along vertical lines in the figure. The discharge current measur-

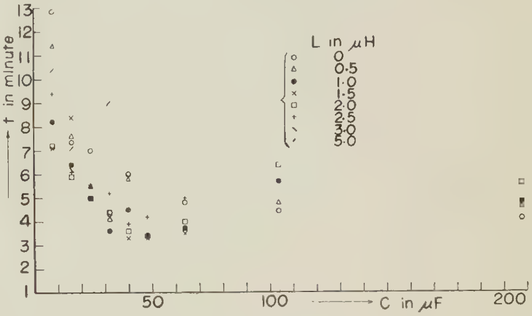

Fig. 2a. Effect of capacity and inductance inserted in the circuit on the working time for the electric discharge drilling of a tungsten plate 3 mm in thickness. Diameter of a tungsten electrode used as cathode is 1.54 mm. Marks representing values of the inductance are illustrated in the figure.

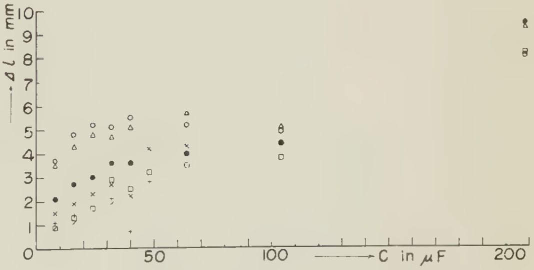

Fig. 2b. Effect of capacity and inductance on the loss of the tungsten electrode for the drilling. Marks representing the inductance are the same as in Fig. 2a.

ed by the dc ammeter M increases with C and L: from 1 ampere at $8\,\mu F$, $2.5\,\mu H$ to 3.2 ampere at $100\,\mu F$, $2.5\,\mu H$. The optimum conditions for drilling speed are $L=1.5\,\mu H$ and $C=40\,\mu F$.

Loss of the electrode also varies with C and L, as is shown in Fig. 2b. The absissa represents the capacity C in μF and the ordinate the loss Δl in mm, which increases with C. At constant C, the loss decreases with the increase of L and reaches nearly to a definite value for L larger than $2\,\mu H$. The conditions for the least loss are $C=8\,\mu F$ and $L=2\,\mu H$.

Diameter of the drilled holes varies with width of the spark gap S, and depends also upon C and L. In Fig. 3, the ordinate represents the diameter ϕ of holes drilled keeping the spark gap in 0.25 mm and using a tungsten electrode 1.54 mm in diameter, and the absissa capacity C. Values of L are represented with the same marks as illustrated in Fig. 2a. As will be seen from the figure the diameter increases with C and L. When C is small, difference between the diameter of the holes and of electrode are about 0.2 mm, and even when C is increased up to comparatively large value such as $64\,\mu F$ the difference is only 0.32 mm for small L. For $C=40\,\mu F$ and $L=1.5\,\mu H$, which are the optimum conditions for the shortest time of drilling and for the least loss of the electrode, the difference is 0.30 mm. Roughness of the electro-machined surface is determined by magnitudes of minute hemispherical droplets of tungsten formed on the surface. Magnitude of these droplets is about 0.02 mm for small values of C and 0.05 mm for large values.

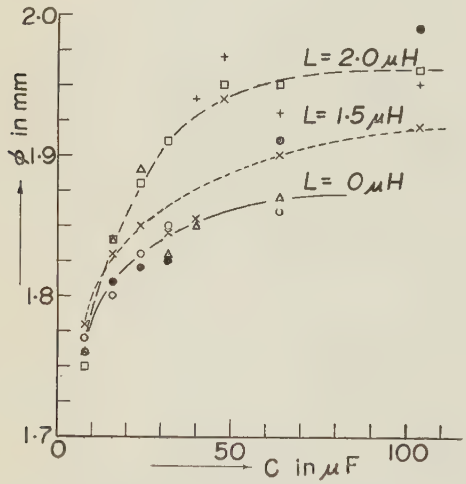

Fig. 3. Variation of diameter ϕ of drilled holes wilh the capacity and the inductance. The marks are the same as in Fig. 2a.

If the plate is kept as cathode, contrary to the experimental conditions mensioned above, the drilling speed becomes slow, and roughness of the machined surface and the difference between the diameter of the hole and of the electrode become increased. As the machining is still possible even in this inefficient case, it is attempted to shorten the working time by the use of alternating current discharges, which can be initiated by elimination of the kenotron K in Fig. 1. Experiments show, however, that the time, the loss and taper of the hole increase remarkably compared with ones obtained by the above method. Thus alternating current discharges are not suitable for machining.

To count the number of quenched discharges starting within one half cycle, a cathode ray oscillograph is inserted in the position O in Fig. 1. Oscillograms show numerous peaks, the number which are about 15 to 30 depending upon values of C and L. These number can be considered as ones of quenched discharges started during the half cycle.

Cutting of screw threads by the present method is done in quenched steel (files) and tungsten carbide plates using brass external threads as the electrode. Fig. 4 shows a photograph of a section of a screw cut in a quenched steel plate 4.4 mm in thickness. Diameter in crest and root of the internal thread cut are 6.90 and 8.19 mm respectively,

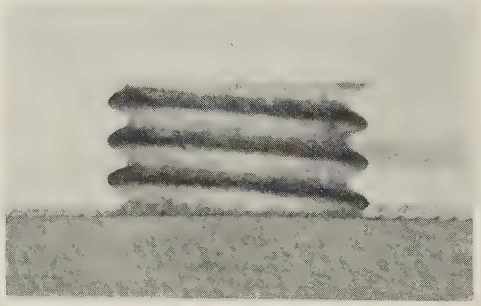

Fig. 4. A section (magnification: 4.1) of an internal thread cut in a file with the use of a brass external thread, 8 mm in diameter of the crest, 6.38 mm in the root and 1.25 mm in the pitch.

and the values of the external ones used as cathode being 8.00 and 6.38 mm. Thus gaps between the two threads are 0.10 and 0.26 mm at root and crest of the internal thread.

§ 4. Interpretation of the Experimental Results

As will be seen from Fig. 2a, time of drilling decreases gradually with the increase of *C* in a range from 8 to 64 μF. Time for large *C*, however, seems to deviate from this mode of decrease. To interpret this fact we must notic that inductance of the leading wire and of condensers, hence the total inductance of the circuit 2, are increased in experiments with the use of large *C* even if inductance *L* inserted is the same. Furthermore, time for a definite *C* reaches minimum at a certain L. Thus it will be reasonable to consider that if we are able to shorten the leading wire in experiments with Large *C*, time for large *C* may be diminished more than that determined experimentally, and minimum time to be obtained at certain *L* will decrease regularly with increase of *C*. This decrease of time with increase of *C* merely means that the electric charge carried by the quenched discharge and thereby mass of the melt of the positive plate increases with *C*. The fact that the time shows a minimum at a certain *L*, however, is explained as due to superposition of two effects. Before proceeding this explanation, the reason must be clarified why the drilling efficiency of the quenched discharges surpasses that by arcing.

In our experiments on the initiation of arc, which will be reported in a short time, it is observed that, when the arc is initiated in methane gas (to diminish the oxidation of the electrodes), melt formed on a top of positive electrode is attracted towards cathode, sometimes being elongated like a needle, and melt on negative electrode becomes flat on the top as if it is pressed by swift gas flow of positive charges. As such phenomena can be expected to occur also in the present quenched discharges, the following explanation on the mechanism of the drilling may be considered to be reasonable. By a quenched discharge of the condenser *C* a minute portion of the anode is heated to a liquid state having a small round surface. The melt thus formed is further elongated towards the cathode by attraction of electric force, until it is formed into a droplet and is blown off. These processes are repeated from 15 to 30 times in each half cycle as is shown by the cathode ray oscillograph above mentioned, and the drilling progresses efficiently. Whereas, if the discharge is the kind of arcing, which starts when *L* is large or *C* is small, the arc current continues to flow during one half cycle. Melting due to such arcing is not localzed upon a small region by conduction of heat, which is supplied slowly and continuously. As the mass and surface area of such melt are considerablly large, rounding of the melt is not remarkable and the attraction towards the cathode will not be large enough to produce a droplet to be sputtered.

By the same consideration as the above, one of the two effects, which minimize the work time at a certain value of *L*, can be explained. Namely, as duration time of the quenched discharge increases with increase of *L*, local melting suitable for formation of droplets to be blown off is hindered by slow supply of heat and by conduction of heat. Thus the time *t* increases with the increase of *L*. On the contrary of this, another second effect of *L* diminishes the time. When *L* is small, the high frequency current flows mainly through the branch circuit *CL* and feebly through the branch *AB*. Therefore, in these *L* ranges the initiation of the quenched discharge becomes uncertain and the working time increases with the decrease of *L*. By combination of these two effects, when *C* is kept constant, the time may be diminished at first and then increased with the increase of *L* passing through a minimum value at a certain value of *L*.

As the mode of loss of the electrode is quite different from that of the plate in the point that no maximum loss is observed with variation of *L*, we must consider that mechanisms of the two losses are different. The following explanation may be allowed for the electrode loss. When the working is done with insertion of large *L*, the surface of the electrode is liquified in a large area and simply becomes flat and is blown off scarcely by pressure of positive ions and of small particles imprining on the electrode. The loss in these states can be considered as being chiefly due to the evaporation, which is proportional to the discharge current. When L is small on the contrary, although initiations of the quenched discharge may be not always certain, materials of the electrode can be sputtered in forms of minute solid and melted particles by collisin of positive ions produced by quenched discharges of large current density, as like some materials can be graved by a sand bluster. Thus, by the considerations stated above it may be said that the loss of anode plate is due to electric attraction acting on droplets of the melt formed on the plate and the loss of cathodic electrode is due to a bluster effect of positive particles produced by the quenched discharge.

In conclusion the author's thanks are due to the Ministry of Education for financial support, and to Mr. N. Kobayashi and Mr. Y. Sasada for their assistance.

On the Ricochet Motion of a Projectile Striking a Water Surface

By Tikao HUZITA
Faculty of Fisheries, Kagoshima University

(Received October 13, 1956)

Analysing the photographs of the ricochet motion, the following results were obtained. (1) The mean hydrodynamical impulsive force is practically independent of the incident angle except for the blunt head projectile. (2) The horizontal component of the force becomes smaller as the incident angle increases and the projectile becomes hard to ricochet as the component nears zero. (3) The point of application of the force recedes as the incident angle increases. (4) The vertical velocity component of the projectile after the ricochet is generally greater than that before.

Furthermore a coefficient of retardation, a coefficient of ricochet, and a coefficient of slip were newly introduced in order to compare the ricochet motion with the motion of repulsing upon a solid wall.

§1. Introduction

The experiments on the motion of a projectile striking a water surface were formerly carried out by Isobe[1], by Hirata[2], and by the writer[3][4] on a bullet, on a harpoon and on a projectile with tailplane respectively. The writer recently made an indoor experiment[5] in which the head shape and the incident angle were changed systematically.

Four kinds of projectile used in this experiment are shown in Fig. 1 and each number of the projectile indicates the apex angle of the head cone. The symbol 60 b indicates Proj. 60 with a resistance ring[5]. Each projectile is 15 mm in diameter, about 62 mm in length and about 28 g in weight.

The arrangement of the apparatus is shown in Fig. 2. The water tank T, 35 cm deep, 23 cm wide, and 140 cm long, has a glass wall GW on one side. On the left side of the tank there is a spring gun G, its spring force being about 10 kg and the projectiles being shot

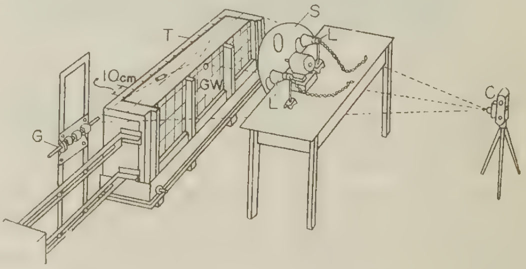

Fig. 2. Arrangement of the apparatus.

horizontally with the initial velocity of 6∼11 m/s. The trajectory of the projectile is photographed on a film and at the same time observed by naked eye through the finder of a reflex camera *C*. Furthermore, in order to illuminate the projectile, two spot light lamps *L* are placed obliquely upwards before the tank. Before the lamps, there is a rotating shutter *S* by which the light is intercepted 115 times per second, and so the image of the projectile is intermittently photographed on the film and the posture of the projectile is clearly observed on the film. An example of the photograph of the trajectory of a projectile is shown in Fig. 3. According to the change in the height of the gun which was 2.5, 5.0, 10.0, 20.0 and 30.0 cm from the water level, incident angle of the projectile varied between 3.6° and 21.5°.

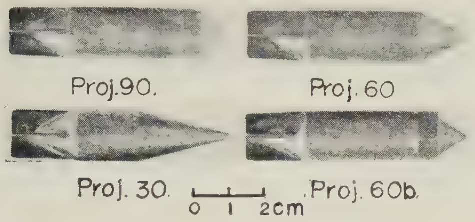

Fig. 1. Models used in the experiment.

As the results of this experiment, the motion of the projectile was classified into four groups, namely, ricochet, swimming, straight forwards and reverse turn, each trajectory being indicated schematically in Fig. 4. Proj. 180 goes always straight forwards into the water independently of its incident angle. Other projectiles make the above mentioned four kinds of motion according as their incident angles. The ranges of the incident angle corresponding to the various kinds of motion of each projectile are tabulated in Table I.

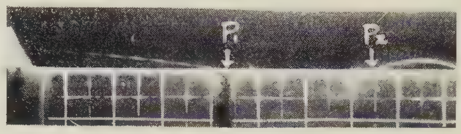

Fig. 3. Photograph of the ricochet motion.

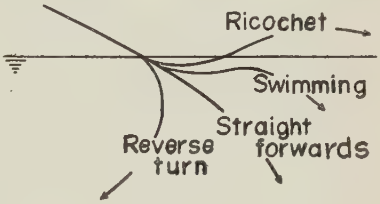

Fig. 4. Classification of the trajectory.

Here in the present study, the writer, analysing the photographs which correspond to the ricochet motion, intends to make clear the ricochet motion observed in the indoor experiment.

Table I. Behavior diagram

Proj.	Incident angle ($\alpha_1{}^0$)												
	2	4	6	8	10	12	14	16	18	20	22	24	26
180	Straight forwards												
90	Ricochet				Swimming			Straight forwards		Reverse turn			
60	Ricochet					Swimming			Straight forwards	Reverse turn			
30	Ricochet					Reverse turn							
60b	Ricochet				Straight forwards								

§ 2. Treatment of the Experimental Results

In Figs. 5 and 6, let the path of the projectile be in the xy-plane, x-axis the water surface, $P_0P_1QP_2P_3$ the path of the projectile and ABC the cross section of the projectile head. $h_1, h_3, s_1, s_2, s_3, \alpha_1$ and α_2 are measured from the photographs. The velocities of the projectile v_1 and v_2 are calculated by the equation of a projectile. Then non-dimensional coefficients:

coefficient of retardation

$$e_x = 1-(v_2 \cos \alpha_2 / v_1 \cos \alpha_1)\,, \qquad (1)$$

coefficient of ricochet

$$e_y = v_2 \sin \alpha_2 / v_1 \sin \alpha_1 \, , \qquad (2)$$

coefficient of slip

$$e_s = s_2/d \, .$$

are newly introduced analogously with the coefficient of restitution $e(=e_y)$ and the coefficient of friction $\mu(=\cot \alpha_1 \cdot e_x/(1+e_y)$. The third coefficient e_s is necessary in order to obtain the mean force instead of the impulse.

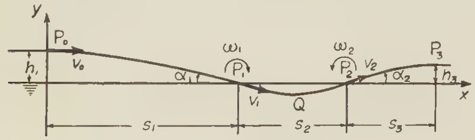

Fig. 5. Schematic diagram of the ricochet motion.

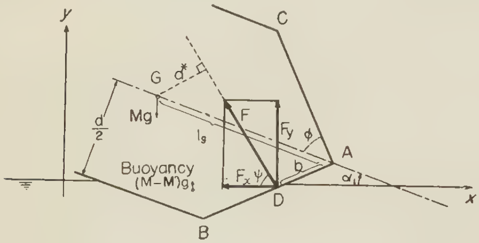

Fig. 6. Forces acting on the projectile.

In Fig. 6 let the mass of the projectile be M, the moment of inertia about the center of gravity (G) be I $(=Mk^2)$, the rotational velocity about the center of gravity be ω, the force exerted by water be F, the point of application of F on AB be D, the gravity force minus the buoyancy be $M'g$, the resultant force of F and $M'g$ be F', the arm length of F and F' about the center of gravity be a^* and $a^{*\prime}$ and the time interval during which the projectile passes through the water be $\varDelta t$. The suffixes and the other symbols are used as indicated in Figs. 5 and 6. Then we obtain

$$M(v_2 \cos \alpha_2 - v_1 \cos \alpha_1) = -\overline{F}_x \cdot \varDelta t \, , \qquad (4)$$

$$M(v_2 \sin \alpha_2 + v_1 \sin \alpha_1) = (\overline{F}_y - \overline{M}'g) \cdot \varDelta t \, , \qquad (5)$$

$$I(\omega_2 - \omega_1) = \overline{F' a^{*\prime}} \cdot \varDelta t \, , \qquad (6)$$

$$\varDelta t = 2s_2/(v_1 \cos \alpha_1 + v_2 \cos \alpha_2) \, , \qquad (7)$$

in which — is used to indicate the time-average value during $\varDelta t$.

In the case of a projectile with tailplane, ω_1 and ω_2 are nearly equal to zero (ω_1 or ω_2 × length of the projectile is always less than 4% of v_1 or v_2 respectively) though the direction of the projectile changes, therefore in the equation (6) $\overline{F'a^{*\prime}} = 0$ but $a^{*\prime} \neq 0$. For convenience sake, if we put $F'a^{*\prime} = \overline{F'}a'$, the simplest form of a' which satisfies these conditions is as follows:

$$a' = a_0'(1 - 2t/\varDelta t) \, . \qquad (8)$$

Then, integrating the equation (6) by using the boundary conditions, we get

$$a_0' = 6I(\alpha_1 + \alpha_2)/\{\overline{F'} \cdot (\varDelta t)^2\}. \qquad (9)$$

From these equations $\overline{F'}$, $\overline{\psi}'$, $\varDelta t$ and a_0' are obtained. The manner in which the arm of the moment about the center of gravity changes can be conjectured from a_0'. The non-dimensional expressions of these quantities are represented by e_x, e_y and e_s as follows:

$$\begin{aligned} \overline{C'} &= 2\overline{F'}/(\rho v_1{}^2 d^2) \\ &= \{\cos^2\alpha_1 \cdot e_x{}^2 + \sin^2\alpha_1 \cdot (1+e_y)^2\}^{1/2} \\ &\quad \times (\varDelta t \cdot v_1/d)^{-1} \cdot (2M/\rho d^3) \, , \qquad (10) \end{aligned}$$

$$\tan \psi' = \overline{\tan} \, \alpha_1 \cdot (1+e_y)/e_x \, , \qquad (11)$$

$$\begin{aligned} a_0'/d &= 12(M/\rho d^3) \cdot (k/d)^2 \cdot (\varDelta t \cdot v_1/d)^{-2} \\ &\quad \times (\alpha_1 + \alpha_2)/\overline{C'} \, , \qquad (12) \end{aligned}$$

$$\varDelta t \cdot v_1/d = 2(s_2/d)/\{\cos \alpha_1 \cdot (2 - e_x)\} \, . \qquad (13)$$

Let the intersecting point of the line of mean force with the surface of the projectile be $\overline{D'}$ and let us denote the length of $A\overline{D'}$ by $\overline{b'}$ and that of AG by l_g. Then

$$\overline{b'}/l_g = \sin(\overline{\psi'} - \alpha_1)/\sin(\overline{\psi'} - \alpha_1 + \phi) \, . \qquad (14)$$

In the case of the restitution upon a solid wall, static forces are usually negligible to the impulsive force and $\overline{F}$ may be put equal to $\overline{F'}$. But in this case, as they amount to about 20% of $\overline{F}$, we must substitute $\sin \alpha_1 \cdot (1+e_y) + (\overline{M}'/M) \cdot (dg/v_{12}) \cdot (\varDelta t \cdot v_1/d)$ for $\sin \alpha_1 \cdot (1+e_y)$ in the formulas (10), (11), (12) and (14), in order to obtain the pure impulsive quantities $\overline{C}$, $\tan \overline{\psi}$, a_0/d and $\overline{b}/l_g$. If Mg is used instead of $M'g$, the error due to this substitution is about 30% of Mg and therefore 6% of $\overline{F}$.

Now, we shall assume the relation between α_1 and each non-dimentional quantity to be a linear functional form. Then, the regression line and the correlation coefficient γ are obtained by treating the results acquired from the above indoor experiment, and as for the significancy of the correlation γ it is tested. These results are shown in Table II, and some of the plotted figures from which the results were obtained are shown in Figs. 7∼12. Each

number distinguishing the kind of projectile indicates the head angle in degrees and Projectile 60 b has a resistance ring[5]).

Taking d (diameter 15 mm) as a standard length, Reynolds' number is $0.9\sim 2.0\times 10^5$, Froude's number is $16\sim 36$, the ratio $\rho v_1^2 d$ to the surface tension (Weber's number) is $0.7\sim 3.9\times 10^4$ and $\{(M-M')/M\}_{max.}$ is 0.3.

§ 3. Discussion of Results

Now, considering the above results, the writer will discuss the nature of the ricochet motion.

a) *Impulsive force*

$\overline{C}$ is shown in Fig. 7 and is about $0.4\sim 0.5$ at a small incident angle. For each projectile except Proj. 90, $\overline{C}$ decreases gradually as α_1 increases, and for Proj. 90, $\overline{C}$ decreases rapidly. Therefore $\overline{C}$ is practically independent of α_1 except for the blunt head projectile.

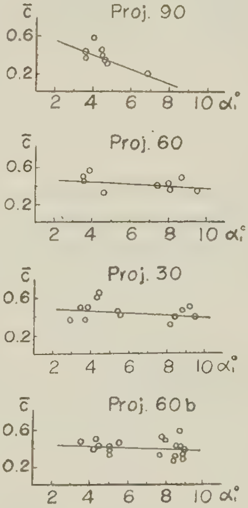

Fig. 7. $\overline{C}$ versus α_1 for Projs. 90, 60, 30 and 60b.

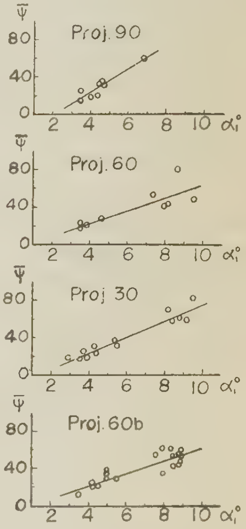

Fig. 8. $\overline{\psi}$ versus α_1 for Projs. 90, 60, 30 and 60b.

$\overline{\psi}$ is shown in Fig. 8 and increases with α_1 and approaches to 90°. Therefore $\overline{F}_x$ becomes smaller as α_1 increases and the projectile becomes easy to slip or difficult to ricochet. Though $\overline{\psi}$ is thought to be smaller than 90°, the incident angles obtained by extrapolating the regression line up to $\bar{\phi}=90°$ are tabulated in the first line, Table III.

a_0/d is shown in Fig. 9 and increases with α_1, and the correlation is small except Projs. 30 and 60 b.

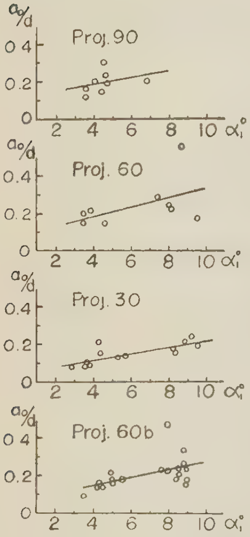

Fig. 9. a_0/d versus α_1 for Projs. 90, 60, 30 and 60b.

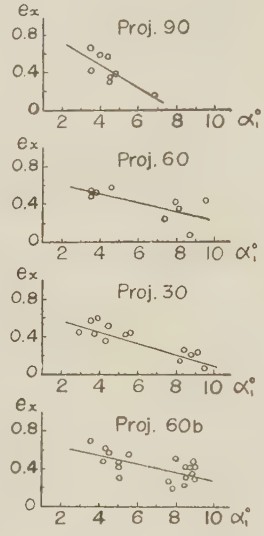

Fig. 10. e_x versus α_1 for Projs. 90, 60, 30 and 60b.

$\bar{b}/l_g$ increases with α_1 and this shows that the point of application of the mean impulsive force recedes from the top of the head cone towards the rear part of the projectile as α_1 increases and this tendency is seen markedly in Proj. 90.

b) *Comparison with a restitution upon a solid wall*

e_x is shown in Fig. 10 and decreases up to zero as α_1 increases, and the slope is steepest for Proj 90. This means that the projectile is apt to slip as α_1 or the head angle ϕ increases. The incident angles corresponding to the limiting condition $e_x=0$ are obtained by extrapolation and tabulated in the second line, Table III.

e_y is shown in Fig. 11 and decreases as α_1 increases and approaches to 1. Contrary to the restitution coefficient and also to the usual conjecture, the ricochet coefficient e_y is, generally, greater than 1. It approaches to 1 and sometimes it is smaller than 1 but within the experimental error. As $e_y=1$ seems to be the boundary between ricochet and restitution, the incident angles corresponding to $e_y=1$ are obtained and tabulated in the third line, Table III.

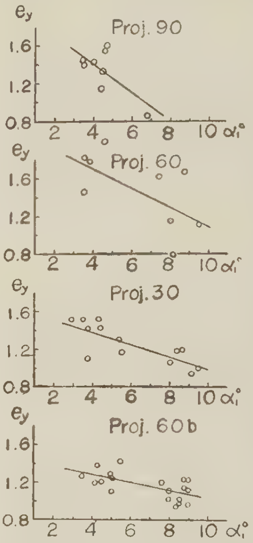

Fig. 11. e_y versus α_1 for Projs. 90, 60, 30 and 60b.

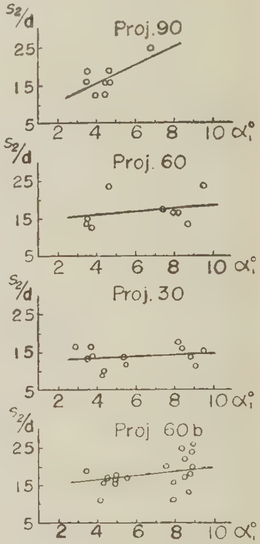

Fig. 12. s_2/d versus α_1 for Projs. 90, 60, 30 and 60b.

s_2/d is shown in Fig. 12 and increases with α_1, and the slop becomes steeper as the head angle increases. This tendency to slip shows the same physical meaning as the tendency

Table III. Critical incident angles obtained by extrapolation or interpolation.

Line	Critical condition	Projectile			
		90	60	30	60b
1	$\bar{\phi}=90°$	9.3°	13.8°	11.6°	14.5°
2	$e_x=0$	8.0°	14.9°	11.6°	16.2°
3	$e_y=1$	6.8°	11.3°	9.8°	10.6°
4	$e_y=0$	13.7°	21.3°	24.9°	35.2°
5	$\alpha_{r.sw.}$	about 9°	about 11°	about 12°	about 9°

of e_x.

α_2 increases with α_1 for Projs. 60, 30 and 60 b, while for Proj. 90 it decreases as α_1 increases.

c) *Critical incident angle between ricochet and swimming*

The critical incident angles between ricochet and swimming ($\alpha_{r.sw.}$) obtained from the above indoor experiments are tabulated in the fifth line, Table III.

The most intuitive condition for this critical angle $\alpha_{r.sw.}$ is $e_y=0$, but as is shown in the fourth line, Table III this is far from the critical condition. The incident angles corresponding to $\bar{\psi}=90°$, $e_x=0$ and $e_y=1$ are close to the critical angle. Accordingly, it may be said that for Projs. 90 and 30 the conditions $\bar{\psi}=90°$ and $e_x=0$, and for Projs. 60 and 60 b the condition $e_y=1$, are more suitable in this experiment.

The conditions of $\bar{\psi}=90°$ and $e_x=0$ mean that the projectile ceases to ricochet when it receives no horizontal force, i. e. when slips. In the case of a solid wall, this corresponds to the fact that the wall is perfectly smooth. Therefore it seems to be extremely interesting to carry out an experiment of restitution upon a perfectly smooth wall. In short, as for the critical condition, there seems to be much to be done.

The regression lines of various coefficients of Proj. 90 are steeper than those of the other projectiles and the regression line of α_2 differs in sign from the others. These facts seem to indicate that the blunt head is disadvantageous for ricochet. From this fact it may be conjectured that a projectile with resistance ring or Proj. 180 (flattened head) is advantageous to be driven into the water, the fact of which has already been verified by the writer[3)5)] and by Hirata[2)].

Acknowledgements

The writer wishes to express his sincerest thanks to Prof. T. Fujiwara of Hiroshima University who has enabled the writer to conduct this research for his useful suggestions and kind encouragement, and also to Prof. T. Maekawa of Hiroshima University for his hearty guidance and valuable discussion through the progress of this subject.

Effect of Plastic Deformation on the Dielectric Breakdown of Silver Chloride Crystals

By Noriaki Itoh and Tokuo Suita

Department of Electrical Engineering, College of Engineering, Osaka University

(Received November 29, 1956)

Effects of plastic deformation on the dielectric breakdown have been observed with alkali halide crystals by several authors and it has been shown that the breakdown strength was affected by plastic deformation to a considerable degree in some cases[1][2]. We investigated these effects with locally deformed silver chloride which is more plastic than alkali halide and seems to be convenient for the study of these effects.

To obtain locally deformed specimens we pressed them in the [110] direction by adding weight through a thin cover glass of thickness 0.15 mm. This method is similar to the prismatic punching developed by Smakula and Klein[3]. Although the punching figure was not clearly observed in our AgCl specimens, it seemed to be evident that the stress under the puncher was larger than that in the other part of the specimen at the beginning of the application of stress. The strain would spread over the whole specimen with the application time, which is known as creep.

The specimens we used were cut from a large block of single crystal grown by Kyropoulos method, their form and dimensions being as shown in Fig. 1. The puncher was applied just upon the edge of the hollow electrode and the breakdown voltage under the stress was measured in both cases where the strained part was at the positive electrode and at the negative electrode. The applied voltage was rectangular pulse repeated 10 cycles/sec, which was raised at the rate of about 3 kv/min until the breakdown occured.

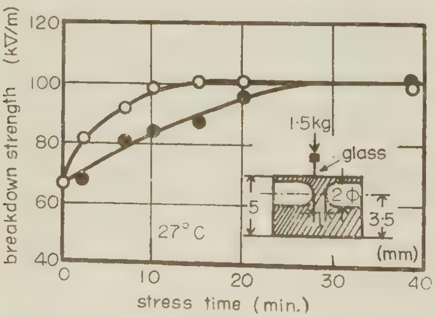

Fig. 1. Dependence of the dielectric breakdown strength of AgCl on the stress time.
○: Stressed on the negative side,
●: Stressed on the positive side.

The dependence of the breakdown voltage on the stress time in the both configurations at room temperature is shown in Fig. 1. The weight of the load was 1.5 kg and the shear stress was 250 kg/cm². It is clearly seen that the breakdown strength increases with the stress time and reaches to a same saturation value in the both cases. The increase of the breakdown voltage is more rapid when the shear stress is applied near the negative electrode. Therefore the strain seems to be more effective to the breakdown when it is applied near the cathode.

If the applied voltage was raised much more rapidly (about 20 kv/min) the effects of the stress were almost negligible, that is, the increase of the breakdnown strength due to mechanical stress occured only when the applied pulse voltage increased slowly. As we have already shown the deposit of silver atoms seemed to play an important role in the dielectric breakdown even in pulse field[4]. Therefore we can conclude that a great deal of silver atoms deposited in the deformed region near the cathode mainly raise the dielectric strength in silver chloride.

We wish to thank to Dr. E. Mizuki and other staffs of Fuji Photofilm Co. for supplying silver halide materials and for their valuable discussions. We also thank to Mr. C. Okazaki for investigating the crystallographic orientation of our crystal blocks by Laue's method.

The Energy Spectrum of Nucleons in the Air Shower

By Y. Tanaka*, K. Suga* and S. Mitani†
Institute for Nuclear Study, University of Tokyo, Tanashi-machi, Kitatama-gun, Tokyo
†*Faculty of Science, Osaka University, Nakanoshima, Kita-ku, Osaka*

(Received November 16, 1956)

A preliminary experiment on the energy spectrum of nucleons in the air shower was carried out at Mt. Norikura Cosmic-Ray Laboratory, University of Tokyo, (2840 m altitude). Two piles of G-M counter trays, E and H, shielded by lead layers were set as shown in Fig. 1. Hodoscope records of both counter piles for the coincidences $(A\geqq 3)+(E_1\geqq 3)$ were obtained. Of these records the events satisfying the condition $(B\geqq 3)+(C\geqq 1)$ were regarded as high-energy nuclear interactions inside the lead layer above Tray B caused by nucleons in air showers. Because the most part of the electronic component of the air shower may be absorbed by 20 cm thickness of lead and the contribution of μ-mesons in these records is expected to be very small in this experiment. These were subdivided into two groups: (I) those with three or more struck counters in Tray E_3, and (II) those with less than three struck counters in the same tray. Average densities of air showers were estimated to be several hundreds per square meter for (I) and several tens per square meter for (II) respectively.

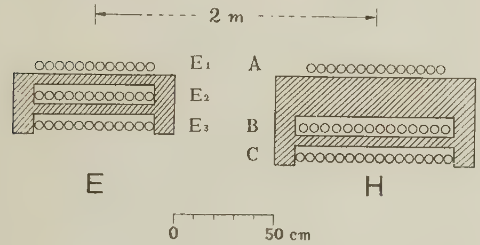

Fig. 1. The arrangement of counter piles.

Supposing that discharges of counters in Tray E_3 were caused by high-energy electrons in the air shower, one may expect that the core of the air shower hit the ground as close as 10 m for (I) and within the range extending from 10 m to 100 m for (II), respectively, in comparison with the results of Cocconi et al1). And if one takes the events originated by single nucleons $(A\leqq 1)+(E_1, E_2 \text{ and } E_3=0)+(B\geqq 3)+(C\geqq 1)$ as group (III) which were observed separately by the same apparatus, these might be more than 100 m apart from the core.

The integral multiplicity-distributions of struck counters in Tray C for these groups are shown in three curves in Fig. 2. There might be cases in which more than one nucleon struck counter-pile (H) simultaneously so that apparently higher multiplicities were observed in Tray C. This effect is important only for showers of very high density in this experiment, and the correction was applied in Fig. 2. These curves can be considered as showing indirectly the energy distributions of nucleons, because the multiplicity in Tray C is the function of the energy of the nucleon on the average. If it is assumed that Curve (III) shows the energy spectrum of single nucleon, i.e. $E^{-1.5\sim 1.8}$ 2), the energy spectra $E^{-0.7\sim 1.1}$ and $E^{-0.9\sim 1.4}$ are obtained for (I) and (II) respectively. The energy of nucleons in this analysis may extend from 10 Bev to 100 Bev3).

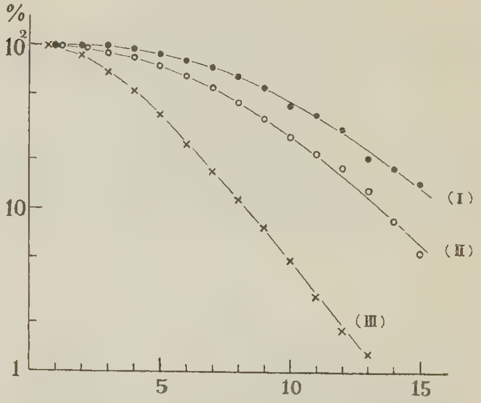

Fig. 2. Integral multiplicity-distributions of struck counters in Tray C for groups (I), (II) and (III). The abscissa is the number of struck counters in Tray C, and the ordinate shows the integral number of events in percentage of the total number in each group.

Of course, the above-mentioned assumption includes several problems and further study should be necessary. However, Fig. 2 seems to show that the energy spectrum of nucleons in the air shower is flatter and, hence, the proportion of high-energy nucleon is larger at the point which is closer to the core than that apart from the core.

In the end, the authors wish to express their heartfelt thanks to Prof. Y. Watase for his very helpful discussions and advice.

Effects of Shock Wave upon Gaseous Discharge

By Shigeo NAGAO
Engineering Faculty, Tohoku University, Sendai

(Received November 27, 1956)

In order to investigate the effects of shock wave upon gaseous discharge we constructed a shock wave-discharge tube as is shown in Fig. 1

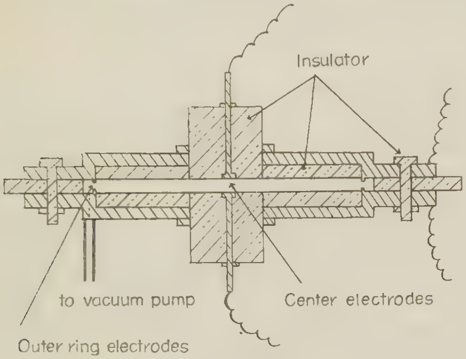

Fig. 1. Shock wave-discharge tube. Gap length of center electrodes: 1 cm.

and measured the lowering of sparking voltages of gap attacked by shock wave. When the tube is evacuated enough, spark discharge induced by the application of impulse voltage upon the outer ring electrodes covers their whole surface and then the cylindrically converging shock wave generated thereby propagates towards the center electrodes, increasing rapidly its strength, i.e. its pressure and temperature[1)2)]. Thus if a voltage well below the sparking value of the gap in normal state had been applied upon the center electrodes, sparking will follow suddenly at the gap when the shock front arrived at the center electrodes.

Fig. 2 shows the circuit used for the measurement of sparking voltage mentioned above and the results are shown in Fig. 3. It may be clear that the greater the capacity and voltage of the condensor used for the initiation of shock wave, the more intense will become the shock wave generated by the sparking between the outer electrodes. In Fig. 3 it is worth noting that even very weak shock wave lowers the sparking voltage of center electrodes upto about the minimum sparking voltage in Paschen's law. This fact may be due to the instantaneous increase of pressure at the center of tube by shock wave, since the product of initial pressure times gap length is slightly below the value which corresponds to the minimum sparking voltage. Oscilloscopic observation of discharging current gives the estimation of time lag of center sparking and shock velocity can be calculated assuming that Mach number of cylindrically coverging shock increases with inverse proportionality of one fifth power of the distance from converging center[2)] and rough estimation of temperature rise near the center electrodes will be possible therefrom. An example of the calculation is shown in Table I. Thus we may conclude that arc discharge without sparking follows immediately after the arrival of an intense shock wave.

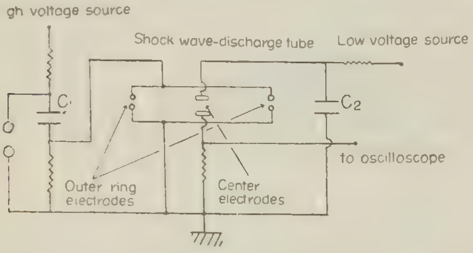

Fig. 2. Circuit used for the measurement of sparking voltage of center electrodes.

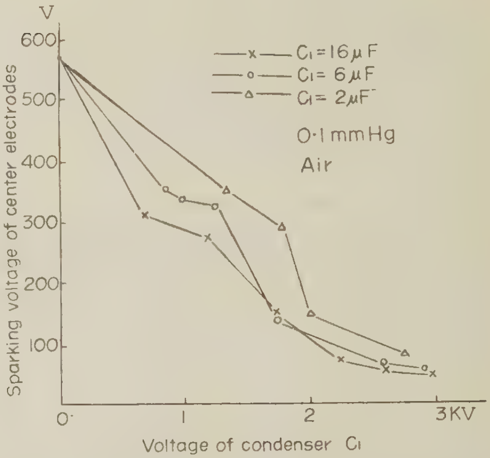

Fig. 3. Sparking voltage of center electrodes.

Table I

Capacity of condensor C_1	16 μF
Capacity of condensor C_2	4000 μF
Voltage of C_1	3 KV.
Voltage of C_2	400 V
Mean discharging current of C_2	1000 A.
Mean shock velocity	2.0 Km/sec.
Temperature at the center electrodes (calculated)	4500° K.

On the Electrical Properties of Degenerate Semiconductors

By Eijirô HAGA

Department of Physics, Faculty of Science, Niigata University

In his recent theoretical work[1] on the electrical conductivity, the writer has succeeded in derving Grüneisen's formula for simple metals and the corresponding one for highly degenerate polar crystals by an elementary method, assuming that the high degeneracy criterion $df_0/d\varepsilon=-\delta(\varepsilon-\zeta)$ is valid. Once this assumption is admitted, then we can easily deduce the so called Mattiessen's rule for the cases where more than one kinds of the sources for the scattering of conduction electrons are present. On the other hand, Kohler[2] has given a general proof that the total resistivity should be in general larger than the simple sum of resistivities due to a single kind of scattering sources. It will, then, be worth while to investigate how the deviations from the Mattiessen's rule take place when the conduction electrons are not perfectly degenerate. In this connection we will also see the relation between the Hall coefficient and the degree of degeneracy.

In this note we treat, as an example, non polar semiconductors in which lattice vibrations and ionized impurities are predominant as the scattering sources. Then, with the same assumptions as done by JL[3], we calculate the two ratios, $F=(\rho_L+\rho_I)/\rho$ and $r=R/(1/nec)=\mu_H/\mu_a$, which are in this case expressible as

$$F=(1+\xi)[1-\xi A(\mu)F_2(\mu)\times\int_0^\infty e^t/(e^t+e^\mu)^2\cdot t/(\xi B(\mu)+t^2)\,dt\,,$$

$$r=(1+\xi)^2A(\mu)F_{1/2}(\mu)/2F^2\times\int_0^\infty e^t/(e^t+e^\mu)^2\cdot t^{9/2}/(\xi B(\mu)+t^2)^2\,dt\,,$$

where

$$\mu=\zeta/kT,\quad \xi=x/(1-x),\quad x=\rho_I/(\rho_L+\rho_I),$$

$$A(\mu)=3e^\mu/[\ln(e^\mu+1)]^2,\quad B(\mu)=3F_2(\mu)/\ln(e^\mu+1).$$

The calculation was carried out numerically using the numerical tables[4] of $F_2(\mu)$ and $F_{1/2}(\mu)$. The results are shown in Figs. 1 and 2 as the functions of x for several μ values. We see that the Mattiessen's rule becomes a good approximation and the Hall mobility approaches to the drift mobility as the degree of degeneracy becomes high enough. We see also that minima of F and r occur at the x values nearly independent on μ.

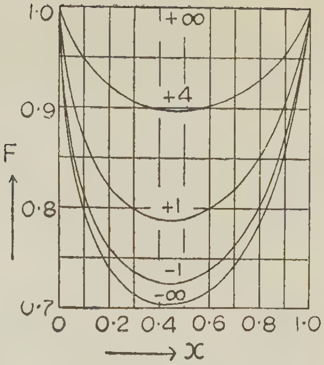

Fig. 1. The dependence of F upon x for several μ values.

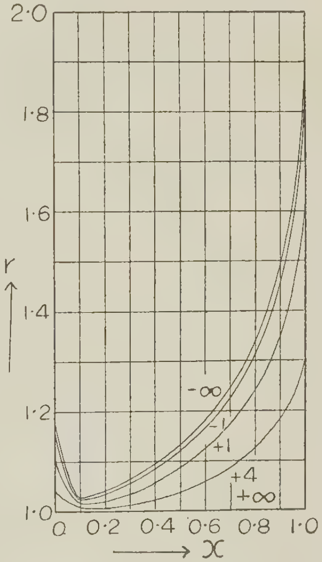

Fig. 2. The dependence of F upon x for several μ values.

The case $\mu=-\infty$ corresponds to the classical statistics previously treated by JL[3].

Preparation of $BaTiO_3$ Single Crystals in Coal Gas Atmosphere

By Kazuo Kawabe
Department of Physics, Osaka University
and Shozo Sawada
Institute of Science and Technology, University of Tokyo

(Received November 13, 1956)

Several investigators have reported on methods of growing barium titanate single crystals using sodium carbonate as a flux.(1)-(4) Sawada, Nomura and Fujii(4) prepared their samples in a nickel crucible put in a kryptol furnace which had reductive atmosphere. We have modified their method by using a resistance furnance (the main constituent of the heater is SiC) and a nickel crucible put in the stream of coal gas to avoid the oxidation. The nickel crucible used in the coal gas stream was hardly oxidized and had almost completely metallic appearance after operation. In air or nitrogen atmosphere nickel reacted with carbonate solution to become black, yielding black crystals which were not ferroelectric.

The solute is the stoichiometrical mixture of TiO_2 and $BaCO_3$ of high purity. The molar ratio of the solute to the flux (Na_2CO_3, c.p.) is about 1 to 4. The composition in volume of the coal gas used is as follows: H_2 about 30 %, N_2 30 %, CH_4 20 %, CO 15 % and the rests 5 %. The furnace is heated up to about 1200°C and is held at this temperature for several hours. A cooling rate of about 25°C/hr seems to be suitable, until a temperature of 1050°C is reached, where the furnace is held for about twelve hours and then cooled again at a rate of about 20°C/hr down to 900°C. At this temperature the still-liquid flux is sucked up through a nickel pipe by a rotary pump and the crystals are annealed by slow cooling down to the room temperature. The crystal plates can be separated from the flux by soaking the crucible in hot water which dissolves the carbonate rapidly.

The thin platelike crystals produced in this way are all tetragonal ones, having a Curie temperature of about 118°C. The size is about several mm on an edge and some one reaches 1 cm and the thickness is $20\sim30\,\mu$. They have *a*- and *c*-domains mixed showing strip patterns under a polarizing microscope. Single *c*-domain crystals are scarcely obtained by this method.

The nickel crucibles employed were commercial ones of about 30 cc in volume. Larger crystals might be expected by using larger crucibles and giving some favorable temperature gradient to the crucible.

We have tried to use KF as a flux in this method. Potassium fluoride was successfully used with platinum crucibles by J.P. Remeika.(5) We have got some large crystals after the same manner as above except the flux, all of them, however, being found to be dark colored. On heating them in air at about 1000°C for about 30~40 hr, they become light brown and have a Curie temperature of 122°C according to the measurement of the dielectric constant. In air atmosphere the nickel crucible was heavily attacked.

This work was done during one of the author's (K.K.) stay at Institute of Science and Technology, University of Tokyo as a fellow of the Yukawa Foundation of Osaka University. He wishes to express his thanks to Dr. S. Nomura of this Institute for valuable discussions, and to Prof. I. Nitta, Dean of the Faculty of Science of Osaka University and Prof. T. Horie for giving him this opportunity all through the 1955 school year.

A Cascade Shower in Nuclear Emulsions

By Senzo TOKUNAGA
Department of Physics, Saikyo University, Kyoto
Kiyoshi NISHIKAWA
Department of Physics, Wakayama University, Wakayama
and Taka ISHII
Department of Physics, Saikyo University, Kyoto

(Received November 20, 1956)

A good example of a cascade shower in nuclear emulsions was analysed, and its energy was determined from its lateral distribution at successive stages of its development comparing with cascade theory, and was found to be 2.5×10^{11} eV. It is possible to measure the energy of high energy γ-rays or electrons with an accuracy of a factor two.

§ 1. Introduction

For high energy events observed in nuclear emulsions in which it is impossible to measure the energy of particle by scattering method, it is very important to decide the energy by any other method. One method is to make use of the phenomena of cascade shower. Here, we described the method to determine the energy of the cascade from its lateral distribution at successive stages of its development through several radiation lengths comparing with cascade theory.

§ 2. Experimental

Our stack, consisting of 48 4-inch by 6-inch Ilford G5 600 micron pellicles, was flown with the emulsion surfaces vertical for 6 hours up to the maximum altitude of 8 mb by a polyethylene balloon in Japan in 1955. The emulsions were processed by the usual temperature development. Cascade showers were sought in the stack. For this purpose the emulsions were line scanned along the horizontal direction at the time of exposure in the lower part of the stack. Several cascades were found, but many of them had great dips and did not develop so much, except the one which had a total length of 4.5 radiation lengths (a length of 1 cm per plate), and was suitable for analysis. We looked for the nuclear event from which neutral π meson, the origin of the primary photon of our cascade, would be emitted, but we could not find such an event.

The electron tracks of the cascade were identified when they had the blob density of plateau value, ran nearly parallel to the core

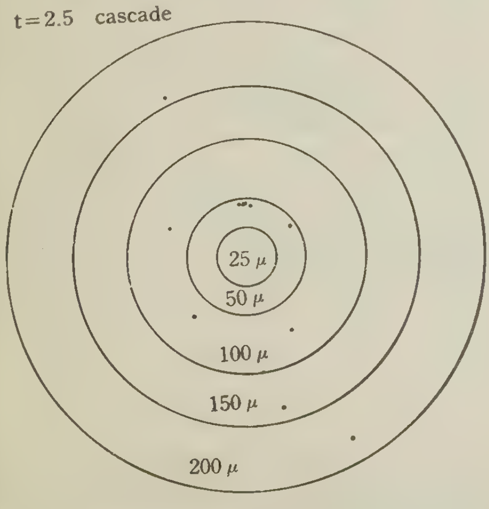

Fig. 1. Target diagram for the cascade shower at 2.5 radiation lengths from the origin.

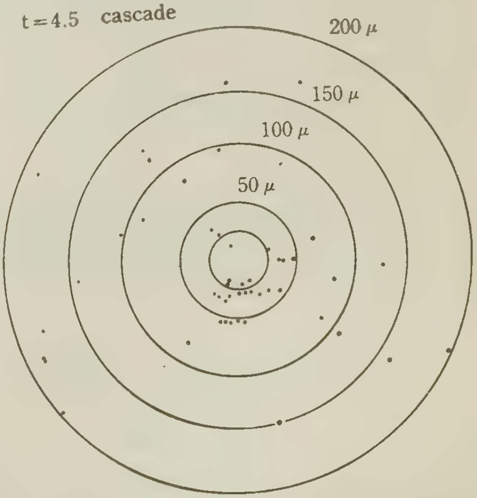

Fig. 2. Target diagram for the cascade shower at 4.5 radiation lengths from the origin.

and had almost the same track lengths.

For this cascade shower target diagrams were obtained at successive stages of its development. In Fig. 1 and 2 two of them were shown. In the figures the points represent electron tracks projected onto a plane perpendicular to the shower axis, and the circles centered on the shower axis are of 50, 100 and 200 microns radius, respectively. The shower axis was determined as the center of mass of particles. In Fig. 4 were shown the observed numbers of electrons within several values of radius r as a function of the distance t in emulsion.

§ 3. Theoretical

In order to compare with the cascade theory the Nishimura-Kamata's function[1), 2)] was used as the normalised structure function $f(r/r_1, s)$, where r denotes the distance from the shower axis on the plane perpendicular to the shower axis and s the shower age.

$$\int_0^\infty f(r/r_1, s)2\pi r dr = 1 \tag{1}$$

$$f(r/r_1, s) = \frac{c(s)}{r_1^2(r/r_1)^{2-s}}\left(1+\frac{4}{s}\frac{r}{r_1}\right)e^{-a(r/r_1)b}$$
$$\simeq \frac{c(s)}{\left(\frac{k}{\mathcal{E}}\right)^2\left(\frac{\mathcal{E}r}{k}\right)^{2-s}} = c(s)\left(\frac{\mathcal{E}r}{k}\right)^{s-2}\left(\frac{\mathcal{E}}{k}\right)^2 \tag{2}$$

where $r_1 = k/\mathcal{E}$, $k = 21$ MeV, $\mathcal{E}$ the critical energy, and $c(s)$ is the function given in ref. 1).

The number of electrons with all energies at a depth t from the point at which a photon of energy E_0 is incident in the stack is given by one dimensional cascade function[3)] (approximation B of ref. 3))

$$\Pi(E_0, 0, t) = \frac{1}{2\pi i}\int\left(\frac{E_0}{\mathcal{E}}\right)^s \frac{M(s)}{s^{1/2}} k(s, -s)e^{\lambda_1(s)t}ds \tag{3}$$

Then the number of electrons lying within an annular ring between radii r and $r+dr$ centered on the shower axis $\Pi(E_0, r, 0, t)2\pi r dr$ is given by the equation

$$\Pi(E_0, r, 0, t)2\pi r dr$$
$$= \frac{1}{2\pi i}\int\left(\frac{E_0}{\mathcal{E}}\right)^s\left(\frac{\mathcal{E}}{k}\right)^2\left(\frac{\mathcal{E}r}{k}\right)^{s-2} c(s)\frac{M(s)}{s^{1/2}}$$
$$\times k(s, -s)e^{\lambda_1(s)t}ds 2\pi r dr \tag{4}$$

Integrating with respect to r, we get the number of electrons Π which are contained within the circle of radius r and

$$\Pi = \int_0^r \Pi(E_0, r, 0, t)2\pi r dr$$
$$= \frac{1}{2\pi i}\int 2\pi\frac{c(s)}{s^{3/2}}\left(\frac{E_0 r}{k}\right)^s M(s)k(s, -s)e^{\lambda_1(s)t}ds \tag{5}$$

The integration with respect to s is calculated by the usual saddle point method, and

$$\Pi = \frac{\sqrt{2\pi}c(\bar{s})(E_0 r/k)^{\bar{s}}M(\bar{s})k(\bar{s}, -\bar{s})e^{\lambda_1(\bar{s})t}}{\bar{s}^{3/2}(\lambda_1''(\bar{s})t + 3/2\bar{s}^2 + (c'/c)')} \tag{6}$$

where $\bar{s}$ is given by

$$-\frac{3}{2s} + \frac{c'}{c} + \lambda_1'(s)t + \ln\frac{E_0 r}{k} = 0 \tag{7}$$

§ 4. Results and Discussion

In Fig. 3, 4, 5, and 6 were shown the results of the calculation using equation (6) for several values of the energies of the incident primary

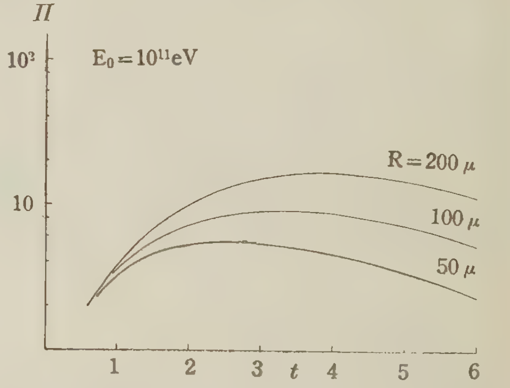

Fig. 3. The radial distribution function for the cascade shower when the energy of the primary photon is 10^{11} eV.

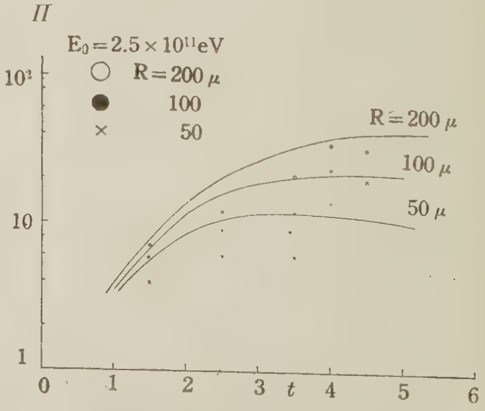

Fig. 4. The radial distribution function for the cascade shower when the energy of the primary photon is 2.5×10^{11} eV, together with the observed radial electron distributions.

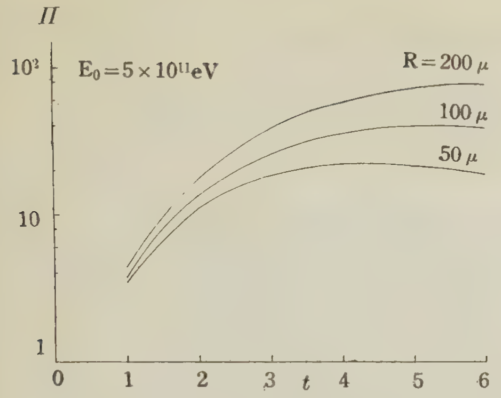

Fig. 5. The radial distribution function for the cascade shower when the energy of the primary photon is 5×10^{11}eV.

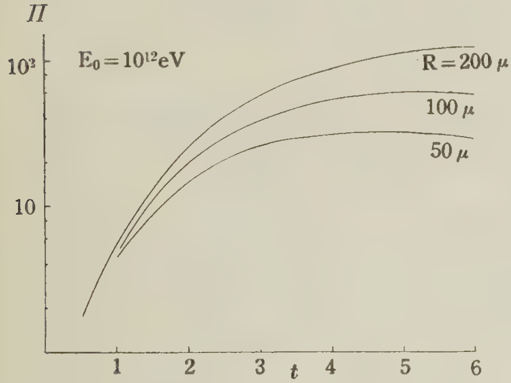

Fig. 6. The radial distribution function for the cascade shower when the energy of the primary photon is 10^{12} eV.

photon. Comparing with our experimental results, the energy of the primary photon of our cascade is estimated to be 2.5×10^{11} eV, the tendency of the development of the cascade differing clearly if the energy is assumed to be 10^{11} eV or 5×10^{11} eV.

From the above result the energy of the cascade shower can be determined with an accuracy of a factor two. It would be significant that we can estimate the energy of particle in the very high energy region with such an accuracy, where it is impossible to determine the energy by the oridinary scattering method.

It will be possible to justify the theory if we find the cascade showers developed by two photons which have their origin in $\pi^\circ\rightarrow2\gamma$ event, in which we can estimate the energy of π°-meson more accurately from the opening angle between the two γ-rays. In our case such a case has not been found. But as the studies with emulsion cloud chambers are now going on, it must soon be found.

Making use of the approximation A of Rossi and Greisen applying the theory by Fernbach and Erges[4], Kaplon and Ritson[5] also estimated the energies of cascade showers in their emulsion cloud chambers. Their results agree with ours within the fluctuations. Recently, Pinkau[6] has also reported the analysis of cascade shower in nuclear emulsions in which he obtained the energy of γ-ray by measuring the energy of each electron track by scattering method. His results are well in accord with ours.

The authors wish to express their gratitude to Prof. O. Minakawa and J. Nishimura for their comments and suggestions. To the members of the Kansai Balloon Group go our sincere appreciation and thanks for making possible the balloon flight.

Layer Structures of Magnetic Oxides

By Shūichi IIDA

Department of Physics, Faculty of Science, University of Tokyo

(Received November 24, 1955)

In most of the ferromagnetic oxides, the anion lattices are constructed by piling up two dimentional trigonal lattice layers in succession. Metallic ions locate on the proper interstices of these anion layers, forming themselves also several kinds of layers. It has been shown that the crystal lattices of these oxides can be constructed uniquely by assuming 1) the layer structures outlined above, 2) requirement of minimizing the sum of electrostatic energy and interionic repulsive energy and, 3) the numbers of cations locating between two neighbouring anion layers are all the same, e. g. equal to that corresponding to the molecular ratio notwithstanding that there may be several kinds of cation structures as such inter-layer cation arragements. From this consideration, 13 M−O−M configurations are derived as possible configurations acting for the superexchange interaction in magnetic oxides. It is shown that the magnetic lattices also have layer structures.

§1. Introduction

The most of the crystal structures of magnetic oxides are so complex that it seems difficult to understand these structures physically; for instance the spinel structure contains fifty-six ions in a unit cell. However, it has been shown by the carefull analysis based upon certain assumptions, that each of these structures is a unique one which can be constructed from the constituent ions having definite ratio of anions to cations. Since these assumptions are so simple and reasonable, by using these ideas, we can understand the crystal structures of various magnetic oxides more deeply than by the usual crystallographic representation. It would become easier to consider possible imperfect structures in these crystals (lattice defect, dislocation, stacking fault, etc.). These ideas can also be applied to many other compounds to elucidiate their crystal structures.

An application of these ideas to the problem of superexchange interaction will be given in the last sections.

§2. Assumptions

Oxides of iron group elements are generally discussed in this paper. It is well known that in almost all of these crystals anions make approximately close packed lattices (face centered cubic lattice or hexagonal close packed lattice). The fact will be mainly due to the large difference in ionic radii between the oxygen ion ($O^{--}=1.32$ A) and the metal ions of iron group elements ($Mn^{++}=0.91$, $Fe^{++}=0.83$, $Fe^{+++}=0.67$, $Co^{++}=0.82$, $Ni^{++}=0.78$, etc.)[1]. It is also well known that the close packed lattices can be constructed by piling up plane trigonal lattices. The plane trigonal lattice has two kinds of interstices, each of which forms itself a plane trigonal lattice. These are shown in Fig. 1. We shall specify each one of these with its phase A, B or C. Then a layer structure ABCABC··· forms a face centered cubic lattice and ABABAB··· forms a hexagonal close packed lattice.

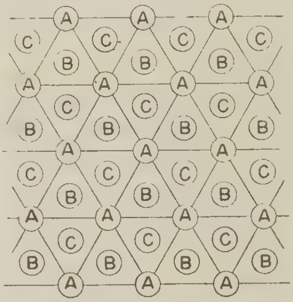

Fig. 1. Mutual configuration of three plane trigonal lattices with phases A, B, and C.

It is our standpoint throughout this paper that every crystal is considered as having a layer structure. Thus the following three assumptions can be derived semi-empirically as the guiding principles.

Assumption I.

In these crystals, oxygen ions form close packed lattices. Therefore, the lattices can be considered as layer structures composed of plane trigonal lattices of oxygen ions*.

Assumption II.

In these crystals, cations locate on proper interstices of their close packed oxygen lattices. The arrangement of cations on various interstices are so determined as to minimize the sum of the interionic repulsive energy and the electrostatic Coulomb energy. The phase selection of the successive oxygen layers (ABC··· or ABA··· etc.) are also ruled by the same principle.

Assumption III.

Cations distribute equally in number to each interspace region present between every two nearest oxygen layers. Therefore, the ionic ratio of cations to anions is maintained as constant at between every two neighbouring oxygen layers; it is equal to the molecular ratio of the crystal.

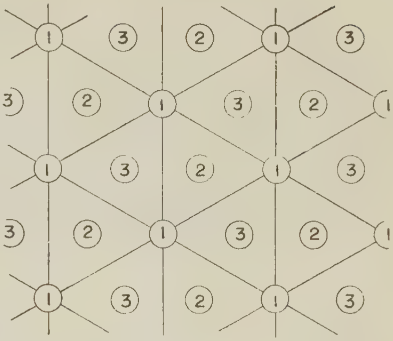
It seems at this stage that Assumption II requires quantitative calculations of the Madelung constant. However, it will be shown later that in almost all cases only qualitative considerations of this sort are enough to understand the actual arrangements of anions and cations. Assumption III might be supported by the requirements for the balance of electrostatic charge or by that for the maximum entropy. However, this assumption is derived here mainly from empirical facts.

§ 3. Subdivisions "S" and "T"

Before entering into the analysis of the actual crystals, several geometrical relations existing in the plane trigonal lattices A, B and C are studied.

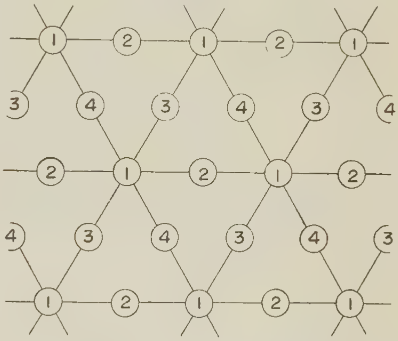
Now we consider first the possible ways of subdivision of a plane trigonal lattice. If we postulate that the sublattices after the subdivision should be all equivalent and be all nearest neighbours with each other, it is possible to find three ways of such subdivision. These are shown in Fig. 2. The unit length of these sublattices are $\sqrt{3}a$, $2a$ and $\sqrt{7}a$ respectively, where a is an unit length of the original lattice. These subdivisions subdivide the original trigonal lattice into 3, 4 and 7 equivalent trigonal sublattices. We shall call these, subdivisions "S", "T" and "U" respectively.

"S" subdivision



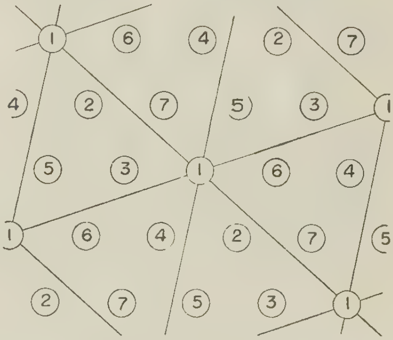
(a), Subdivision "S" (with three sublattices).

"T" subdivision



(b), Subdivision "T" (with four sublattices).

"U" subdivision



(c), Subdivision "U" (with seven sublattices).

Fig. 2. Three ways of subdivision for a plane trigonal lattice.

---

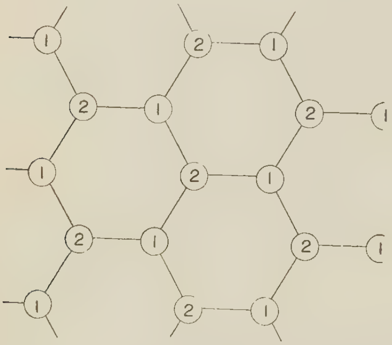
* In this stage, we disregard entirely the deviations from the geometrical lattice points that exist often in actual crystals.

We concern ourselves with "S" and "T" subdivisions in this paper. "U" subdivision is rather artificial. It should be noticed that if one sublattice in "S" subdivision is removed from the original lattice, then the remaining lattice forms a honey-comb lattice, and on the other hand in "T" subdivision, the remaining lattice forms a "kagome" lattice as shown in Fig. 3. For the sake of the later analysis we define the individual sublattices on the three plane trigonal lattices A, B and C as

SA1 SA2 SA3 TA1 TA2 TA3 TA4
SB1 SB2 SB3 or TB1 TB2 TB3 TB4
SC1 SC2 SC3 TC1 TC2 TC3 TC4 .

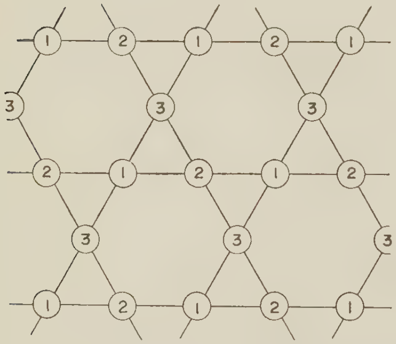
The mutual relation of these sublattices are shown in Fig. 4(a) or (b). In "T" subdivision, TA1+TB1+TC1 forms also a trigonal lattice and TA1, TB1 and TC1 form "S" subdivision in this trigonal lattice. TA2+TB2+TC2, TA3+TB3+TC3, and TA4+TB4+TC4 also have the same relation.

"S1+S2"



(a), honey-comb lattice as composed of two sublattices in "S" subdivision.

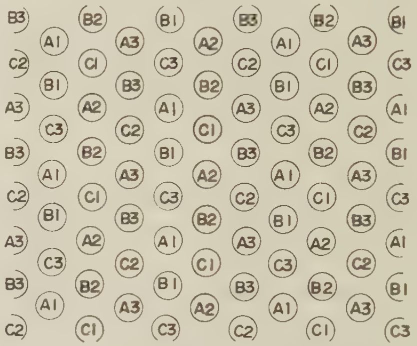
"T1+T2+T3"



(b), "kagome" lattice as composed of three sublattices in "T" subdivision.

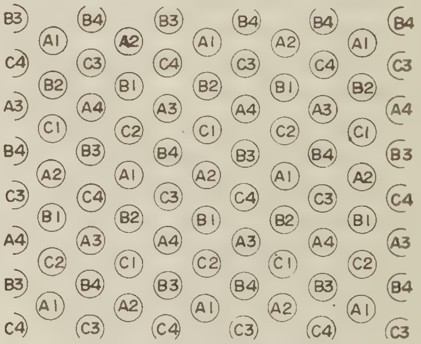
Fig. 3. Plane trigonal lattices with vacant sublattice.

"S" subdivision



(a), in "S" subdivision

"T" subdivision



(b), in "T" subdivision

Fig. 4. Notation of individual sublattices on three plane trigonal lattices A, B, and C.

It should be noticed here that subdivisions "S" and "T" subdivide the trigonal lattices by completely different ways and there is no simple correlation between them. It has been found actually that the whole crystals in which some ions form close packed lattices can be classified into three groups, namely, 1) having no subdivision (NaCl, NiAs, ZnO, ZnS, CdI_2, $CdCl_2$ types etc.), 2) obeying "S" subdivision (Cr_2O_3, $TiFeO_3$, Ni_3S_2 types etc.), and 3) obeying "T" subdivision ($MgAl_2O_4$, $BaFe_{12}O_{19}$, Fe_7S_8, $LaMnO_3$, $HFeO_2$ types etc.)[2]. If two crystal structures belong to "S" and "T" group respectively, there is no habit plane of good registry. At low temperatures, Fe_3O_4 transforms into γFe_2O_3 by further oxidation, and not into αFe_2O_3, in spite of the fact that the true equilibrium state is αFe_2O_3. The phenomenon will be explained by the fact that both Fe_3O_4 and γFe_2O_3 belong to "T" group and can transform continuously from one to another, while αFe_2O_3 belongs to "S" group.

§ 4. Iron-Oxygen Crystals

Now the analysis of the actual crystal structures will be given. For convenience, we explain first iron-oxides in detail. These are wüstite (FeO, NaCl type), magnetite (Fe_3O_4, $MgAl_2O_4$ type) and α hematite (Fe_2O_3, Cr_2O_3 type).

1) FeO[2].

According to Assumption I, a plane trigonal lattice of O^{--} ions is taken as the first layer. Let the phase of the layer be A (Diagram 1). Then Assumptions II and III promise that the phase of next Fe^{++} layer should be B or C, and Fe^{++} ions should occupy the whole lattice points of the same layer. If we assume the layer is B, then we must conclude the next O^{--} layer is C according to Assumption II. The diagram thus constructed is shown in Diagram 1. In the diagram, z means vertical distances of the layers. It will be easy to understand why wüstite has NaCl type structure.

Diagram 1. Structure of FeO.

2) αFe_2O_3[2].

Like the previous case, we first set an O^{--} ion layer of phase A (Diagram 2). By Assumption III, the next Fe^{+++} ion layer must occupy two thirds of the lattice points of a plane trigonal lattice of phase B. Then, it will be required by assumption II, that the lattice should be subdivided by subdivision "S" and two of the three sublattices be occupied. Let them be SB2 and SB3. They form an honey-comb lattice. The next O^{--} ion layer must be C. The configuration thus obtained is shown in Fig. 5.

αFe_2O_3

Diagram 2. Structure of αFe_2O_3.

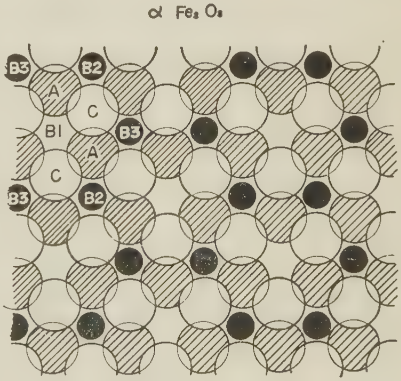

Fig. 5. Projection of α Fe_2O_3 crystal as seen from <111> asis. It corresponds to a cross section at $z=1$ in Diagram 2.

It will be clear that the positions SB1 become the positions with minimum energy for the next Fe^{+++} ions. Consequently, the next Fe^{+++} ion layer is SB1 as shown in Diagram 2. But according to Assumption III, one more layer is necessary and the sublattice SB2 or SB3 seems most probable for this. In this case, the existence of Fe^{+++} ion layer on SB1 sublattice denies the possibility of occupation of A positions for the next Fe^{+++} ions. Let it be SB2, the next layer should be an A layer of O^{--} ions. Repeating these procedures, Diagram 2 is easily constructed, which shows that the structure is a hexagonal one. It should be noticed that the initial SB2+SB3 layer of Fe^{+++} ions must separate into two layers SB2 and SB3 by the influence of underlying SB3 layer of Fe^{+++} ions. Diagram 2 is drawn after the consideration of this effect. Oxygen ions also have small displacements from the geometrical positions. These are discussed in section 6.

3) Fe_3O_4[2].

In this case there are two kinds of iron ion: Fe^{++} and Fe^{+++}. But here we disregard the difference of the two ions[3]. By a similar way to that of the preceding case, we can construct Diagram 3. Let the first O^{--} ion layer be of phase A. It is uniquely determined by Assumption III that the next $Fe^{(+)}$ ion layer should follow subdivision "T" and one sublattice becomes vacant. Let it be TB1+TB2+TB3. Then the next O^{--} ion layer must be C. The configuration constructed in this way is shown in Fig. 6, as seen from z axis. With the aid of the figure, it will be clear that the next $Fe^{(+)}$ ion layer is in TB4. However, because of Assumption III, more $Fe^{(+)}$ ion layers must be present. These are TA4 and TC4. The occupation of $Fe^{(+)}$ ions on TC4 sublattice is caused by the electrostatic energy requirement from $Fe^{(+)}$ ions in TB4 and TA4 sublattices. The next O^{--} ion layer must be B. Repeating these precedures we can construct Diagram 3. It represents the spinel structure. It should be noticed that in this case, the $Fe^{(+)}$ ions occupy two different interstices of the oxygen lattice; one is the tetrahedral position and the other is the octahedral position. They correspond to 8(a) and 16(d) sites of the spinel crystal respectively[4].

§ 5. Other Examples

By the explanation of the previous section, it will be understood that each one of the crystal structures of iron-oxygen system can be constructed uniquely by the assumptions I, II and III. The reason why these assumptions are varid so simply for these crystals may be due to the fact that the cohesive energy of the crystals is of purely ionic nature and the oxygen ion has a larger ionic radious than that of the iron ion. The theory can be applied to almost all oxides of iron group elements.

It can be applied also to almost all magnetic compounds. Although some deviations from our theory appear often in these crystals, it will be interpreted as showing the difference in the binding nature in these crystals from the simple theory; it can be ascribed partly to the variety in ionic radii of the component ions and partly to the covalent nature of their binding force. Several examples will be introduced hereafter.

4) FeS[2].

The structure before the α transformation (T > 140°C)* is shown in Diagram 4 and is generally called NiAs type structure. The difference from the structure of FeO is that the two nearest iron ion layers do not elude overlapping in this crystal. This will be due to the homopolar binding tendency of S^{--} ions. Many of the magnetic compounds consisting of iron group elements and metalloid elements (S, Se, Te, As, Sb, Bi, etc.) have the same crystal structure[2]. Various properties of these compounds would be influenced by the mentioned homopolar binding tendency of this structure[6].

5) Fe_7S_8[7].

Bertaut has found by a X-ray study that a superstructure Fe_7S_8 exists. The structure is shown in Diagram 5. In this case, it is obvious that "T" subdivision should be used and it becomes also easy by using the same scheme to understand the structures of

6) $BaO\cdot 6Fe_2O_3$[8].

The structure is called magnetoplumbite structure and is shown in Diagram 6. The structure can easily be understood by approving the existence of close packed layers consisting of O^{--}, Ba^{++} and Fe^{+++} ions. In this layer, Ba^{++} ions occupy the special positions which are usually occupied by O^{--} ions. This fact will be due to the large ionic radius of Ba^{++} ion (1.38 A). The layer lies between two spinel units and "T" subdivision is used.

Diagram 8. Structure of $KFe_{11}O_{17}$.

7) $LaMnO_3$[9].

The structure is called perovskite structure and is shown in Diagram 7. In this case also, the ionic radius of La^{+++} ion is so large that O^{--} ions and La^{+++} ions construct together a face centered cubic structure. Mn^{+++} ions locate on all the octahedral interstices which are surrounded only by O^{--} ions in this close packed lattice. "T" subdivision is used.

8) $KFe_{11}O_{17}$[8].

The structure is shown in Diagram 8. In this case the ionic radius of K^{+} ion is so large that a K^{+} ion in TC4 position is considered to play the same role as three O^{--} ions at TA1+TA2+TA3 positions.

§ 6. Discussion

It should be remarked here that in the actual crystals there are often some deviations from the geometrical lattice points which are mentioned above. These deviations are induced usually by the lack of certain symmetry existing occasionally in the original geometrical lattices, and the deviations occure so as to reduce the total cohesive energy, which are easily comprehensibe. Therefore, for instance, the presence of parameter u in the spinel structure[2], and u, v in the rhombohedral sesquioxide (αFe_2O_3)[2] can be expected *a priori* from the original structures. These deviations occur normally so as to equate approximately all the contact distances between cation and oxygen ion for these cases.

As an example, in Fig. 7, the atomic arrangement of αFe_2O_3 are shown in the actual proportions. (a=5.427 A[10], α=55°16′, u=0.105, v=0.295[11], $r(O^{--})$=1.32 A, $r(Fe^{+++})$=0.67 A). The projection to (110) plane is shown in (a), and that to (001) plane, in (b) (hexagonal coordination). The induced displacement of each ion from the geometrical position are illustrated in the figure. In the left side of Fig. 7(a), the original position of each layer is shown. As illustrated already in Diagram 2, each Fe^{+++} ion layer splits into two in order to increase Fe–Fe distances, resulting in the simple displacements of Fe^{+++} ions along ⟨001⟩ or ⟨00$\bar{1}$⟩ direction. The displacements of oxygen ions are understood easily as the consequence of these cation displacements. The displacements of oxygen ions are shown in Fig. 7(b) by short lines. It will be also clear that the direction of each displacement is unique. In the figure, oxygen ions in C layer changes their positions such that they approach to the nearest SB2 positions in the same (001) plane. The contact distances between oxygen ion and iron ion become 2.07 A or 1.97 A in αFe_2O_3[12].

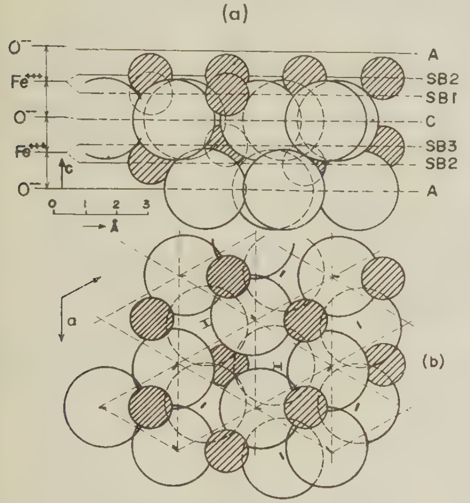

Fig. 7. Atomic arrangement in αFe_2O_3. (a), as projected to (110) plane; (b), as projected to (001) plane. Short lines indicate the induced displacements of oxygen ions from the geometrical positions. All configurations are written in actual proportion.

But there are several crystals in which the deformation occurs unusually which can not be expected from the symmetry of the original lattice. Tetragonal deformation of spinel structure (Mn_3O_4, $ZnMn_2O_4$[1], $CuFe_2O_4$[13]), deformation to MnP structure from NiAs structure (MnAs,[14], FeAs[12]), etc. are such cases. In these cases it will be necessary to make clear the driving force for such deformation. It will be necessary in such cases to introduce the consideration of covalency. However[13], we do not concern ourselves with such topics in the present paper.

It is well known that in the actual crystal growth from the melt or the solution, each crystal grows layer by layer probably with the aid of screw dislocations in the center[15]. At these circumstances each ion might sought its favouroble position on the surface of the mother crystal, in obedience to the law similar to the assumptions which we postulated in section 2. In the compound like as treated in the present paper, the growing surface coincide frequently with the layer surface being considered now. This fact might indicate that there are some relationships between the idea developed in the present paper and the mechanism of the actual crystal growth.

§ 7. Possible Types of Super Exchange Interaction

In the arrangement of ions discussed above, we can find thirteen kinds of super exchange interactions[16] with different cation-anion-cation configurations. These are shown in Table I. In the table, the first column indicates the interaction angle $\angle M_1OM_2$, (M_1, M_2 mean interacting cations, O means intermediate oxygen), and the second column, the M_1–O, M_2–O distances. The configurations in which M_1–O and M_2–O are contact distances are only listed. There are two contact distances p and q corresponding to tetrahedral and octahedral positions respectively. The third column indicates the corresponding configurations expressed by our notations with the relevant oxygen ion layer having A phase, and the fourth and fifth columns indicate the possibility of each configuration in cubic and hexagonal sequence of oxygen. The last two columns indicate whether the interaction connects the cations at different side (upper or lower) of the intermediate oxygen layer or not. As is shown, most of the strong coupling (having large interaction angle) are of inter layer nature. Therefore, it can be supposed from this table that magnetic coupling also have often layer like structure. As will be shown in the next section, in the actual crystals this expectation is realized in almost all cases; their dominant interactions are those of inter-layer nature. However, it should be noticed that this does not mean that all the spin magnetic moments present between two adjacent oxygen ion layers are parrallel. The last line of the table indicates the special super exchange configuration appearing in $BaFe_{12}O_{19}$[8]. It should be remarked that the interaction angles or the M–O distances shown in the

Table I. Possible M_1-O-M_2 configurations in magnetic oxides.

The tabulated configurations can be responsible for superexchange interaction. The interaction angles $\angle M_1OM_2$ and the oxygen ion-metal ion distances M_1-O, M_2-O are those for the ideal geometrical arrangements in which oxygen ions make regular close packed arrangements.

$p=\sqrt{3/8}\ a=0.612a$, and $q=\sqrt{1/2}\ a=0.707a$, where a means nearest O-O distance.

The third column indicates the individual configurations. For instance, $T^{B}_{C}\mathrm{i}(1/4)-\mathrm{A}(0)-T^{C}_{B}\mathrm{i}(+1/4)$ means two configurations, in which one is the configuration from M_1 at TBi position (Fig. 4(b)) with $z=-1/4$ (z means the vertical coordinate of each ion measured by the interlayer distance of oxygen layers, i.e. $\sqrt{2/3}a$, to M_2 at TCi position with $z=+1/4$ intermediated by an oxygen ion at A position with $z=0$. The relevant oxygen ion layer is constantly assumed to be A phase at $z=0$.

Cubic or Hexa. mean that the configuration may appear in the cubic or hexagonal sequence of oxygen layers (BAC and CAB, or BAB and CAC).

Inter or Intra layer means the configuration in which M_1 and M_2 belong to the different side or the same side of the intermediate oxygen ion layer.

table do not correspond accurately to the actual angles or distances in many cases. The fact is due to the presence of the induced displacement of each ion from each geometrical position, as we mentioned in the foregoing section.

§ 8. Interpretation of Magnetic Coupling in Actual Crystals

By using the result of the crystal structure analysis (Figs. 4(a), (b), and Diagrams 1, 2, $\cdots$, 8) and Table I, we shall give the interpretation of the structures of magnetic coupling in several actual crystals. It should be noticed that all these magnetic lattices also have layer structures in which the ions in such layer have the same spin orientation.

1) FeO.

In this case, all cations are on octahedral positions and accordingly, all z in Table I are $\pm 1/2$. Therefore configurations II and VIII are only responsible for super exchange interaction. Interaction II should be dominant, having certainly negative sign. This interaction is of interlayer nature. Thus cations at TAi, TBi and TCi positions construct an antiferromagnetic lattice of spins. There are four such sublattices TA1+TB1+TC1, TA2+TB2+TC2, TA3+TB3+TC3, and TA4+TB4+TC4. There are two ways for the mutual spin relations among these four lattices effectively. One is cubic (Néel type) and the other is rhombohedral[17]. It should be noticed that the VIII type interactions are cancelled out in both cases and it does not contribute to select one from the two. Actually, rhombohedral structure is realized. Therefore, it has a layer structure as shown in Diagram 1.

2) αFe_2O_3*[11].

In this case also, all cations are on octahedral positions and configurations IV, VIII, and XI should be responsible for superexchange interaction. It will be most reasonable to assume the interaction IV is dominant and negative. This interaction is also of interlayer nature and it predicts perfect antiparrallelism of successive cation layers as shown in Diagram 2. Here, it should be remarked in this case that the induced deformation of crystal lattice from the geometrical arrangement changes the configuration IV into two slightly different configurations. Therefore, we consider the interaction IV as consisting of two different configurations: One, IV_1 has the equal M–O distances and the other, IV_2 has two M–O distances in which one is slightly different (longer) from that in the former. They correspond to SB3–C–SB1 and SB2–C–SB1 at $z=1$ in Diagram 2.

---

* Note added in proof—Quite recently Y. Y. Li[1] has pointed out that the interaction XI is important in αFe_2O_3 and Cr_2O_3. However, Li has missed the presence of IV_2 interaction. We have given a detailed discussion in J. Phys. Soc. Japan. **11** (1956) 1300[12].

The spin arrangement in Cr_2O_3 are also shown in Diagram 2. Though there are two cation layers between two neighbouring oxygen layers, it has also a layer structure. The structure can be understood by assuming that the interaction IV_1 has negative sign, whereas the interaction IV_2 has positive sign.

3) Fe_3O_4.

In this case cations are on both octahedral positions and tetrahedral positions. This case was treated already by Gorter[18, 4] considering the higher order interactions. In our consideration, the configurations present are V and VIII. It should be expected that V interaction is dominant and has negative sign. The interaction V covers all the magnetic lattice and results in the well-known ferrimagnetism[19, 4] in spinels as shown in Diagram 3. It will be clear that in this case also the magnetic lattice has a layer structure.

In this case also oxygen ions displace slightly from their geometrical positions[2]. Though these displacements distorts the configurations V slightly, the distortion is similar to every configuration V and, contrary to the preceding case, all configurations V are equivalent after the deformation.

4) $BaO \cdot 6Fe_2O_3$[8].

In this compound the oxygen layers which contain barium ions contain also iron ions and a new type of interaction is present which is named as IV′ in Table I. The interaction IV′ may be considered to be fairly strong. This interaction bind the spinel units present at both sides of the layer so as to result in ferrimagnetism.

6) $LaMnO_3$[9, 20].

In this compound configuration II is only responsible for exchange interaction. Normally it operates as super exchange interaction and antiferro-magnetism is realized The manganese ions in this case are all in trivalency state. But, when lanthanum ions are substituted partly by alkaline-earths ions (Ca, Sr, etc.), the tetravalency state of manganese ions appears associated with the participation of double exchange interaction In this case the situation is very complex and the actual magnetic structures become beyond the scope of our scheme.

7) FeS.

In this case also all cations are on octahedral positions. Therefore, configurations IV, VIII, and XI are present. It is doubtful whether we can extend Anderson's theory of directional super exchange interaction of magnetic oxides to sulphides. However, if we assume it can be applied to sulphide, the dominant interaction should be the interaction IV, and perfect antiparrallelism of successive cation layers are expected. According to the Bertaut's analysis[5], it is expected that the configuration IV splits into six different configurations after α transformation (T < 140°C).

If NiAs structure deforms to MnP structure as has been suggested also in MnAs[14], the configuration IV splits into two different configurations.

§ 9. Conclusion

By the analysis of this paper, it will become clear that the crystal structure of magnetic oxides are comprehensible by the model of layer structures on a purely ionic base, and the magnetic superstructure are also comprehensive by the same model. Generally, the magnetic oxides often contain vacancies of cation or interstitial cations. It will be hoped to apply our theory further to the study of these point imperfections in crystal lattices. We hope also to extend our theory to the study of one dimentional or two dimentional imperfections in these crystals (dislocations, or stacking faults).

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 3, MARCH, 1957

Anisotropy in Polarized Barium Titanate Ceramics[†]

By Masakazu MARUTAKE and Takuro IKEDA

Kobayasi Institute of Physical Research, Kokubunji, Tokyo

(Received October 18, 1956)

Dielectric constants ε_1^T and ε_3^T (perpendicular and parallel to the direction of the polarization) and elastic compliance coefficients s_{11}^E, s_{33}^E and s_{44}^E of fully prepolarized $BaTiO_3$ ceramics are measured, and are compared with the dielectric constant ε^0 and the elastic compliance coefficients s_{11}^0 and s_{44}^0 of the unpolarized ceramics.

Anisotropy is small (a few percent). By semi-quantitative calculations, it is shown that the 180°-reversals of domains mainly remain after the poling process, and that anisotropy is due to the piezoelectric interactions among single crystals which constitute the ceramic.

§1. Introduction

In piezoelectric applications, $BaTiO_3$ ceramics are used usually after they are polarized in a d.c. electric field of about 20 kV/cm. In this poling process, domain orientations are altered and there remains the remanent polarization. Meanwhile, $BaTiO_3$ single crystal is highly anisotropic in the tetragonal phase; for instance, $\varepsilon_1^T=4500$ and $\varepsilon_3^T=200$ for the dielectric constants[1)], and $s_{11}^E=1.1\times10^{-12}\,\mathrm{cm^2/dyne}$ and $s_{33}^E=2.3\times10^{-12}\,\mathrm{cm^2/dyne}$ for the elastic compliance coefficients[2)] at room temperature. Therefore, if 90°-rotations of domains remain after the poling process, the dielectric and elastic constants of the polarized ceramics are expected to be very different from those of the unpolarized ones. From this point of view, the anisotropy of the polarized $BaTiO_3$ ceramics was studied in the tetragonal phase.

The unpolarized ceramic is isotropic, and has one dielectric constant ε^{*0}, two elastic compliance coefficients s_{11}^{*0} and s_{44}^{*0}, and does not show the piezoelectric effects. (Superscript * denotes the constant of the ceramic to distinguish it from that of the single crystal[3], and 0 denotes the constant of the unpolarized ceramic.) The polarized ceramic, on the other hand, has the symmetry of $C_n(n=\infty)$[4], and has the following matrix elements for the dielectric, the piezoelectric and the elastic constants.

[†] Main part of this paper was read at the meeting of the Acoustical Society of Japan, held on May 14, 1953.

$$\begin{pmatrix} \varepsilon_1^* & 0 & 0 \\ 0 & \varepsilon_1^* & 0 \\ 0 & 0 & \varepsilon_3^* \end{pmatrix} \qquad (1)$$

$$\begin{pmatrix} 0 & 0 & 0 & 0 & d_{15}^* & 0 \\ 0 & 0 & 0 & d_{15}^* & 0 & 0 \\ d_{31}^* & d_{31}^* & d_{33}^* & 0 & 0 & 0 \end{pmatrix} \qquad (2)$$

$$\begin{pmatrix} s_{11}^* & s_{12}^* & s_{13}^* & 0 & 0 & 0 \\ s_{12}^* & s_{11}^* & s_{13}^* & 0 & 0 & 0 \\ s_{13}^* & s_{13}^* & s_{33}^* & 0 & 0 & 0 \\ 0 & 0 & 0 & s_{44}^* & 0 & 0 \\ 0 & 0 & 0 & 0 & s_{44}^* & 0 \\ 0 & 0 & 0 & 0 & 0 & 2(s_{11}^*-s_{12}^*) \end{pmatrix} \qquad (3)$$

In this study, ε_1^{*T}, ε_3^{*T}; d_{31}^*, d_{33}^*; s_{11}^{*E}, s_{33}^{*E}, s_{44}^{*E} were measured at the temperatures between 10°C and 80°C, and were compared with ε^{*0}, s_{11}^{*0} and s_{44}^{*0}.

Furthermore, for comparison, the dielectric constant ε_3^{*T} and the elastic compliance coefficient s_{11}^{*E} were measured under a biasing d.c. electric field. Though these measurements were reported by many authors[5][6][7], we repeated here especially to make clear the behaviors in a weak biasing field.

§2. Experimental Procedures and Results

BaTiO$_3$ ceramics were sintered at about 1400°C from the mixtures of BaCO$_3$ and TiO$_2$ (reagent-grade) in an ordinary way. These specimens have the Curie temperature at 115°C, and the density of about 5.5.

(1) *Dielectric Measurements*

The dielectric constants were measured with a Q-meter at 50 kc (far below the mechanical resonant frequency of the specimen).

The specimen was polarized, first, along the z-axis (*cf.* Fig. 1) in a d.c. field of 20 kV/cm, and ε_3^{*T} was measured after the specimen was aged for 2 days at 75°C. Then, ε_1^{*T} along the x-axis was measured, by applying air-drying silver electrodes (P$_2$) after old electrodes (P$_1$) were removed. Finally, ε^{*0} was measured, after the specimen was depolarized by heating above the Curie temperature and was aged again. ε^{*0}, ε_1^{*T} and ε_3^{*T} are shown in Fig. 2, and it is found that at room temperature ε_1^{*T} and ε_3^{*T} are larger than ε^{*0} (*e.g.* $(\varepsilon_1^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=3\%$ and $(\varepsilon_3^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=12\%$ at 20°C), but that ε_3^{*T} is smaller than ε^{*0} at the temperatures above 60°C.

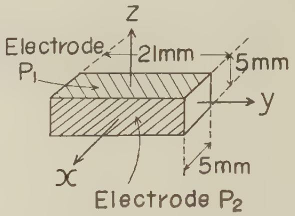

Fig. 1. Specimen for dielectric measurements.

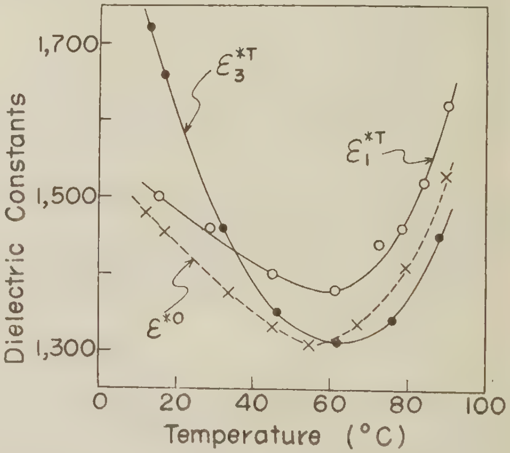

Fig. 2. Dielectric constants of the polarized and the unpolarized ceramic.

Generally, the dielectric constant of ferroelectric materials is reduced by a biasing electric field. We also measured the dielectric constant ε_3^{*T} by applying various d.c. voltage at 27°C and 78°C. A rectangular plate of $10\times8.1\times0.6\,\mathrm{mm}^3$ was used as specimen. The results are shown in Fig. 3 and Fig. 4.

On the virgin curve (ABC), it will be seen, ε_3^{*T} increases at first with the biasing field (AB), and then decreases rapidly (BC). Next, returning to the zero bias (CDE), ε_3^{*T} increases smoothly with the decreasing field; and when the biasing field is reversed, ε_3^{*T} decreases, first very rapidly (EF), and then slowly (FG). These cycles can be repeated in the same way, and at the zero bias (E) ε_3^{*T} is larger than at the starting point (A).

Unsymmetrical curves like Fig. 3 and Fig. 4 were previously obtained by Roberts[5] and recently by Mesnard and Eyraud[7], and we shall conclude later (§ 3) that these phenomena are mainly due to the piezoelectric interactions among single crystallites. These phenomena, however, are relaxation processes, and the time during which the biasing voltages are applied changes the shape of the curve. Sakudo[8] has obtained a symmetrical butterfly-type curve (Fig. 5) when the biasing field is changed at the period of 1/50 sec., while in our measurements ε_3^{*T} was measured after the biasing voltage was applied for about 5 minutes.

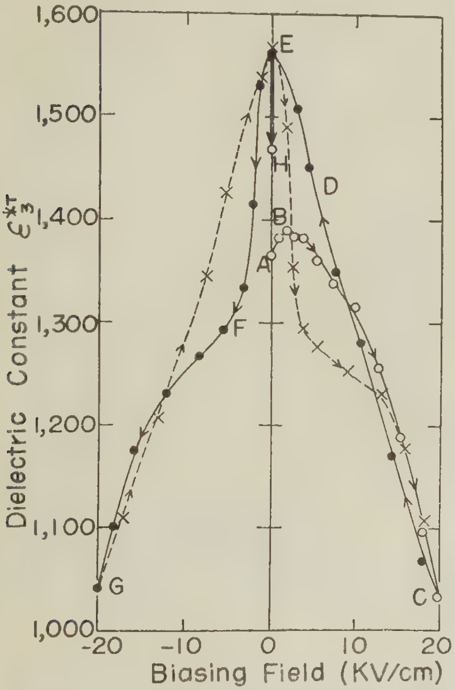

Fig. 3. Effects of the biasing field on ε_3^{*T} (27°C).

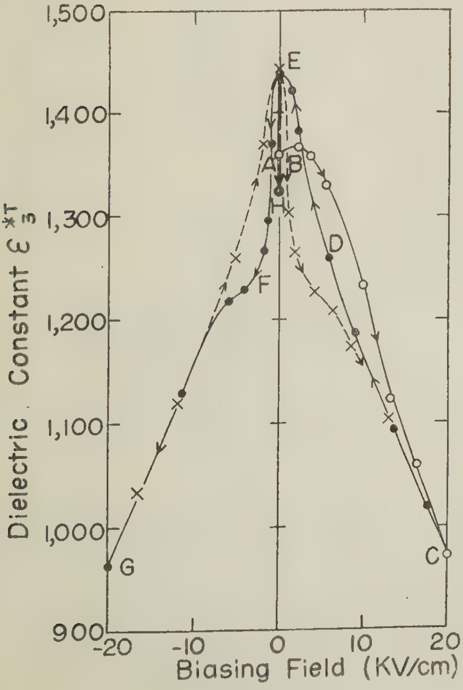

Fig. 4. Effects of the biasing field on ε_3^{T} (78°C).

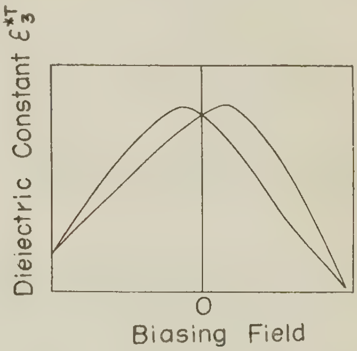

Fig. 5. Effects of the biasing field (short duration) on ε_3^{*T} (after Sakudo[8]).

It is also noted that the aging process (in a larger scale of time) plays a great rôle, and that the value at the starting point (A) is that measured after being aged for a day at 80°C, while the value at the zero bias (E) is that of unaged state, so that the latter decreases considerably (from E to H) at the fully aged state.

(2) *Elastic Measurements*

The elastic compliance coefficients s_{11}^{*E}, s_{33}^{*E}, s_{44}^{*E}; s_{11}^{*0}, s_{44}^{*0} were measured at the temperatures between 10°C and 90°C, and s_{11}^{*E} was also measured in the various biasing electric field at 23°C. The elastic constants were obtained from the resonant frequencies of bars (with rectangular or circular sections), which were measured either by the self-resonance method (s_{11}^{*E} and s_{33}^{*E}) or by the composite-bar method (s_{11}^{*E}, s_{44}^{*E}, s_{11}^{*0}, s_{44}^{*0} and the measurements under the biasing field).

(i) s_{11}^{*E} and d_{31}^{*}

Resonant and antiresonant frequencies f_R and f_A of the lengthwise compressional vibrations of the bar were measured (Fig. 6) after the specimen was polarized at 18 kV/cm at room temperature and was aged for a day at 80°C.

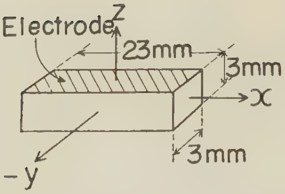

Fig. 6. Measurements of s_{11}^{*E} and d_{31}^{*}.

s_{11}^{*E} and d_{31}^{*} are calculated from the following equations:

$$\left.\begin{aligned} f_R &= \frac{1}{2l}\sqrt{\frac{1}{\rho s_{11}^{*E}}}\,, \\ \frac{f_A - f_R}{f_R} &= \frac{4}{\pi^2} k_{31}^2\,, \\ k_{31}^2 &= \frac{4\pi d_{31}^{*2}}{s_{11}^{*E}\varepsilon_3^{*T}}\,; \end{aligned}\right\} \quad (4)$$

where ρ is the density and l is the length of the specimen. The results are shown in Fig. 8 and Fig. 9.

(ii) s_{33}^{*E} and d_{33}^{*}

Resonant and antiresonant frequencies f_R and f_A of the lengthwise compressional vibration of the bar were measured by applying the electric field along the direction of the length (*cf.* Fig. 7), after the specimen was polarized at 15 kV/cm at room temperature and was aged for a day at 80°C.

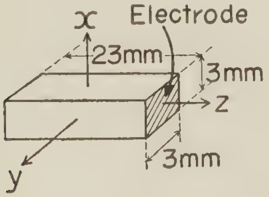

Fig. 7. Measurements of s_{33}^{*E} and d_{33}^{*}.

s_{33}^{*E} and d_{33}^{*} are calculated from the following equations:

$$\left.\begin{aligned} f_R &= \frac{1}{2l}\sqrt{\frac{1}{\rho s_{33}^{*E}\{1-(1-8/\pi^2)k_{33}^2\}}}\,, \\ \frac{f_A - f_R}{f_R} &= \frac{4}{\pi^2} k_{33}^2\,, \\ k_{33}^2 &= \frac{4\pi d_{33}^{*2}}{s_{33}^{*E}\varepsilon_3^{*T}}\,. \end{aligned}\right\} \quad (5)^{\dagger}$$

In these measurement, the capacity of the sample was small (about 5 $\mu\mu F$), and accordingly, the errors due to the stray capacity (2 $\mu\mu F$) were corrected in determining the antiresonant frequency f_A. The results are shown in Fig. 8 and Fig. 9.

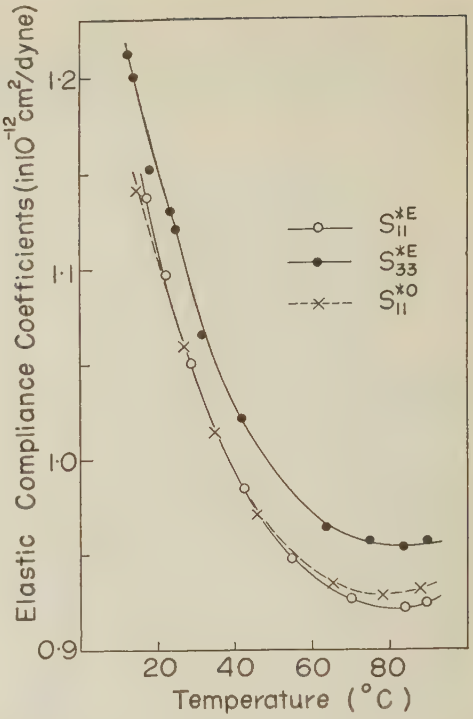

Fig. 8. Elastic compliance coefficients s_{11}^{*E} s_{33}^{*E} and s_{11}^{*0}.

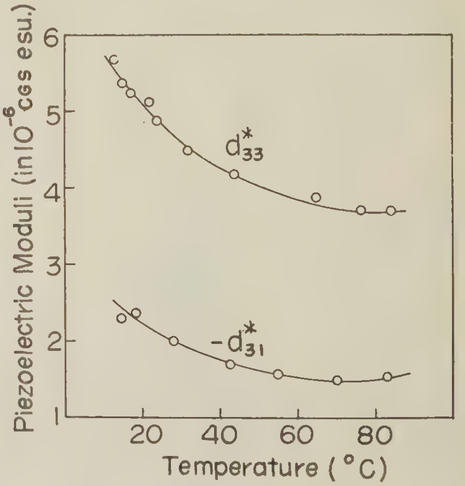

Fig. 9. Piezoelectric moduli d_{31}^{*} and d_{33}^{*}.

(iii) s_{11}^{*0} and s_{11}^{*E} in a biasing electric field.

The elastic compliance coefficient s_{11}^{*0} of the unpolarized ceramic was measured by the composite-bar method (*v.* ref. 10), and is shown in Fig. 8. By the same method, s_{11}^{*E} was measured by applying the various biasing voltage, and the results are shown in Fig. 10.

---

† *v.* notes added in proof (1) at the end of the paper.

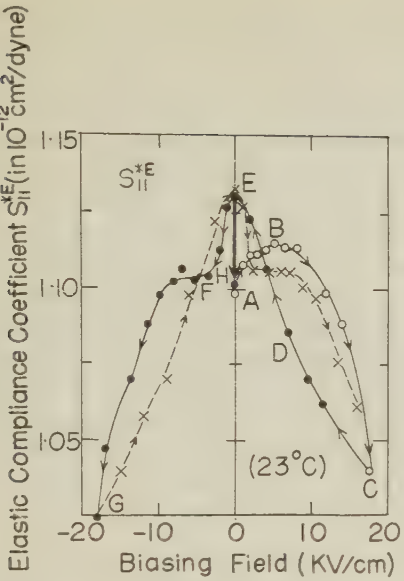

Fig. 10. Effects of the biasing electric field on s_{11}^{*E} (23°C).

(iv) s_{44}^{*0} and s_{44}^{*E}.

s_{44}^{*0} and s_{44}^{*E} were measured also by the composite-bar method (*v.* ref. 10), and the results are shown in Fig. 11.

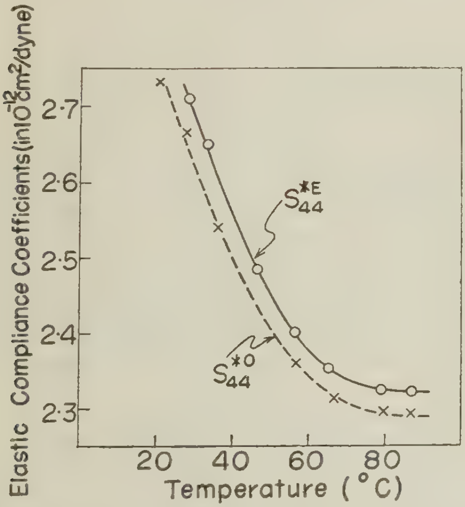

Fig. 11. Elastic compliance coefficients s_{44}° and s_{44}^{*E}.

(v) Results.

In these measurements of elastic constants, following results were obtained.

(a) At room temperature, s_{33}^{*E} and s_{44}^{*E} are larger, respectively, by a few per cent than s_{11}^{*0} and s_{44}^{*0} (*e.g.* $(s_{33}^{*E}-s_{11}^{*0})/s_{11}^{*0}=3.5\%$ and $(s_{44}^{*E}-s_{44}^{*0})/s_{44}^{*0}=4\%$ at 20°C). s_{11}^{*E}, however, does not differ from s_{11}^{*0} within experimental errors at room temperature, and the former is smaller than the latter at the temperatures above 60°C; these behaviors are similar to those of the dielectric constant ε_3^{*T}.

(b) s_{11}^{*E} shows the similar behaviors to those of ε_3^{*T} when the biasing voltage was applied along the *z*-axis. (A, B, C, ···, H in Fig. 10 corresponds, respectively, to those points in Fig. 3 and Fig. 4.)

§ 3. Discussions

Physical contants of the BaTiO$_3$ ceramics are certainly mean values of those of the single crystals which constitute the ceramic, but the evaluation of the mean values is very comlicated, because (1) each single crystal is composed of domains, (2) each domain shows piezoelectric effects, and (3) internal strains in the single crystal may change its physical constants. We shall consider thses effects in the following.

In the tetragonal phase, the unit cell of the single domain deforms from the cube and the length of the unit cell is larger along the *z*-axis by about 1% than along the *x*-axes. Accordingly, when the ceramic passes through the Curie point, very large internal stresses will be produced in the single crystals the axes of which are uniformly distributed, if there exist no internal stresses in the cubic phase. These stresses are minimized when each single crystal splits up into three kinds of domains (the *z*-axis of each kind is perpendicular to those of other kinds) and the total volume of each kind of domains is 1/3 of that of whole the crystal. The existence of the *herringbone* type domains (Fig. 12), as observed recently by Kulcsar[11] and Cook[12], may support these considerations, because herringbone type domains will appear at the place where

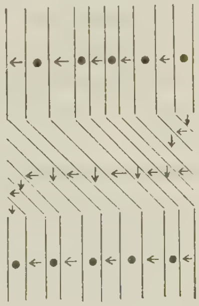

Fig. 12. Herringbone type domains (after Kulcsar[11] and Cook [12]).

three kinds of domains coexist. Hence, in the tetragonal phase, the internal stresses may be reduced and may not play a great rôle.

When the electric field is applied, 90°–rotations of domains will take place as well as 180°–reversals in favor of the poling field, and the dielectric constant $\varepsilon_3{}^{*T}$ and the elastic compliance coefficient $s_{11}{}^{*E}$ of the ceramic are reduced very much as was shown in Fig. 3 and Fig. 10.

In the non-biased prepolarized ceramic, however, the remanent polarization is considered mainly due to the 180°–reversals of domains, because 90°–rotations are accompanied with mechanical strains and will not remain after the poling field is removed. If only 180°–reversals of domains remain in the prepolarized ceramic, the anisotropy is caused by the piezoelectric interactions among the single crystals (or single domains) which constitute the ceramic. Piezoelectric interactions are very important in determining the dielectric and elastic constants in unpolarized ceramics, as was shown by one of the authors[3], and they contribute also to the change of the dielectric and elastic properties in polarized ceramics. Namely, the dielectric constant of the unpolarized ceramic is a mean of those values which are intermediate between the free and the clamped dielectric constants of the single crystal. In the polarized ceramic, which is piezoelectric as a whole, the "freedom", so to speak, of the single crystal is restored to a certain extent, and the dielectric constant of the prepolarized ceramic is raised because the dielectric constants of each single crystal approach to the free dielectric constants. (In the case of the multi-domain single crystal, Drougard and Young[13] discussed such effects on the dielectric constant.) On the elastic compliance coefficients s^*'s the situations are similar—namely, the constant s's of the single crystal approach to s^E's when the ceramic is polarized, while they are intermediate between s^E's and s^D's when the ceramic is unpolarized; and the constants s^{*E}'s of the ceramic become larger when polarized than when unpolarized.

The unsymmetrical curves shown in Fig. 3, Fig. 4 and Fig. 10 are also explained in the same way. Namely, at the points F's on these curves, the ceramics are depolarized and are non-piezoelectric, though 90°–rotations of the domains occur to some extent by the biasing field. Accordingly, the curves show minima at the points F's (also see the point F in Fig. 13).

Furthermore, to confirm above discussions, the dielectric and elastic constants of the polarized ceramic were calculated on the assumption that the ceramic is made up of spherical single domain crystallites, in the same way as the constants of unpolarized ceramic were calculated[3].

When the ceramic is perfectly polarized, all the 90°–rotations and 180°–reversals occur and the z-axes of the crystallites are assumed to be distributed uniformly within the angle of $\pi/4$ around the direction of the polarizing field (Strictly speaking, this distribution is not correct[14][15].), and the calculated values in this case at 20°C are as follows.

$$\left.\begin{aligned}\varepsilon_1{}^{*T}/\varepsilon^{*0}&=1.40\,,\\ \varepsilon_3{}^{*T}/\varepsilon^{*0}&=0.58\,;\\ s_{11}{}^{*E}/s_{11}{}^{*0}&=0.74\,,\\ s_{33}{}^{*E}/s_{11}{}^{*0}&=1.38\,.\end{aligned}\right\}\qquad(6)$$

The observed values at 20 kV/cm are (Fig. 3 and Fig. 10):

$$\left.\begin{aligned}\varepsilon_3{}^{*T}/\varepsilon^{*0}&=0.76\,,\\ s_{11}{}^{*E}/s_{11}{}^{*0}&=0.93\,.\end{aligned}\right\}\qquad(7)$$

As will be seen from Eq. (6), the elastic compliance coefficient $s_{33}{}^{*E}$ is expected to increase with the biasing field. From this point of view, the resonant frequency of the thickness compressional vibration of a circular plate (diameter: 30 mm, thikness: 2.8 mm) was measured by the self-resonance method, and the results are shown in Fig. 13. The prepolarized and aged specimen is biased firstly at the positive (favored) direction (ABCDE), and then the field is reversed (EFG); the point

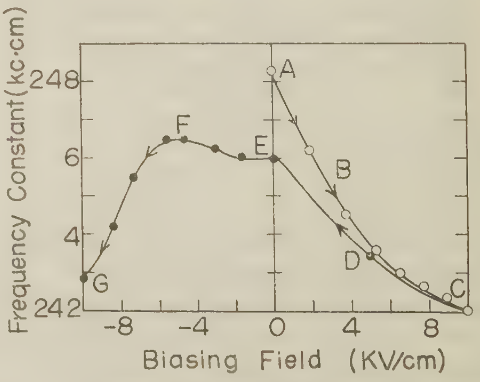

Fig. 13. Resonant frequency for the thickness compressional vibrations (24°C).

F shows the depolarized state. Although the frequency constant in this case does not give the value of $s_{33}{}^{*E}$ directly, we may conclude that $s_{33}{}^{*E}$ increases with the biasing field.

If we can measure the dielectric constant $\varepsilon_1{}^{*T}$, it will also increase with the biasing field, and it is to be noted that these effects should not be confused with the saturation phenomena as observed above the Curie temperature.

Now let us continue the calculation. When only the 180°-reversals are perfect and any 90°-rotations do not remain, the z-axes of the single crystals are distributed uniformly within the right angle around the direction of the polarizing field, and the calculations in this case show

$$\left.\begin{aligned}&(\varepsilon_1{}^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=4\%\,,\\&(\varepsilon_3{}^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=10\%\,,\\&(s_{11}{}^{*E}-s_{11}{}^{*0})/s_{11}{}^{*0}=0.7\%\,,\\&(s_{33}{}^{*E}-s_{11}{}^{*0})/s_{11}{}^{*0}=5\%\,,\\&(s_{44}{}^{*E}-s_{44}{}^{*0})/s_{44}{}^{*0}=3\%\,.\end{aligned}\right\}\qquad(8)$$

Observed values of non-biased prepolarized ceramics are (Fig. 2, Fig. 8 and Fig. 11):

$$\left.\begin{aligned}&(\varepsilon_1{}^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=3\%\,,\\&(\varepsilon_3{}^{*T}-\varepsilon^{*0})/\varepsilon^{*0}=12\%\,;\\&(s_{11}{}^{*T}-s_{11}{}^{*0})/s_{11}{}^{*0}=0\%\,,\\&(s_{33}{}^{*E}-s_{11}{}^{*0})/s_{11}{}^{*0}=3.5\%\,,\\&(s_{44}{}^{*E}-s_{44}{}^{*0})/s_{44}{}^{*0}=4\%\,.\end{aligned}\right\}\qquad(9)$$

These experiments are also in agreement with the measurement by Moseley[16]) who measured $s_{11}{}^{*E}$, $s_{33}{}^{*E}$ and $s_{11}{}^{*0}$ at room temperature, and with the measurements by Bechmann[17]) who measured all dielectric, piezoelectric and elastic constants shown in (1), (2) and (3) also at room temperature.

From above considerations, we can conclude that in the poling process 180°-reversals of domains remain mainly and that anisotropy is mainly due to the piezoelectric interactions (*cf.* (8) and (9)). Some proportions of 90°-rotations of domains may also remain in the polarized ceramic, and it explains why $\varepsilon_3{}^{*T}$ and $s_{11}{}^{*E}$ are smaller, respectively, than ε^{*0} and $s_{11}{}^{*0}$ at the temperatures above 60°C (Fig. 2 and Fig. 8).

Finally, we shall consider the aging effects studied by Mason[9]). He showed that the piezoelectric moduli in the polarized ceramic diminish gradually after the ceramic is polarized, and that the dielectric constant and the elastic compliance coefficients also diminish at the same time. The cause of these aging effects is considered to be the same as that of the anisotropy in the polarized ceramic which has just been discussed; namely the changes of the piezoelectric interactions among the crystallites cause the changes of the dielectric and elastic constants, as some part of the domains returns to the more stable orientations and the piezoelectric effects, hence, diminish as a whole. Mason also showed that the decrease of the piezoelectric effects reduces the dielectric constant and the elastic compliance coefficients in his phenomenological treatments[9]), and our conclusion is that it is mainly piezoelectric interactions that causes the changes of the dielectric and elastic constants in Mason's theory.

Also we shall point out here that the effects of the change of the orientation of domains due to 90°-rotation are considered to be smaller, because the dielectric constant $\varepsilon_3{}^{*T}$ and the elastic compliance coefficient $s_{11}{}^{*E}$ of the polarized ceramic are smaller at the aged state than at the unaged one (*cf.* E and H in Fig. 3, Fig. 4 and Fig. 10), while the reverse is the case if the orientations of domains are predominant in determining the dielectric and elastic constants.

Piezoelectric interactions discussed above, however, do not explain all of the aging effects, because aging effects appear also in the unpolarized ceramics, which show no piezoelectric effects, when the temperature is reduced through the Curie temperature. There may be an unstable state, so to speak, when the crystal structure changes suddenly from cubic to tetragonal and the crystat splits up into multi-domains, and the dielectric constant, for instance, may be raised because the domain boundaries are movable even in a weak field in such an unstable state, as Mason suggested in his paper. We cannot, however, discuss in more detail here, because further informations will be necessary about the nature of the behaviors of domains as studied by Little[18]).

§4. Summary and Acknowledgements

In this study, following results were obtained.

(1) In the prepolarized ceramic (in the tetragonal phase), the change of domain structures is, in the greater part, due to the 180°-reversals, and most of 90°-rotations of domains do not remain after the poling field is removed.

(2) The anisotropy in the prepolarized ceramic is within several per cent, and is mainly due to the piezoelectric interactions among the single crystals which constitute the ceramic. The piezoelectric interactions also make the dielectric and elastic constants unsymmetrical as functions of biasing field.

(3) The aging effects are also due to the piezoelectric interactions in some part, but other causes must be considered to explain the aging of the unpolarized ceramic.

In conclusion, the authors wish to express their hearty thanks to Mr. A. Takeda for helpful discussions and to Mr. K. Utino for the aid of the preparation of the specimens. Their thanks are also due Mr. T. Sakudo of the Electrotechnical Laboratory who showed them his unpublished data. This work was supported by the Scientific Research Expenditure of the Ministry of Education.

Notes added in proof: (1) The derivation of Eq. (5) is shown in detail in C. V. Stephenson's paper (J. Acoust. Soc. Amer. **28** (1956) 1192). (2) In the previous paper10), we calculated the elastic constants of the porous materials, and were not aware of J. K. MacKenzie's work (Proc. Phys. Soc. (London) **63B** (1950) 2). Our results are identical with his formulae, though the derivation and the expressions are different. For this carelessness, one of the authors (M. M.) is responsible.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 3, MARCH, 1957

Lattice Energies and Other Properties of Crystals of Alkaline Earth Chalcogenides*

By Maurice L. HUGGINS** and Yosio SAKAMOTO***

Research Laboratories, Eastman Kodak Co., Rochester, N.Y., U.S.A.

and

Department of Chemistry, Faculty of Science, Hirosima University

(Received October 23, 1956)

The lattice energies of the 20 binary compounds composed of Be^{++}, Mg^{++}, Ca^{++}, Sr^{++}, Ba^{++}, O^{--}, S^{--}, Se^{--} and Te^{--} have been computed by previously well-tested procedures. Because of lack of sufficiently reliable compressibility data, the computations have been made with two different assumptions regarding the magnitude of the constant a in the exponent of the repulsion energy term. These two assumptions yield lattice energies which differ, in most cases, by about 20 kcal.

In general, a single value of the "constant energy radius" suffices for each type of ion. For the beryllium compounds, however, it was necessary to use different radii for the Be^{++} ion for each compound. In MgTe also, a slightly different Mg^{++} radius from that deduced for the other magnesium compounds was required. These irregularities may be related to the fact that these crystals have "tetrahedral" structures, unlike the others, with significant but unknown amounts of covalent bonding.

The characteristic constants deduced should be useful in the theoretical treatment of many properties dependent on interactions between ions, both in these crystals and in other systems. For these crystals, the interionic distances, compressibilities and maximum infrared lattice-vibration frequencies have been computed.

By combining the computed lattice energies with thermochemical data, electron affinities (for the addition of *two* electrons to each of the electronegative atoms) have been computed and compared. Based on these results, the authors' best estimates, in kcal/mole, are as follows: O, -162 ± 15; S, -99 ± 15; Se, -117 ± 15; Te, -97 ± 20.

§ 1. Introduction

This paper reports the results of calculations of lattice energies and several related properties for the alkaline earth chalcogenides[1], i.e., the oxides, sulfides, selenides and tellurides of beryllium, magnesium, calcium, strontium and barium. These results are more extensive and presumably more accurate than those previously published for some of these substances by Mayer and Maltbie[2], de Boer and Verwey[3], van Arkel and de Boer[4], Fowler[5], Kapustinskiĭ and Yatsimirskiĭ[6] and others.

The theory underlying the calculations is that of Born and Mayer[7]. The general procedure followed that of Huggins and Mayer[8] and Huggins[9] for the alkali halogenides[1]. As an important step in the work, a set of "constant energy radii"[10], characteristic of the ions concerned, was calculated. Using these, lattice energies, equilibrium distances between the centers of closest ions, compressibilities, characteristic maximum infrared lattice-vibration frequencies, and electron affinities were computed.

It may be noted that Brauer[11], from a consideration of elastic constant and dielectric constant data for MgO, has concluded that in that crystal there are noncentrosymmetric, hence noncoulombic, forces of considerable magnitude, the coulombic forces being reduced to those corresponding to effective charges of ±1.83 electron charge units per ion. Since the significance of this is not clear and since the data needed for similar calculations for the other crystals with which we are concerned are lacking, the previous treatment, in which centrosymmetric forces were assumed, has been adopted in the present work.

§ 2. The Lattice Energy Equation

The lattice energy at 0°K was assumed to be given by the following equations:

$$E_{\mathrm{L}} = -10^{-10}\left(\frac{N_{\mathrm{Av}}}{J}\right)(\Phi+\Psi)\,, \qquad (1)^{7),9),12)}$$

$$\Phi = -\frac{4\alpha_{\mathrm{Mad}}e^2}{r_0} - \frac{C_{\mathrm{AB}}}{r_0{}^6} - \frac{D_{\mathrm{AB}}}{r_0{}^8} + bc_{+-}M\exp\left[a(r_{\mathrm{A}}+r_{\mathrm{B}}-r_0)\right] + \frac{bc_{--}M'}{2}\exp\left[a(2r_{\mathrm{B}}-k_2r_0)\right] + \frac{bc_{++}M'}{2}\exp\left[a(2r_{\mathrm{A}}-k_2r_0)\right]\,. \qquad (2)^{7),9)}$$

The symbols in these equations have the following significance:

E_{L} = lattice energy per mole, in kilocalories.
N_{Av} = Avogadro's number = 6.02283×10^{23}.
J = joule equivalent = 4.1840 abs. joule/cal. (defined).
Φ = average potential energy per "molecule", in ergs.
Ψ = zero-point energy per "molecule", in ergs. This is7) approximately equal to $9h\nu_{\max}/4$, where
h = Planck's constant = 6.6242×10^{-27} erg sec., and
$\nu_{\max}$ = maximum infrared frequency, for oscillation of the lattice of positive ions relative to the lattice of negative ions.
α_{Mad} = Madelung's constant, referred to r_0, for univalent ions. (The value given for the $B4$ type in Table I is for the ideal values of the axial ratio and atomic parameter, corresponding to close-packing of spheres. Use of the experimental axial ratios and parameters leads to results which are only slightly (0.0001 to 0.0005) larger.)
e = electron charge = 4.8024×10^{-10} e.s.u.
r_0 = equilibrium distance between closest ions. (r_0 chosen for the $B4$ type: r_0 (eff.) = $(9a^2c)^{1/3}/4$, where a and c are the lattice constants.)
C_{AB}, D_{AB} = van der Waals constants, calculated as described below.
$b = 10^{-12}$ erg.
M = number of closest unlike neighbor ions (Table I).
M' = number of closest like neighbor ions (Table I).
a = repulsion constant, equal to the reciprocal of Born and Mayer's7) ρ.
r_{A} = constant energy radius for a positive ion (Table III).
r_{B} = constant energy radius for a negative ion (Table III).
c_{+-}, c_{++} and c_{--} are factors to allow roughly for the dependence of the overlap repulsion energy between two ions on their charges and the numbers of electrons in their outermost shells. They are taken, respectively, as 1.75, 3.00 and 0.50 for the beryllium compounds and 1.00, 1.50 and 0·50 for the others. These values were obtained by substituting into an approximate equation given by Pauling13). They may be very inaccurate, especially for the beryllium compounds. Trial calculations showed, however, that, although the assumption of quite different values (even putting them all equal to unity) led to slightly different values of the constant energy radii, approximately the same interionic distances and lattice energies were obtained.
k_2 = ratio of the shortest distance between like neighbors to that between unlike neighbors (Table I).

Table I. Constants Pertaining to Structure Type.

Structure type	Compounds	α_{Mad}	M	M'	k_2	S_6'	S_6''	S_8'	S_8''	k_1
$B3$ ZnS(cubic)	BeS, BeSe, BeTe	1.6381	4	12	$2\sqrt{2}/\sqrt{3}$	4.354	0.762	4.104	0.253	3.079
$B4$ ZnO	BeO, MgTe	1.6413	4	12	$2\sqrt{2}/\sqrt{3}$	4.354	0.762	4.104	0.253	3.079
$B1$ NaCl	All others	1.7476	6	12	$\sqrt{2}$	6.5952	1.8067	6.146	0.800	2

§ 3. The Repulsion Constant "a"

Experimental compressibility data have been reported by Bridgman[14-17] for 11 of the substances dealt with; Durand[18] has published a value for MgO; and Parodi[19] has quoted, without reference, experimental values for CaO and BaO. It was hoped that these data could be used, as by Born and Mayer[7] for the alkali halogenides, to determine what value of the repulsion constant a to employ. However, the experimental values are quite inaccurate. Bridgman[16] writes: "The nine compounds of calcium, strontium and barium are probably the least satisfactory [of the substances measured]. The compressibility of the sulfides of these is probably too high because of the presence of a comparatively large amount of amorphous material, and the selenides and tellurides had a tendency to chemical instability." Moreover, the measurements were all made with powdered samples, except that in the case of MgO a single crystal was also studied. The experimental compressibility of the crystal powder was 67% larger than that for the single crystal. Because of this very large discrepancy, it seems unwise to trust any a values deduced from the experimental compressibilities.

The calculations reported here were made with two values of a: 3.00 and $2.50\times10^8\,\text{cm}^{-1}$. The differences between the two sets of results indicate the magnitude of the errors which would be produced by an incorrect choice of this constant. The first value is the same as that used by Huggins[9] for the alkali halogenides; the constant energy radii in the two series of compounds are therefore strictly comparable and should be applicable, for example, to crystals such as CaF_2, containing ions from both series. The second choice of a is close to that (2.55×10^8) deduced from Bridgman's[17] compressibility measurements on the MgO single crystal.

Since this paper was essentially completed, new compressibility measurements of the powdered oxides have been reported by Weir[20] The results are included in Table IV. With the aid of approximations which should not introduce much error, he has computed values of Born and Mayer's repulsion constant ρ for all but BeO. The reciprocals, a, are as follows: MgO, 2.4; CaO, 2.5; SrO, 3.0; BaO, 1.9 (in units of $10^8\,\text{cm}^{-1}$)*. The barium oxide data are of doubtful value since the specimen used was not very pure.

§ 4. Van der Waals Attraction Constants

The van der Waals attraction terms contribute relatively little to the lattice energies, but, in the calculation of other properties dealt with here, they are far from negligible. The constants C_{AB} and D_{AB} for the crystals are related[21] to the constants (c_{AA}, d_{AA}, etc.) for the interaction between pairs of ions by the equations

$$C_{AB}=S_6'c_{AB}+S_6''(c_{AA}+c_{BB})/2 \qquad (3)$$

and

$$D_{AB}=S_8'd_{AB}+S_8''(d_{AA}+d_{BB})/2\,. \qquad (4)$$

The magnitudes of the S constants for the $B1$ and $B3$ structures, as given by Mayer[21),22)], are listed in Table I. For the $B4$ structures, the same values as for $B3$ have been assumed. This should be a close approximation.

Theoretically[23),24)], for ions having the same effective number of polarizable electrons, the van der Waals c constants should be proportional to the 3/2 power of the polarizability and, hence, to the 3/2 power of the atomic or ionic refraction, R. For an isoelectronic sequence, such as O^{--}, F^-, Ne, Na^+, Mg^{++}, it seems reasonable to assume a rectilinear change of the ratio $c/R^{3/2}$. Thus, the constant c_{MgMg} has been computed from the relation

$$\frac{c_{MgMg}}{R_{Mg}^{3/2}}=\frac{3}{2}\frac{c_{NaNa}}{R_{Na}^{3/2}}-\frac{1}{2}\frac{c_{FF}(\text{in NaF})}{R_F^{3/2}(\text{in NaF})}\,, \qquad (5)$$

and likewise the constant c_{OO}, for the interaction between two oxide ions in MgO, has been computed from the relation

$$\frac{c_{OO}(\text{in MgO})}{R_O^{3/2}(\text{in MgO})}=\frac{3}{2}\frac{c_{FF}(\text{in NaF})}{R_F^{3/2}(\text{in NaF})}-\frac{1}{2}\frac{c_{NaNa}}{R_{Na}^{3/2}}\,. \qquad (6)$$

The values of c_{MM} and c_{XX}, for the alkali and halogenide ions, have been taken from Mayer[21]. The R_M and R_A values, for the alkali and alkaline earth ions, have been taken from Pauling[25]. Each is assumed to have the same magnitude in all crystals containing

[*] Our recalculated values, with $F_{T,P}$ (in Eq. 19) ±1, are 2.6; 2.4; 3.0; 1.9 (with $r_{Ba}=1.7_2$ A and $r_O=1.1_7$ A), resp.; and BeO, 3.4 (with $r_{Be}=0.34$ A and $r_O=1.41$ A) (The use of "3.4" leads to the electron affinity value of -245 units, which, however, is hardly probable).

the ion in question. The values of R_X and R_B have been obtained by subtracting the appropriate R_M and R_A from the R_{MX} and R_{AB} refractions published by Spangenberg[26] and Haase[27].

For the interaction between unlike ions, Kirkwood[28] has deduced the relationship

$$c_{AB}=K\alpha_A\alpha_B\Big/\left[\left(\frac{\alpha_A}{n_A}\right)^{1/2}+\left(\frac{\alpha_B}{n_B}\right)^{1/2}\right], \quad (7)$$

where α_A and α_B are the polarizabilities, n_A and n_B are the effective numbers of polarizable electrons in the two species, and K is a constant. From the relationship

$$\alpha_A \text{ or } \alpha_B=\frac{3R}{4\pi N_{Av}}, \quad (8)$$

one then obtains the equation

$$\frac{2}{c_{AB}}=\frac{R_A}{R_Bc_{AA}}+\frac{R_B}{R_Ac_{BB}}\,. \quad (9)$$

From equations for the c and d constants given by Mayer[21], with Eq. (8), the following relations are readily derived:

$$d_{AA}=\frac{8\pi N_{Av}}{n_Ae^2}\cdot\frac{c_{AA}^2}{R_A}, \quad (10)$$

$$d_{BB}=\frac{8\pi N_{Av}}{n_Be^2}\cdot\frac{c_{BB}^2}{R_B}, \quad (11)$$

$$d_{AB}=\frac{4\pi N_{Av}}{e^2}\left(\frac{c_{AA}}{n_AR_A}+\frac{c_{BB}}{n_BR_B}\right)c_{AB}\,. \quad (12)$$

Although there are 8 electrons in the outermost shell of each of the ions, except Be^{++}, with which we are concerned, Mayer[21] has computed 3.2 as the *effective* number for chloride ion in NaCl and KCl, and 4.0 for iodide ion in KI. Herzfeld and Wolf[29] have computed 4.6 for argon and 5.6 for xenon. In the present work, a value of 5.5 has been taken for all the ions. Then

$$d_{AA}=0.1\ \times10^{44}c_{AA}^2/R_A\,, \quad (13)$$

$$d_{BB}=0.1\ \times10^{44}c_{BB}^2/R_B\,, \quad (14)$$

$$d_{AB}=0.05\times10^{44}\left(\frac{c_{AA}}{R_A}+\frac{c_{BB}}{R_B}\right)c_{AB}\,. \quad (15)$$

The isoelectronic sequence procedure, described above, is inapplicable to the beryllium compounds. For these, c_{BeBe}, c_{BeB}, d_{BeBe} and d_{BeB} were taken as zero, and c_{OO}, d_{OO}, c_{SS}, d_{SS}, etc. were estimated by extrapolation from the values of these constants in the series BaO, SrO, CaO, MgO, etc.

The C_{AB} and D_{AB} values, computed with the aid of the relationships just given, are listed in Table II.

Table II. Van der Waals Constants, Expansion Coefficients, and Zero-point and Thermal Energy Factors.

§ 5. Interionic Distances and Constant Energy Radii

For each of the two assumed values of a, sets of values of r_A and r_B were computed by successive approximations from the experimental r_0 values and the equation

$$a[r_0-(r_A+r_B)]=-\ln\frac{\tau}{r_0}+\ln(bc_{+-}Ma)+\ln\{1+S\exp[(1-k_2)ar_0]\}\,, \tag{16}$$

with

$$\tau=\frac{4\alpha_{\rm Mad}e^2}{r_0}+\frac{6C_{\rm AB}}{r_0^6}+\frac{8D_{\rm AB}}{r_0^8}-3T\theta k_1\frac{\alpha}{\beta}r_0^3 \tag{17}$$

and

$$S=\frac{k_2M'}{2Mc_{+-}}\{c_{--}\exp[a(r_B-r_A)]+c_{++}\exp[a(r_A-r_B)]\}\,. \tag{18}$$

These equations are like those previously used for the alkali halogenides[8], except for the introduction of the factor θ in the relatively small last term of Eq. (17). This factor, designated as $(1+c-f)\upsilon$ by Sakamoto (Ref. 12, Eq. 22), results from a more precise theoretical analysis of the variations of the zero-point energy (Ψ) and the thermal energy with temperature[37),38)]. Estimated values are given in Table II.

This table also lists the values used for the expansion coefficient, $\alpha=(\partial V/\partial T)_P/V$, entering into the last term of Eq. (17). Except for the cases for which references are given, these are estimated values.

For the compressibility, $\beta=-(\partial V/\partial P)_T/V$, estimates, based in part on the experimental values listed in Table IV, were used until the final approximation, when the computed values were employed. T was taken as 298°K. The constant k_1, defined as $V/N_{\rm Av}r_0^3$, has the values given in Table I.

The r_A and r_B values obtained are collected in Table III.

These radii and Eqs. (16), (17) and (18) were then used to compute the calculated interionic distances given in Table IV. These are seen to be in substantial agreement with the best experimental values. It should be noted that this agreement is but little affected by uniformly increasing (or decreasing) all the positive ion radii by a few hundredths of an ångström unit, and simultaneously decreasing (or increasing) the negative ion radii by the same amount and making a few minor adjustments.

It was impossible to obtain good agreement for the beryllium compounds with a constant value of $r_{\rm Be}$. This may be attributed to various causes. It may result primarily from the (probably incorrect) assumption that the same value of the repulsion constant a is applicable to all the compounds. The neglect of covalent bond contributions in these "tetrahedral" crystals may also be important. Incorrectness of the Pauling c_{+-}, c_{++} and c_{--} factors may cause some error, and inaccuracies in other approximations may contribute.

Table III. Constant Energy Radii.

A or B	r_A or r_B in 10^{-8} cm $a=2.5$ $\times 10^8\,{\rm cm}^{-1}$	$a=3.0$ $\times 10^8\,{\rm cm}^{-1}$
Be^{++} in BeO	0.75	0.52
BeS	0.66	0.44
BeSe	0.64	0.42
BeTe	0.62	0.40
Mg^{++} in MgO	1.10	0.93
MgS	1.10	0.93
MgSe	1.10	0.93
MgTe	1.15	0.97
Ca^{++}	1.31	1.17
Sr^{++}	1.44	1.31
Ba^{++}	1.58	1.46
O^{--}	1.27	1.35
S^{--}	1.62	1.69
Se^{--}	1.71	1.78
Te^{--}	1.86	1.93

In the case of MgTe also, the calculated and experimental values of r_0 differ considerably (by 0.04 to 0.05 A), if $r_{\rm Mg}$ is taken to be the same as in the other magnesium compounds.

Pending better knowledge of the true magnitudes of a in these crystals and of the other factors just mentioned, a has been assumed to be the same for the beryllium compounds and MgTe as for the others, and values of $r_{\rm Be}$ and $r_{\rm Mg}$ have been computed which lead to agreement between the experimental and calculated interionic distances. These have been used in the calculation of the lattice energies and other properties.

Constant energy radii are given in Table III to two decimal places only. Although

slightly better agreement between calculated and experimental r_0 values could be obtained by using some radii to three decimal places, this was considered to be without significance. The probable error of many of the experimental values is not much less than 0.01 A.

§6. Compressibilities and Lattice Frequencies

By using the constant energy radii of Table III and the calculated interionic distances of Table IV, compressibilities have been computed by means of the equation[7],[9]

$$\beta=\frac{9k_1 r_0^3 F_{T,P}}{r_0^2\left(\frac{\mathrm{d}^2\Phi}{\mathrm{d}r_0^2}\right)}, \tag{19}$$

where $F_{T,P}$ is a complex function involving α, β, the variation of β with temperature and pressure, and the heat capacity. As for the alkali halogenides, $F_{T,P}$ has been taken as unity. In further justification, its value for MgO, for which the requisite experimental data are available, was computed to be 1.0_2 using the equation given by Huggins[9], or 1.01 ± 0.04 using the refinements introduced by Sakamoto (Ref. 12, Eq. 23).

The compressibilities calculated for MgO (especially that obtained with the smaller value of a) are in good agreement with the experimental single-crystal data. There is also good agreement with the new experimental data of Weir for the oxides, except in the case of BeO, for which our calculated values were expected to be too large, because its $F_{T,P}$ might be smaller than unity like LiF's (0.85) or covalency contributions were ignored and the magnitude of a might have been underestimated for the tetrahedral crystals, and in the case of BaO, for which his result is of dubious accuracy, because the material used was not of high purity. As was to be expected, the computed compressibilities are somewhat smaller than the other experimental values obtained from crystal powders.

The calculated compressibilities agree reasonably well with those deduced quantum-mechanically for six compounds by Brück[48] and for two compounds by Ždanow, *et al.*[47] There is rough agreement also with the results of calculations by Fowler[5], using methods similar to those used here, but less refined.

Characteristic maximum lattice frequencies for the $B1$ (sodium chloride) type crystals were computed from the relationship[9]

$$\nu_{\max}=\left\{\frac{ba^2\left(1-\dfrac{2}{ar_0}\right)\exp\left[a(r_A+r_B-r_0)\right]-\dfrac{30c_{AB}}{r_0^8}-\dfrac{56d_{AB}}{r_0^{10}}}{2\pi^2\mu}\right\}^{1/2}, \qquad (20)$$

where

$$\mu=\frac{M_AM_B}{N_{Av}(M_A+M_B)} \qquad (21)$$

and M_A and M_B are the atomic weights of A and B.

Very few experimental values have been published for the lattice frequencies for these crystals, and they are rather contradictory. Those which appear to be most reliable are listed in Table IV.

The calculated values of β and $\nu_{\max}$ in this table, are for room temperature. Estimates have been made for the change of $\nu_{\max}$ on cooling to 0°K, by using the derivative of Eq. (20) with respect to temperature. This change is negligible, in comparison with other errors.

§ 7. Lattice Energies

Lattice energies at 0°K have been calculated, using Eqs. (1) and (2). Ψ was computed from the characteristic frequencies of Table IV, Col. 13. These were estimated from the directly measured values (Col. 12), specific

heat data, and the trends shown by the data for the alkali halogenides[9] and by the calculated frequencies (Cols. 10 and 11). Correction was made for the difference between r_0 at room temperature and at the absolute zero, by means of an equation given by Sakamoto (Ref. 12, Eq. 54). See Table IV, Col. 5. This correction makes no difference larger than 3 kcal in any of the computed energy contributions (Cols. 2–6 of Table V), nor larger than 0.3 kcal in their sum (Cols. 7 and 8).

Table V shows the negatives of the computed contributions of the different kinds of energy to the total lattice energy, together with the algebraic sum of these contributions. For comparison, the best of the previously published values are included. There is general agreement, but, in view of the more precise treatment of various pertinent factors, the present results are believed to be more reliable than the earlier ones.

The molal lattice energies computed on the basis of $a = 3.0 \times 10^8\,\mathrm{cm}^{-1}$, like the corresponding repulsion energies, are generally about 20 kcal higher than those computed using the smaller *a*. The probable error of the average of these calculated lattice energies can reasonably be assumed to be of about half this magnitude, except for the "tetrahedral" crystals. Covalent bond energy contributions in the latter may be far from negligible[50]. The neglect here of such contributions may thus result in considerable error.

§ 8. Electron Affinities

The heat content increments for the reaction

$$AB_{cr} \longrightarrow A_{gas}^{++} + B_{gas} + 2e_{gas}^{-} \qquad (22)$$

at 298°K and 1 atmosphere have been computed (Table VI, Col. 2). The heats of formation of AB_{cr} used for this, except for CaS, are those considered best by Kubaschewski and Evans[52]. In most instances, they are based directly on experimental measurements and are identical with, or very close to, the values adopted by Rossini, *et al.*[53], of the U. S. National Bureau of Standards. For MgSe, CaTe, SrTe and BaTe, however, the

* Assumed.

heats of formation given are merely estimates, based on assumptions regarding series regularities. In the case of CaS, the experimental value has been used here, in preference to Kubaschewski and Evans's estimate, which is 5.3 kcal lower. The probable errors of the heats of formation, estimated by these authors, are given in Col. 3. For the heats of formation of A_{gas}^{++} and B_{gas}, on the other hand, the values selected by Rossini, *et al.* have been used exclusively. The probable errors of these values are a few kilocalories.

From the figures in Col. 2, by subtraction of 10 RT and addition of the heat capacity integral, $\int_0^{298} C_P \mathrm{d}T$, for the crystal, one obtains (Col. 5) the corresponding heat change at 0°K. Experimental data are available for the evaluation of the heat capacity integral for six of the compounds. For the others, estimates have been made, with the aid of the (estimated) $\nu_{\max}$ values and an equation given by Sakamoto (Ref. 12, Eq. 57).

The lattice energy is the increase in heat content for the reaction

$$AB_{cr} \longrightarrow A_{gas}^{++} + B_{gas}^{--} . \qquad (23)$$

The electron affinity (for the addition of *two* electrons to the B atom) is the decrease in heat content for the reaction

$$B_{gas} + 2e_{gas}^{-} \longrightarrow B_{gas}^{--} . \qquad (24)$$

It is thus the difference between the ΔH values for reactions (22) and (23).

The electron affinities so calculated for the chalcogens are all negative. For each of the two assumed values of a, they are reasonably consistent, at least for the $B1$ type compounds, but show definite trends. The two sets of electron affinities, like the two sets of lattice energies and the two sets of repulsion energies, differ by about 20 kcal, in most cases.

To estimate the most probable true values of the electron affinities, several factors must be considered. In the first place, the probable errors of the heat of formation data, on which they depend directly, are, in most instances, rather large, as mentioned above.

A second factor is the neglect of overlap repulsion energies between like ions, other than those which are closest together. This factor might be appreciable for crystals containing small ions.

A third factor is the error introduced by assuming the constant a to have the same value for all the compounds.

In the fourth place, the lattice energies computed for the tetrahedral compounds are doubtless too low, by unknown amounts, because of the neglect of covalent bond contributions. This neglect tends to make the values of the electron affinity, calculated from BeO, BeS and MgTe too negative.

Finally, there may be errors due to polarization (departure from spherical shape) of the larger, more deformable ions, when combined with much smaller ions of the other kind. (This is the "primary polarization", previously discussed by Sakamoto (Ref. 12, Note 13)). From this consideration, the lattice energies and electron affinities computed for compounds (MgO, CaO, SrO, BaO, SrS, BaS, SrSe, BaSe and BaTe), composed of ions having radii which do not differ much, would be expected to be somewhat more reliable, other things being equal, than those computed for compounds of ions with very different radii.

On the basis of these ideas and the computed electron affinities in Table VI, the authors propose the following, as their best estimates of the true electron affinities:

O: -162 ± 15 S: -99 ± 15
Se: -117 ± 15 Te: -97 ± 20 .

The differences between the electron affinities are believed to be somewhat more precisely known than the individual values, since the differences do not change much with a change in the assumed value of a, nor with mutually consistent changes in the assumed values of the constant energy radii.

The irregularity in the series is thus believed to be real. It was also shown by the earlier calculations[5),6),58)].

In the final column of Table VI are the differences between the calculated electron affinities (Col. 8) for the individual compounds and the authors' best estimates, just given. The large values of this difference for BeO, BeS and MgTe can probably be attributed to neglect of the covalent bond energy. It seems unlikely, however, that this is of importance in MgSe, which has the NaCl type structure, with coordination number 6. The large value of the "supplementary lattice energy" for this compound and the fact that the trend in the series MgO⟶BaO is opposite to that in the other series (MgS⟶BaS, MgSe⟶BaSe, MgTe⟶BaTe) suggest that these differences are due largely to the energy of polarization deformation of the larger ions by the smaller ones (primary polarization energy).

There seem to be no experimental data with which the calculated electron affinities can be directly compared[59].

The *first* electron affinities of oxygen and sulfur (for addition of *one* electron) have been studied by many experimental and theoretical methods, but different investigators still do not agree, even approximately[59-63]. Further discussion and comparison with the present results do not seem profitable at this time.

§ 9. Acknowledgments

The senior author (M.L.H.) wishes to express his appreciation to Osaka and Kyoto Universities for inviting him to join their faculties and to his Japanese colleagues for their warm hospitality. The financial aid of a Fulbright grant is also gratefully acknowledged.

Note added Feb. 7, 1957

In the foregoing calculations, as in former calculations[2,3,7-9] of this sort, noncoulombic repulsion energies between pairs of ions other than those closest together (unlike ions) and those which are next closest (like ions) were neglected. To determine whether this is justifiable, we have computed the effect of including terms for repulsions between third nearest neighbors—for the $B1$ type, for example, those between unlike ions which are at diagonally opposite corners of each eighth-unit cube.

Better agreement with the experimental interionic distances is now obtained, if the following new constant energy radii are used (r in 10^{-8} cm; a in 10^{8} cm^{-1}):

For $a=2.5$:

$r_{\rm Be}=0.72$, 0.64, 0.63 and 0.61, in BeO, BeS, BeSe and BeTe, resp.

$r_{\rm O}=1.26$ (Note the new r_0 (calcd., BaO): 2.781.)

For $a=3.0$:

$r_{\rm Be}=0.50$, 0.43 and 0.41, in BeO, BeS and BeSe, resp.

N.B. $r_0(\text{new})-r_0(\text{old})=9$ to -5×10^{-11} cm.

The only new values of compressibility, β, overlap repulsion energy, ORE, total lattice energy, TLE, electron affinity, EA, and supplementary lattice energy, SLE, which differ from those previously listed (in Tables IV–VI) by more than one unit in the last place, are those given below *in italics* (in the same units as before).

	β		ORE		TLE		$-$EA			SLE
a:	2.5	3.0	2.5	3.0	2.5	3.0	2.5	3.0	Av.	Av.
BeO	*0.47*	*0.35*	*286*	*237*	*1038*	*1088*	*127*	*176*	*152*	*10*
BeS	*0.90*	0.65	*181*	*144*	*858*	*895*	*39*	*76*	*58*	*41*
BeSe	*1.05*	0.74	*165*	*128*		*857*				
BeTe	*1.32*		*136*		*765*					
MgO	0.60	0.47		*172*		*936*		*176*		
MgS			*137*	112	*762*		69		81	18
CaO	*0.84*	0.68	158	135	*818*	840	147	170		3
SrO	1.02	0.83	*142*		*771*		*147*		157	*4*
BaO	*1.22*		*127*	108	*726*		*142*		152	*10*

The changes from the previous results are thus very minor ones. They are certainly negligible, relative to other inaccuracies, except possibly for the case of BeO. Our best estimates of the (two-electron) electron affinities remain as before, except that for Se we now prefer the value: -116 ± 15 kcal/mole.

The values in the footnote in § 3 now become, resp.: 2.5, 2.3,···1.15,···0.32, 1.40,··· and -251.

On Electrical Resistivity and Hall Coefficient of PbTe Crystals

By Kisaburo SHOGENJI and Susumu UCHIYAMA

Department of Electrical Engineering, Faculty of Engineering, Nagoya University, Nagoya

(Received November 19, 1956)

The electrical resistivity and Hall coefficient of p-type synthetic PbTe crystals and those after heat treatment in the air were measured at various temperatures down to liquid air temperature. By heat treatment at moderate temperature in the air the resistivity and Hall coefficient of the crystals increased. An analysis of the data on Hall coefficient shows that the intrinsic energy gap is about 0.3 ev. and the mobility ratio $b=\mu_e/\mu_n$ is about 2.5 at 300°～400°K. The activation energy of the acceptor levels is very small. The mobility of the hole is approximately proportional to $T^{-5/2}$. Discussions concerning this question are presented.

§ 1. Introduction

PbTe crystal is similar to PbS and PbSe cristals. This group of semiconductors has been investigated recently by many authors1)-9). These materials are known to have the following properties. They become n-type or p-type according not only to the condition during preparation but also to the heat treatments. This change in type depends upon what atmosphere arrounds the crystal during the heat treatment. Even if the heat treatment does not change the type of conduction it is often the case that it changes the numbers of denors and/or acceptors. Accordingly it has happened frequently that the crystal undergoes an irreversible change during the measurements at higher temperatures, and the results obtained have some uncertainties. The discrepancy between the intrinsic energy gap reported earlier8) and that reported later1)2)6) is considered to be attributed to this phenomenon9).

The resistivity and Hall coefficient of p-type PbTe crystals and their changes introduced by heat treatments are reported in this paper. The measurements were made in the temperature range from 450°K to liquid air temperature. An anomalous reversal of the sign of Hall coefficient, which was reported by Putley1) to have taken place in the extrinsic temperature range, was carefully looked for during the heat treatments, but we could not observe it. The matter relating to the sign reversal will be described in a separate paper. By heat treatment in air at about 400°K, the resistivity and the Hall coefficient increased. The experimental results are analyzed and some characteristic values are obtained.

§ 2. Experimental Procedures

Preparation of Crystals. The crystals used were synthetic single crystals. The method of preparation is similar to that of Lawson10). The lead was zone-refined in vacuum several times and the tellurium was distilled in vaccum. The resultant materials were mixed in the proportion of atomic equivalents. They were put into a fused silica tube crucible, which had a conical bottom in order that the crystal began to solidify at the bottom. Then the crucible was evacuated and sealed off. After being heated at about 1000°C for 8 hours in a furnace, the crucible was lowered slowly through the region of high temperature gradient in the furnace, the speed of lowering being about 1 mm/3 min.

Measurements. The crystal obtained by the above procedure was shaped to a rectangular parallele piped of 10× 4 × 1 mm³ in size. Platinum wires of 0.3 mm in diameter were attached to the both ends of the specimen as the current leads. The platinum wire was bent to form a sharp edge and heated by passing a current through it, then the edge was pressed to the end of the specimen to be welded. The ends of the specimen to be welded were covered by paraffin wax before welding11). The potential probes were platinum wires of 0.1 mm in diameter whose tips were sharpened. They were attached to the specimen by condenser discharge through their contacts[12]. The specimen was held in a cage by the current leads and potential probes as shown in Fig. 1. The diameter of the cage was 15 mm.

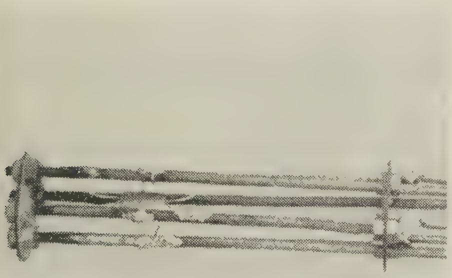

Fig. 1. Photograph of specimen and cage for measurement.

The measurements were made by usual *d. c.* method. In determining the Hall coefficient sets of four measurements were made in order to avoid associated electromotive forces such as due to IR drop and thermoelectromotive force: the four measurements were done by reversing the directions of both *d. c.* currents flowing the specimen and the coil of the magnet separately. In measuring the resistivity the average values for both directions of the current were used, although the values obtained in the two directions were practically the same.

The specimen was placed in a furnace which had non-ferromagnetic wire as a heater, when the measurements at higher temperatures were made. In measuring at low temperatures a Dewar vessel and a furnace within it were used and liquid air was used for lowering the temperature. The temperature was measured by copper-constantan thermocouple put closely to the specimen.

§ 3. Experimental Results

The resistivity ρ and the Hall coefficient R measured are shown as a function of temperature in Figs. 2∼5. Figs. 2 and 3 show the curves for various specimens. The curves labelled *Cu* are for the specimens cut from the same ingot which was doped with 0.01% copper. The curves *Cu*-132 and *Cu*-133 are those for the specimen *Cu*-131 after being heat treated in air at about 440°K for 5 hours and 10 hours respectively. Figs. 4 and 5 are for a series of measurements carried out on a specimen, and show the change of the electrical properties of the specimen produced by heat treatment in air at 400°K. Table I indicates the total time duration of heat treatment, which the specimen was subjected to before each measurement.

Table I.

Curve	P11	P12	P13	P14	P15
Time duration of heat treatment		0.5 days	3.5 days	9.5 days	24.5 days
N_A-N_D calculated from R_{exh}	2.5×10^{18}	1.2×10^{18}	7.8×10^{17}	5.9×10^{17}	4.8×10^{17}

The Hall coefficient in the extrinsic temperature range is almost constant as shown in Figs. 3 and 5. For impure specimens the Hall coefficient increases slightly at temperatures a little below the transition temperature to the intrinsic range. For copper-doped specimens with higher Hall coefficient which are considered to have so-called compensated impurities, the Hall coefficient begins to decrease at a lower temperature and continues to decrease, without kink (*Knick*), to the intrinsic values with increasing temperature. These figures show that the activation energy of acceptor levels is very small. The transition temperature to the intrinsic range is about 500°K. As the temperature rises the Hall coefficient inverts its sign before the temperature reaches the intrinsic range, though Figs. 3 and 5 do not show the whole of their behaviours. This indicates that the mobility of electron is larger than that of hole, at least in this temperature range. As the heat treatment proceeds, the extrinsic Hall coefficient becomes gradually larger.

The temperature coefficient of the resistivity at the extrinsic range is positive, as expected from the constant Hall coefficient independent of temperature in this range. The variation of the resistivity with temperature is pretty large, especially at higher temperatures. The mobility μ_h of the hole calculated from R/ρ is plotted as a function of the temperature in Figs. 6 and 7. From these figures it is seen that the relation $\mu_h \propto T^{-5/2}$ holds almost for the whole temperature range of our experiments. As easily seen, this strong temperature dependence corresponds to the fact that the temperature dependence of the resistivity is large as shown in Figs. 2 and 4.

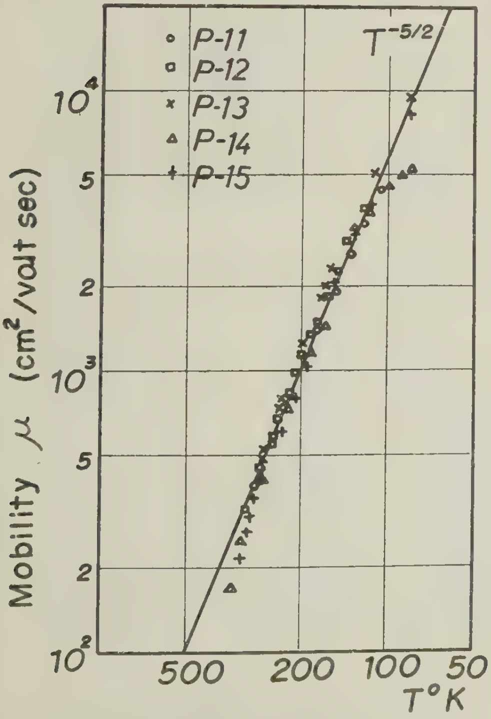

Fig. 7. Mobility (II), corresponding to Figs. 4 and 5.

temperature range could not be obtained, because in the measurements at higher temperatures there was a fear that the properties of the specimen might change irreversibly and consequently the measurements of the change of the properties introduced by heat treatments would be disturbed. The intrinsic energy gap, therefore, cannot be obtained from the slope of the intrinsic curves. The resistivity curves are especially steep at the temperatures slightly below the intrinsic range, and it should be noticed that the resistivity becomes larger at these temperatures than those expected from the Hall coefficient and the temperature dependence of the mobility. This is, perhaps, due to the fact that the mobility becomes abnormally small. Therefore we shall content ourselves, in this section, only with analyzing the data of Hall coefficient putting aside those of resistivity.

We assume that acceptor levels, whose number is N_A per unit volume, exist within the forbidden band. The activation energy of the levels is very small, as is deduced from the variation of Hall coefficient with temperature. It is assumed that the number p of the holes in the full band and the number n of the electrons in the conduction band are related by the equation

$$p=n+N_A\,. \tag{1}$$

The mobility ratio $b=\mu_e/\mu_h$ is assumed to be constant in our temperature range, where μ_e and μ_h are the mobilities of the electron and the hole respectively. The Hall coefficient is generally expressed by

$$R=\frac{r}{e}\frac{p-nb^2}{(p+nb)^2}\,. \tag{2}$$

Here r is assumed to be 1 for the sake of simplicity. From the above two equations, we obtain

$$\frac{n}{N_A}=\frac{1}{2(b+1)}\left\{2+c(b-1)\sqrt{1+\frac{4(c-1)}{2+c(b-1)}}-1\right\}, \tag{3}$$

where

$$c=R_{exh}/R,\quad R_{exh}=1/eN_A\,.$$

Denoting the term on the right hand side of Eq. (3) by $f(c, b)$, we can write

$$n=fN_A\,. \tag{4}$$

On the other hand

$$pn=CC'T^3\exp\left(-E_G/kT\right),$$

$$C=2(2\pi m_e kT/h^2)^{3/2}, \quad C'=2(2\pi m_h kT/h^2)^{3/2}\,, \tag{5}$$

where E_G is the width of the forbidden band, m_e and m_h are effective masses of the electron and the hole. Then from Eqs. (1), (4) and (5)

$$f(f+1)N_A{}^2=CC'T^3\exp(-E_G/kT) \tag{6}$$

and

$$\ln(N_A{}^2/T_c{}^3)=\ln CC'-\ln f(f+1)-E_G/kT_c\,. \tag{7}$$

We denote a temperature by T_c, at which the ratio of the value of a Hall coefficient curve to its exhaustion value becomes $1/c$, *i.e.* $R_{exh}/R=c$. For given c and given R_{exh} or N_A, T_c is obtained from the curves of Fig. 8. When curves of $\ln(N_A/T^{3/2})$ *vs.* $1/T$ are plotted for various values of c as a parameter, they must be a group of straight lines whose slopes are to give a value of E_G. They are shown in Fig. 9. The linearity of the curves is fairly good, and the value of E_G is determined as 0.34 ev.

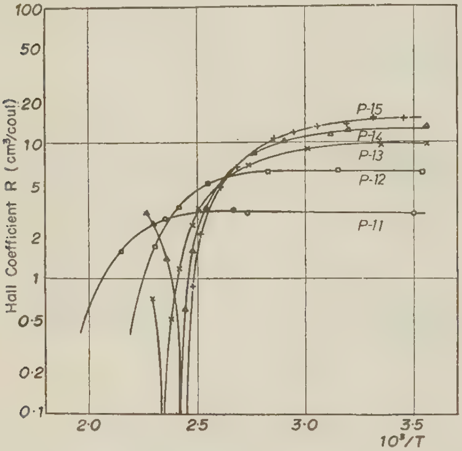

Fig. 8. Hall coefficient near the intrinsic reversal temperature.

The values of $CC'/f(f+1)$ for various values of c can be obtained from the intersections of the lines and the ordinate axis in Fig. 9, thus we can get $\ln CC'/f(f+1)$ *vs.* c relation from the experimental data. This relation is to be compared with the curves calculated from Eq. (3) for various values of b as a parameter. If, among the above theoretical curves, we find the curve which represents the experimental points well, the value of b corresponding to the curve must be one looked for as the mobility ratio. The theoretical curves and the experimental points are shown in Fig. 10. From this procedure b is estimated to be about 2.5, though this can give merely approximate value. The value of m_em_h/m^2 can be determined from the intersection of the curve and the ordinate axis in Fig. 9 after the value of b is determined. It is estimated to be 0.67.

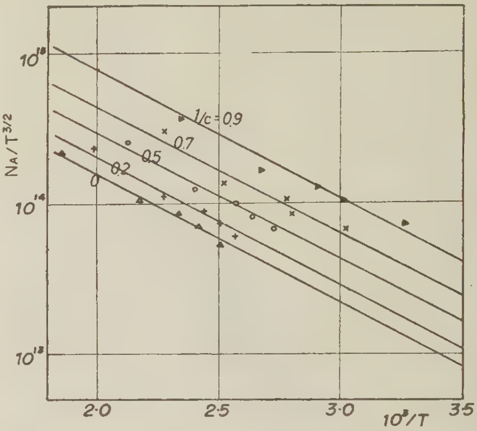

Fig. 9. Curves for determining the volue of E_G.

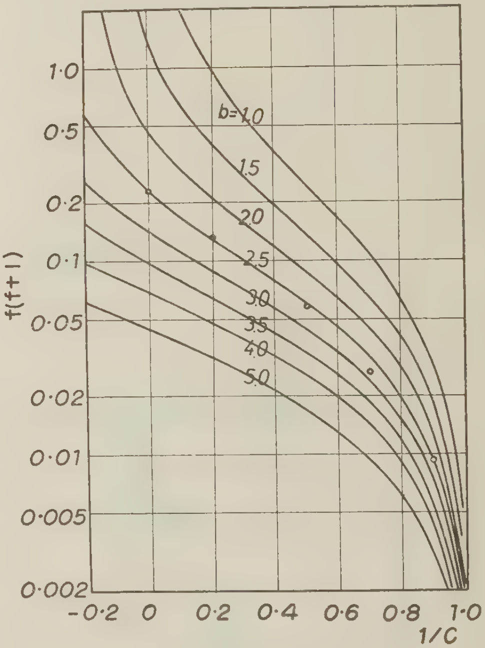

Fig. 10. Graph for determining the value of b, comparison between the theoretical curves and experimental points.

§ 5. Mobility

As is well known, this group of semiconductors has mobility proportional to $T^{-5/2}$. Petritz and Scanlon[6)] attempted to explain the mobility of PbS from the standpoint that it was affected principally by the optical mode of lattice vibration. However their attempt were not successful for higher temperatures. Difficulty of their interpretation at higher temperatures, they thought, was due to an inadequate expression of scattering cross section for electron whose energy was greater than $k\Theta$, Θ being the characteristic temperature.

Formerly they[13)] analyzed the mobility of PbS using the equation

$$\frac{1}{\mu}=\frac{1}{A\exp(\Theta/T)-1}+\frac{T^{3/2}}{B}, \qquad (8)$$

where the first term is related to the optical mode of lattice vibration and the second the acoustical mode. They found that Θ was about 1100°K and the effective mass was 0.17 m. On the other hand Hirahara and Murakami[4)] analyzed their mobility data of PbSe crystal by the equation

$$1/\mu=aT^{-3/2}+bT^{3/2}+c\{\exp(\Theta/T)-1\}^{-1}, \qquad (9)$$

where the first term represents the reciprocal of the mobility when scattering of ionized impurity centres only disturbs the motion of the carriers, the second concerns the acoustical mode of lattice vibration and the third the optical mode. They found that for characteristic temperature lower than 800°K Eq. (9) cannot represent the experimental data well.

An attempt to make Eq. (9) fit to our experimental data is made, and leads to the results that the characteristic temperature must be of the order of 1100°K in order to fit in the whole temperature range. This result is similar to the case of PbS[13)]. The characteristic temperature obtained is higher than the expected one. It was reported to be 194°K for PbS. As to PbTe approximately 150°K was given as the Debye temperature, which was deduced from specific heat measurement[14)]. In the above procedures the simple model of energy band structure is assumed tacitly. A consideration based on complicated band structure should be made in connexion to this point.

If the motion of the hole is affected mainly by the optical mode of lattice vibration and the value of $m_e m_h/m^2$ obtained in last section is assumed, the effective mass m_e of the electron in the conduction band is 0.51 m and m_h of the hole in the full band 0.94 m. Then the mean free path of the hole is estimated as shown in Fig. 11.

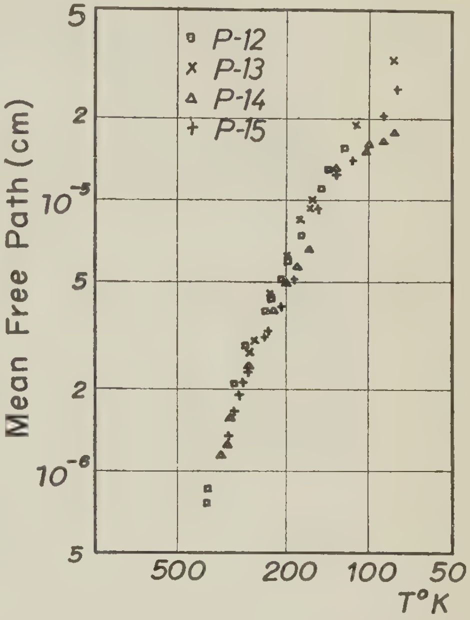

Fig. 11. Mean free path, corresponding to Figs. 4, 5 and 7.

§ 6. Discussion

It has been reported by many authors that this group of semiconductors undergoes an irreversible change of the electrical properties when it is heated above a certain temperature. This change depends upon the atmosphere in which the crystal is disposed during heat treatment. For instance, PbS changes to p-type in the sulphur vapour and n-type in vacuum. Our experiments showed that a crystal melted in the hydrogen atmosphere was of n-type and that heating of a p-type crystal to higher temperature in air causes the decrease of its Hall coefficient. These facts indicate that acceptors are principally due to excess tellurium or oxygen atoms or deficient lead atoms and that denors are due to excess lead or hydrogen atoms, though their precise situations in crystal structure cannot be known.

Heat treatment at moderate temperature, *e.g.* 400°K, even in air makes the Hall coefficient of a p-type crystal higher. And this effect is reported by Putley[1)] to be independent of the atmosphere. This may be due to reduction of some crystal imperfections such as defects or irregularities, hence a part of denors or acceptors may be due to the crystal imperfections in many crystals.

The activation energy of the acceptor levels is very small. This is thought to be connected with the high dielectric constant of this material. The refractive index, which is to be the square root of high frequency dielectric constant, is given to be $5^{15)}$. The energy gap of the forbidden band was not determined from the data in the intrinsic range, but it was estimated from other results of this experiment to be 0.34 ev., which proved to agree with those obtained from optical data$^{16)}$ and the recent data of intrinsic experiments$^{1)5)}$, while its variation with temperature was left untouched in this paper. The mobility ratio was determined in this paper. Smith$^{2)}$ stated that the mobility ratio was not constant but increased by fairly large amount with temperature. The value of the ratio calculated in this paper was obtained by using the data above 300°K.

The strong dependence of the mobility upon temperature has been already reported by many authors and is also verified in this paper. An explanation based on a conception that the mobility is affected by both acoustical and optical mode of lattice vibration gives good agreement between experimental and theoretical values, but it leads to a difficulty that the characteristic temperature must be assumed as high as 1100°K, as in the case of PbS. Difficulty might be removed if we introduce a consideration that the complexity of the band structure has some contribution to the temperature dependence of the mobility.

In conclusion, the writers wish to express their sincere acknowledgements to Professor Y. Sakaki and Professor K. Ariyama for their kind guidances and encouragements throughout the course of the work.

On the Superstructure of the Ordered Alloy Cu_3Pd*
II. X-ray Diffraction Study

By Makoto HIRABAYASHI and Shiro OGAWA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received September 25, 1956)

The structures of the ordered copper-palladium alloys in the composition range from 15.5 to 28.5 atomic per cent Pd were investigated by X-ray diffraction, using both single crystals and power specimens. The alloys with the composition of 20.8 to 25.8 atomic per cent Pd have an anti-phase domain structure in a fully ordered state cooled slowly from 450°C to room temperature in four months. This structure is formed from the elementary face-centered tetragonal lattice, in which the atoms arrange themselves as in the ordered alloy Cu_3Au but step-shifts occur at a definite period along the tetragonal axis. On the other hand, the alloys of 27.3 and 28.5 atomic per cent Pd were confirmed to possess a more complicated anti-phase domain structure characterized by the two kinds of out-of-step, which was already elucidated by the electron diffraction study in Part I. Variation of both the lattice parameters and the periods of anti-phase domain with composition were also studied.

§ 1. Introduction

The copper-palladium alloys in the vicinity of the composition Cu_3Pd have a disordered face-centered cubic lattice at temperatures above about 470°C. Below this temperature, according to Jones and Sykes[1], the ordered phase is in equilibrium and is subdivided into α' and α'' phases. According to them, the structure of α' phase, which exists in the composition range from about 8 to 18 %* Pd, is the face-centred cubic lattice with the atomic arrangement of the Cu_3Au type, while α'' phase, existing in the composition range from about 18 to 28 % Pd, is built up from the face-centered tetragonal cells in terms of the original disordered face-centered cubic cells. But the arrangement of atoms in this superlattice could not definitely be determined by them. In Part I[2], Watanabe and one of the present authors (S.O.) studied the superstructure of this alloy by electron diffraction, and elucidated a complicated anti-phase domain structure present stably in α'' phase. Recently Schubert, Kiefer, Wilkens and Haufler[3] studied the ordered structures with large periods of anti-phase domains in many binary and ternary systems, and reported that the structure of the ordered alloy Cu_3Pd seemed to coincide with the model proposed in our short communication[4]. On the other hand, Geisler and Newkirk[5] concluded that the Cu-Pd alloy, containing 20 % Pd, has an ordered structure of the modified Ni_4Mo-type. This structure was supported by the recent work of Jaumot and Sawatzky[6].

The present work was undertaken to examine the ordered structure of α'' phase by X-ray diffraction study, using single crystals mainly and powder specimens. In the present paper, it will be shown that the observed results essentially agree with those of the electron diffraction study, and then our results will be compared with the previous works and discussed.

§ 2. The Proposed Models of the Superstructure of α'' Phase

First of all, for the sake of interpretation of the results of the X-ray diffraction study described in § 4, we show several models of the structure of the ordered α'' phase proposed by various workers. Fig. 1 reproduces the model of the superstructure elucidated by the electron diffraction study in Part I[1]. This model is a two dimensional anti-phase domain structure, namely, as mentioned in Part I, this is thought of as formed from the elementary face-centered tetragonal lattice, in which the

* In the present paper, all percentages refer to atomic per cent.

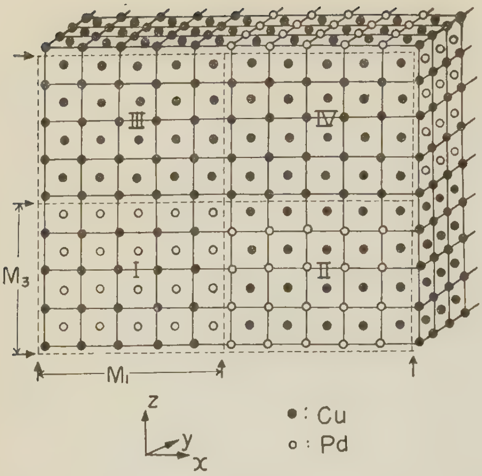

Fig. 1. Model of the two-dimensional anti-phase domain structure with $M_1=5$ and $M_3=4$. Out-of-steps occur at places indicated by arrows.

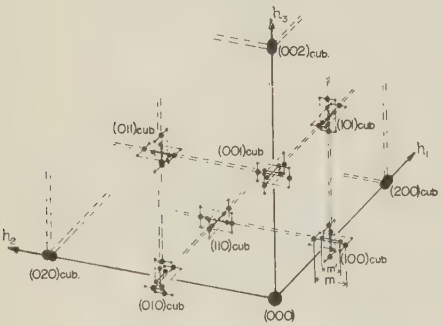

Fig. 2. Intensity distribution in reciprocal space for the actual crystal with the two-dimensional anti-phase structure. This figure is six-fold super-position of the fundamental reciprocal lattice corresponding to the model of Fig. 1.

atoms arrange themselves as in the structure of the ordered alloy Cu$_3$Au but "*the first kind*" and "*the second kind*" of step-shift, $\pm(\boldsymbol{a}_1 \pm \boldsymbol{a}_2)/2$ and $\pm(\boldsymbol{a}_3 \pm \boldsymbol{a}_1)/2$, occur at every M_3-th atom and M_1-th atom along the z and x directions respectively. $\boldsymbol{a}_1$, $\boldsymbol{a}_2$ and $\boldsymbol{a}_3$ are the fundamental lattice vector along the x, y and z axes in terms of the fundamental cells, and the fundamental tetragonal axis coincides with the z direction. Fig. 2 is the intensity distribution in reciprocal space corresponding to an actual crystal of α'' phase. In this figure the splits of the superlattice reflections have two distinct values of separation, m and m', being given by $(1/M_3)a_3^*$ and $(1/M_1)a_1^*$ respectively. a_1^* and a_3^* are reciprocal lattice constants corresponding to $\boldsymbol{a}_1$ and $\boldsymbol{a}_3$ respectively.

Fig. 3 shows the model of the structure of the fully ordered alloy Cu$_4$Pd, proposed by Newkirk and Geisler[5]. This structure belongs to the space-group $C_{4h}^2-P_{42/m}$, containing 20 atoms arranged in a tetragonal symmetry ($a=5.826$ Å, $c=7.328$ Å). It is easily seen that the intensity distribution in reciprocal space given by this structure is entirely different from that of our model depicted in Fig. 2.

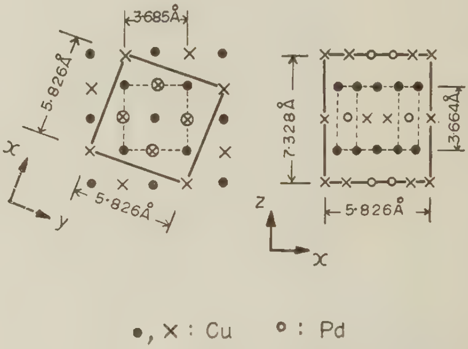

Fig. 3. The ordered structure of the alloy Cu$_4$Pd proposed by Geisler and Newkirk. Original cubic unit cell is shown by the dotted lines.

Schubert *et al.*[3], on the other hand, reported that the ordered alloys containing 18 to 25 % Pd have one-dimensional anti-phase domain structure, characterized by the first-kind of out-of-step, as shown in Fig. 4. The step-shift is lined up along the tetragonal axis of the fundamental cells. This structure has

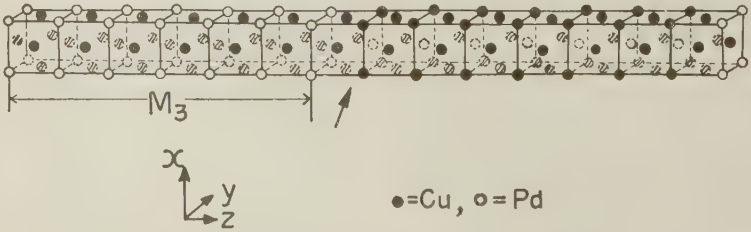

Fig. 4. The one-dimensional anti-phase domain structure with the period $M_3=7$. The arrow indicates the occurrence of step-shift.

also been reported for the alloy of 22 % Pd in our short communication[4] and resembles that found in the partially ordered states of Cu_3Au[7]. The intensity distribution in reciprocal space given by this structure is shown in Fig. 5(a), in which the tetragonal axis lies along the h_3 direction. For the actual case, since the tetragonal axis will distribute along the three original cubic axes, the reciprocal lattice has to be given as Fig. 5(b).

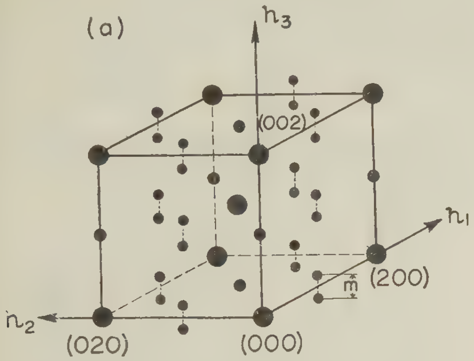

Fig. 5 (a). Fundamental intensity distribution in reciprocal space induced from Fig. 4.

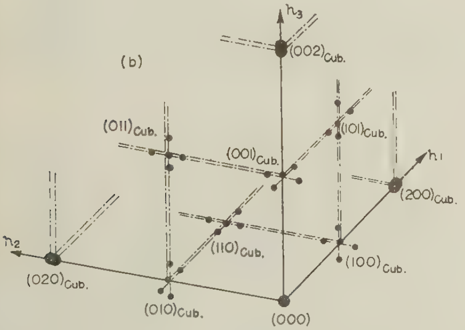

Fig. 5 (b). Three-fold superposition of the intensity distribution in (a), corresponding to the actual state of the ordered alloy.

§ 3. Experimental Procedures

a) Preparation of specimens

Seven specimens of the copper-palladium alloys, which possessed 15.5, 16.3, 20.8, 25.2, 25.8, 27.3 and 28.5 % Pd, were prepared from electrolytic copper (99.9 %) and pure palladium (99.9 %), each alloy weighing approximately 5 gr. The metals were melted in an evacuated thin quartz tube. The large crystals were often easily grown by slow cooling of ingots, but the single crystals were grown by the Tammann-Bridgman method in ceramic tubes, as previously reported[8]. After homogenization at temperatures below the solidus in vacuum, the single crystals were etched by $HCl+CrO_3$ aqueous solution or aqua regia and reduced to about 0.2 mm in diameter. The filed powder specimens were also used to determine the lattice parameters in both disordered and ordered states.

b) Heat treatment

The ordering process of the alloy of Cu_3Pd takes place so slowly that a very long period of heating below the transition temperature is necessary to obtain the fully ordered state[1,9]. To investigate preliminarily the well ordered state, the single crystals were annealed for two weeks in the temperature range between 450°C to 200°C, as follows; the specimens were initially brought to the disordered state, then heated at 450°C for 2 days, at 400°C and 350°C for 3 days, and at 300°C, 250°C and 200°C for 2 days respectively, and slowly cooled down to room temperature. In order to obtain the specimens in the completely ordered state, they were annealed over a period of four months, i.e. at 400°C for 23 days, at 350°C for 17 days, and at temperatures between 350°C and 200°C for 90 days, then slowly cooled in the furnace to room temperature. During the ordering treatment all specimens were sealed in evacuated glass ampules.

c) X-ray examination

Keeping either a [100] or a [110] direction of the original cubic crystal as the vertical axis, oscillation photographs were taken, and some series of stationary-crystal photographs were sometimes also taken to investigate in detail around certain reciprocal lattice points. With Cu or Fe radiation, X-ray diffraction patterns were recorded on the cylindrical films (Fuji non-screen 200 Type) of 10 cm or 8 cm in diameter. In the study of polycrystalline specimens, the lattice parameters were determined by means of the graphical-extrapolation method, using a 114.6 mm Debye-Scherrer camera. In some cases, in order to study the weak superlattice lines, a focusing camera was used together with a curved quartz monochromator.

§ 4. Experimental Results

a) Two weeks annealed state

The preliminary investigation was done for the two specimens, containing 20.8 and 25.2 %

Pd, after being annealed for 2 weeks. The observed results for the former crystal will be mainly described below. Photo. 1(a) and (b) are the oscillation photographs of the alloy of 20.8 % Pd. These patterns show that the superlattice reflections $(010)_{\text{cub.}}$ and $(110)_{\text{cub.}}$ split apparently into three and five spots, respectively. By comparing these photographs with Fig. 6(a) and (b), which are respectively the (100) and the $(1\bar{1}0)$ planes of the reciprocal lattice depicted in Fig. 5(b), it is clearly shown that the splitting of each superlattice reflection can well be interpreted by assuming the presence of one-dimensional anti-phase domains, characterized by the first kind of out-of-step and lined up along the tetragonal axis, as already given in Fig. 4. Therefore, indices of the splits of $(110)_{\text{cub.}}$ group in Photo. 1(a) are $(1\ 0\ 1\pm1/2M_3)$, $(0\ 1\ 1\pm1/2M_3)$ and (110), as described beside this pattern. Also the satellites of $(010)_{\text{cub.}}$ correspond to $(0\ 1\ \pm1/2M_3)$ and the central spot (001) is superposed by another pair of satellites $(1\ 0\ \pm1/2M_3)$*. While, in Photo. 1(b) the satellites of $(010)_{\text{cub.}}$ group are $(1\ 0\ \pm1/2M_3)$, and the central spot (001) is superposed by $(0\ 1\ \pm1/2M_3)$.

Table I.

Superlattice reflection $h\ k\ l$	Separation of satellites m	Period of aut-of-step M_3
1 0 0	0.062	6.7
1 1 0	0.060	7.0
2 1 0	0.060	7.0
2 1 1	0.056	7.5
3 0 0	0.060	7.0
2 2 1	0.058	7.2
3 1 0	0.058	7.2
3 2 0	0.058	7.2
4 1 0	0.060	7.0
3 2 2	0.060	7.0
	Mean value=7.1	

The period of out-of-step or the domain length, M_3, was determined from the splittings of certain superlattice reflections. For the alloy of 20.8 % Pd, Table I lists the separation of satellites in reciprocal space and the domain lengths determined from them. The mean value of M_3 is 7.1 and agrees quite well with that obtained from the powder photographs, using monochromatic focusing camera.

Further, the relative intensities of these splitting reflections were photometrically measured for both single and poly-crystal diffraction patterns and were compared with those calculated from the structural model shown in Fig. 4. Table II gives the observed and calculated relative intensities of the satellites of $(001)_{\text{cub.}}$ and $(110)_{\text{cub.}}$ groups, in which the intensity of either $(001)+(0\ 1\ \pm1/2M_3)$ or (110) reflection is taken as unity. The calculated values were obtained from $(\text{L.P.})F^2\cdot G_3{}^2$, where (L.P.) is the Lorentz-polarization factor, F the structure factor, and G_3 the Laue function along the z direction, being given by Guinier and Griffoul7) and by Raether7). The values calculated with $M_3=7$ agree almost well with the observed ones.

Table II. Relative intensities of satellites of superlattice reflections of the alloy containing 20.8 % Pd.

h	k	l	Relative intensities observed	Relative intensities calculated with $M_3=7$
1	0	$-1/2M_3$	0.25	0.23
0	0	1	1	1
0	1	$\pm1/2M_3$		
1	0	$+1/2M_3$	0.20	0.23
1	0	$1-1/2M_3$	0.35	0.46
0	1	$1-1/2M_3$	0.32	0.46
1	1	0	1	1
0	1	$1+1/2M_3$	0.25	0.37
1	0	$1+1/2M_3$	0.28	0.37

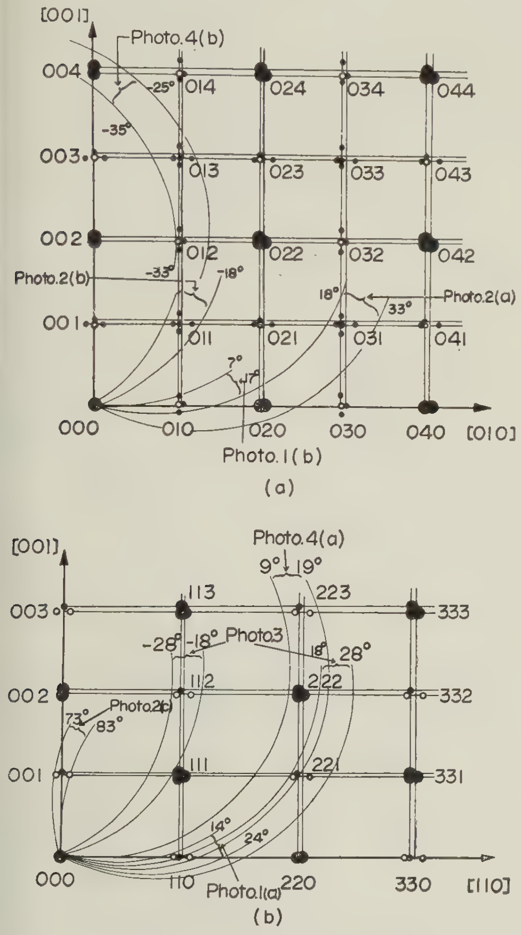
The alloy of 25.2 % Pd gave analogous diffraction patterns to those of the 20.8 % Pd alloy, except that the period of out-of-step was determined as 5.1 and the ratio c/a was 0.991.

b) *Four months annealed state*

Five single crystals containing 20.8, 25.2, 25.8, 27.3 and 28.5 % Pd were studied in the fully ordered state, cooled slowly in four months. In this state, the splitting manner of superlattice reflections was investigated to confirm in more detail the intensity distribution in reciprocal space. Photo. 2(a), (b) and (c) are the parts of oscillation photographs of the crystal of 20.8 % Pd using Cu radiation, showing split of some superlattice reflections. From these patterns, it was elucidated that the five splitting spots of superlattice reflections $(110)_{cub.}$ and $(011)_{cub.}$ lie on the (001) and (100) relplanes respectively, as just was represented in Fig. 6. In Photo. 2(a), the $(031)_{cub.}$ reflection

---

* Since the axial ratio c/a of this alloy is 0.993, the separation due to the tetragonality is so small that (001) is hardly distinguished from $(1\ 0\ \pm1/2M_3)$ in this photograph.



(a)

(b)

Fig. 6(a) and (b). (100) and $(1\bar{1}0)$ planes in the reciprocal lattice of Fig. 5 (b) respectively. The lune-shaped areas are sections through the relplanes swept out by the oscillating sphere of reflection of Cu Kα radiation, and each corresponds to each of Photos. 1～4. Full and open small circles show schematically the split superlattice points lying on and not on the planes concerned respectively.

plits appreciably in five spots lying on the 100) relplane, owing to the tetragonality, lthough the $(011)_{cub.}$ reflection in Photo. 2(b) plits only in three spots. Since the axial atio decreased to 0.991 at this stage, it is clearly seen, by comparison between Photo. 1 and Photo. 2(c), that the satellites of $(001)_{cub.}$ reflection displace towards the lower angle side than the central spot (001). Thus all these patterns are well interpreted by the anti-phase domain structure described in Fig. 4, as well as the pattern in Photo. 1 of the two weeks annealed state.

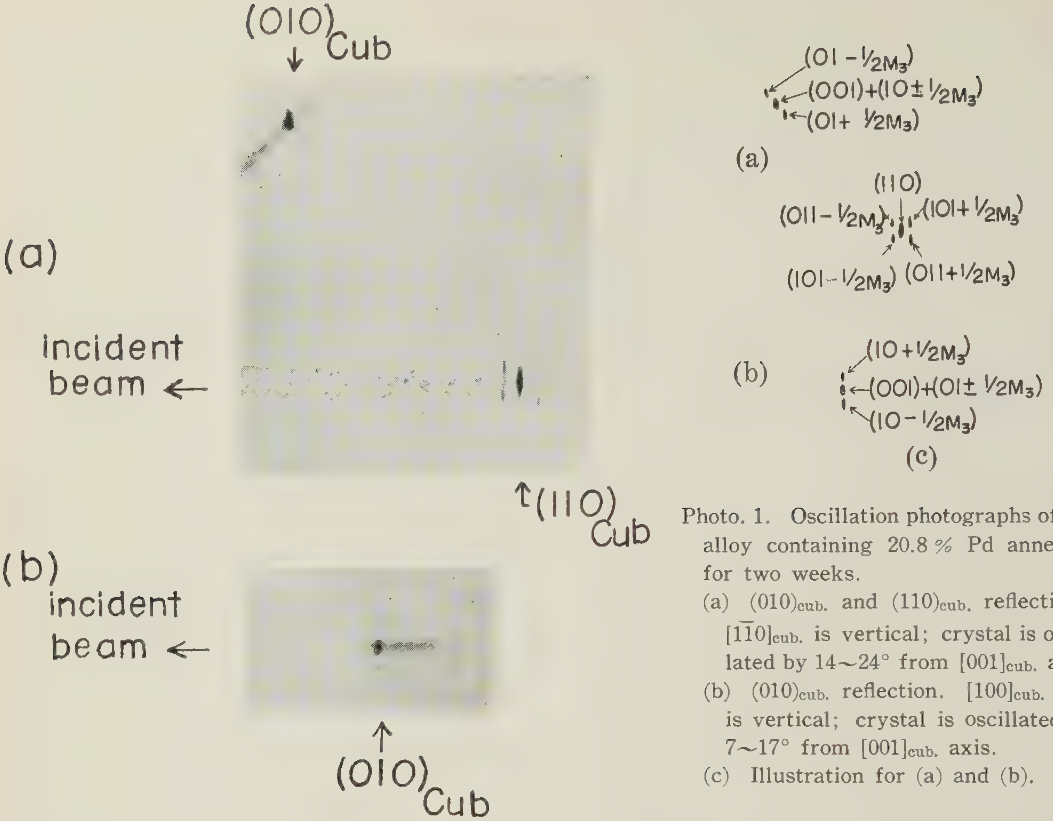

Photo. 1. Oscillation photographs of the alloy containing 20.8 % Pd annealed for two weeks.
(a) $(010)_{\text{cub.}}$ and $(110)_{\text{cub.}}$ reflections. $[1\bar{1}0]_{\text{cub.}}$ is vertical; crystal is oscillated by 14∼24° from $[001]_{\text{cub.}}$ axis.
(b) $(010)_{\text{cub.}}$ reflection. $[100]_{\text{cub.}}$ axis is vertical; crystal is oscillated by 7∼17° from $[001]_{\text{cub.}}$ axis.
(c) Illustration for (a) and (b).

The alloys of 25.2 and 25.8 % Pd also give closely analogous splitting of superlattice reflections to that of the 20.8 % Pd alloy. In Photo. 3, which shows the superlattice reflections of $(112)_{\text{cub.}}$, $(\bar{2}\bar{2}1)_{\text{cub.}}$ and the high angle side of $(\bar{1}\bar{1}0)_{\text{cub.}}$ of the 25.2 % Pd alloy, it should be noticed that the intensities of the two pairs of satellites of these reflections are considerably different from each other. The relative intensities of the splits of the $(112)_{\text{cub.}}$ group were photometrically measured, and the observed results are listed in the second column of Table III. This table shows that the relative intensities of the one pair of the satellites $(1\ 2\ 1 \pm 1/2M_3)$ to the central reflection (112) agree almost with the calculated ones, in which M_3 is assumed to be 5, but the other pair $(2\ 1\ 1 \pm 1/2M_3)$ has fairly less intensities. Hence we can conclude that the *c* axis of the ordered face-centered tetragonal lattice, i.e., the direction of line-up of anti-phase domains, is distributed not equally to three principal axes of the original cubic lattice. This circumstance is, however, special, and a uniform distribution of the tetragonal axis was observed in many cases.

Photo. 4(a) and (b) are the oscillation photographs of the alloy of 25.8 % Pd, giving some splitting groups of superlattice reflections, such as $(110)_{\text{cub.}}$, $(221)_{\text{cub.}}$, $(223)_{\text{cub.}}$, $(012)_{\text{cub.}}$ and $(013)_{\text{cub.}}$, besides the normal reflections. The vertical splittings of the normal spots, such as $(222)_{\text{cub.}}$, $(224)_{\text{cub.}}$ and $(004)_{\text{cub.}}$, seem to mean the occurrence of polycrystallization of the specimen caused by lattice distortion accompanying the ordering reaction.

From the following diffraction patterns of the alloys containing 27.3 and 28.5 % Pd, the complicated two-dimensional anti-phase domain structure depicted in Fig. 1 was confirmed to exist stably. Photo. 5 is a series of the stationary crystal photographs for the $(012)_{\text{cub.}}$ reflection of the alloy of 27.3 % Pd, with

---

* It is undeniable that the electron diffraction results do not compromise with the present X-ray diffraction results about the stable region of the two-dimensional anti-phase domain structure. The reason for this is, however, not clear at the present stage.

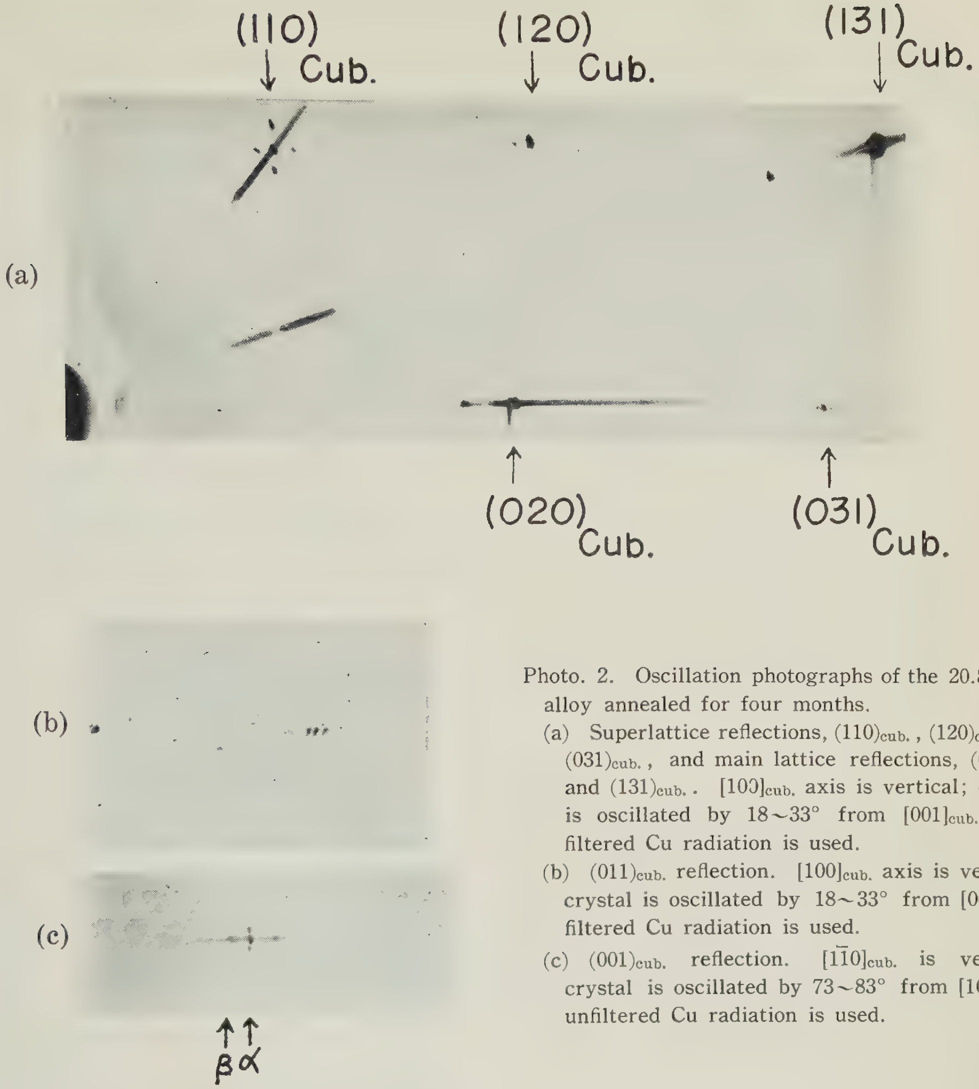

Photo. 2. Oscillation photographs of the 20.8 % Pd alloy annealed for four months.

(a) Superlattice reflections, $(110)_{cub.}$, $(120)_{cub}$, and $(031)_{cub.}$, and main lattice reflections, $(020)_{cub.}$ and $(131)_{cub.}$. $[100]_{cub.}$ axis is vertical; crystal is oscillated by 18～33° from $[001]_{cub.}$ axis; filtered Cu radiation is used.

(b) $(011)_{cub.}$ reflection. $[100]_{cub.}$ axis is vertical; crystal is oscillated by 18～33° from $[001]_{cub.}$; filtered Cu radiation is used.

(c) $(001)_{cub.}$ reflection. $[1\bar{1}0]_{cub.}$ is vertical; crystal is oscillated by 73～83° from $[100]_{cub.}$, unfiltered Cu radiation is used.

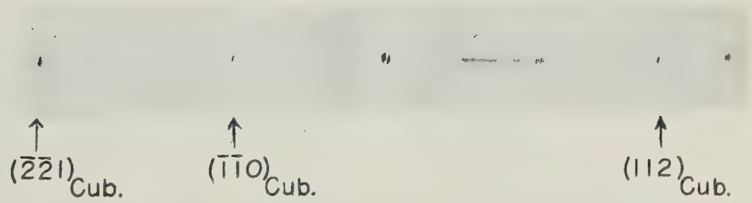

Photo. 3. Oscillation photograph of the ordered alloy of 25.2 % Pd. $[1\bar{1}0]_{cub.}$ is vertical; crystal is oscillated by 18～28° from $[001]_{cub.}$ axis. Unfiltered Cu radiation is used.

$[001]_{cub.}$ axis vertical. The $(012)_{cub.}$ reflection bears a resemblance to the $(110)_{cub.}$ reflection in the electron diffraction pattern in Fig. 8(a) of Part I and shows a double splitting of the satellites, whose indices are given in Table IV. Although the central spot, No. 9 in this table, has been observed also in the electron diffraction patterns, it can not be expected from the anti-phase domain model alone such as shown in Fig. 1. This fact, however, may

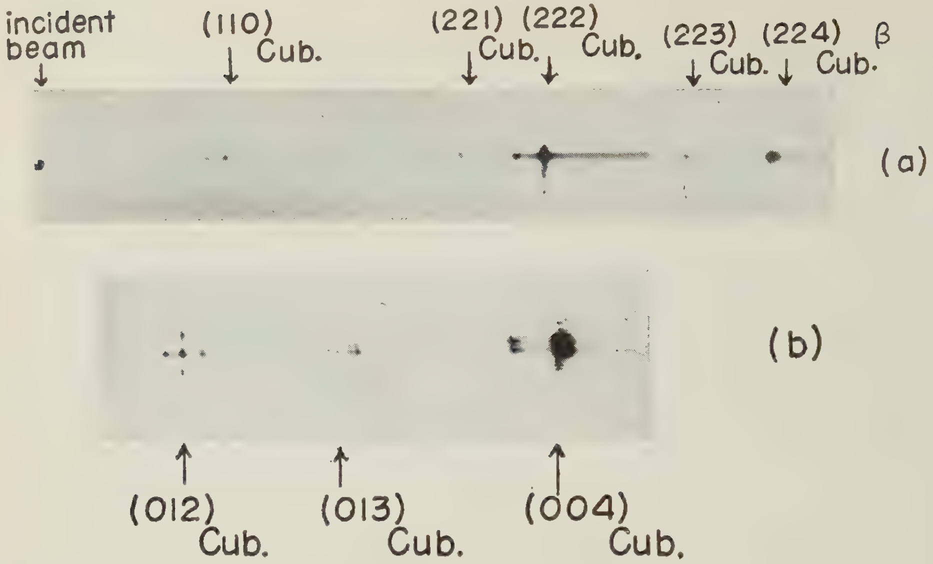

Photo. 4. Oscillation photographs of the ordered alloy of 25.8 % Pd. Unfiltered Cu radiation is used.

(a) $[1\bar{1}0]_{\text{cub.}}$ is vertical; crystal is oscillated by 9∼19° from $[001]_{\text{cub.}}$ axis.

(b) $[100]_{\text{cub.}}$ is vertical; crystal is oscillated by 25∼35° from $[001]_{\text{cub.}}$ axis.

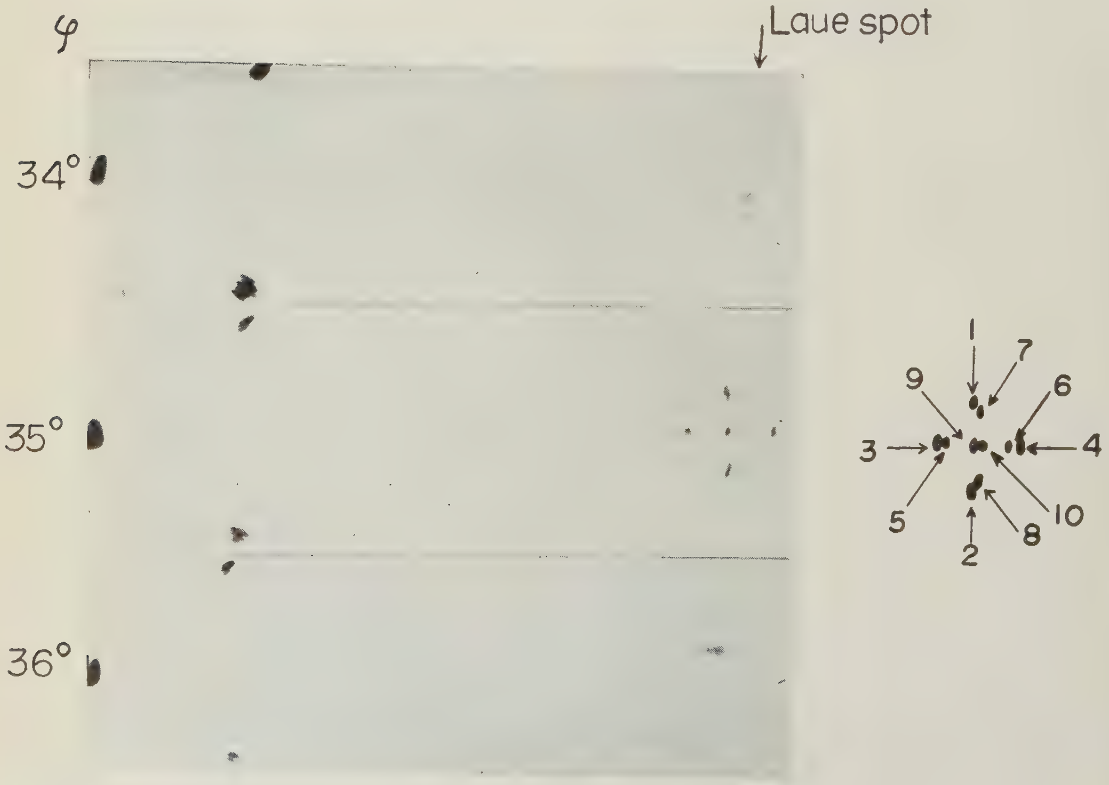

Photo. 5. Series of stationary crystal photographs of the $(012)_{\text{cub.}}$ reflection group of the alloy containing 27.3 % Pd. Unfiltered Fe radiation is used; $[100]_{\text{cub.}}$ axis is vertical; $[001]_{\text{cub.}}$ axis makes 34∼36° with beam direction. Indices of split spots are to be referred to Table IV.

be interpreted by considering coexistence of both the one-dimensional and the two-dimensional anti-phase domain structures, since the former type of anti-phase structure can give rise to the central spot, as mentioned before. Photo. 6 is an example of the oscillation photographs of this alloy, using unfiltered Fe radiation, and it shows the $(0\bar{1}3)_{\text{cub.}}$ reflection flanked by a new type of satellites. The difference between diffraction patterns of the one-dimensional and the two-dimensional anti-phase domain structures will clearly be seen by comparison between Photo. 2(a) or Photo. 4(b) and Photo. 6; namely in the last pattern the weak split spots, indicated by 1′, 2′, 3′ and 4′, are seen above and below the equatorial line, in addition to the spots on this line, while in the former two only five splits lying on this line are observable. The splits of the superlattice reflection in Photo. 6 can entirely be explained by the intensity distribution in reciprocal space as given in Fig. 2, and the indices of all splits are also given in Table IV. The two periods of anti-phase domain, M_1 and M_3, were obtained from the two kinds of separation of the satellites, being respectively 4.0 and 3.2 atomic distances.

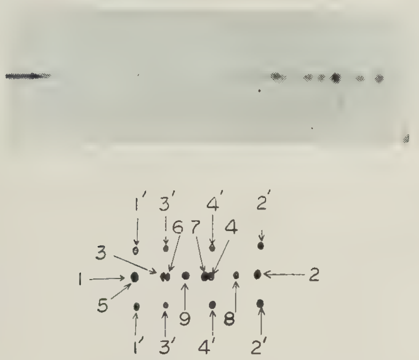

Photo. 6. Oscillation photograph of the alloy of 27.3 % Pd. Split $(013)_{\text{cub.}}$ reflection is shown. $[100]_{\text{cub.}}$ is vertical; crystal is oscillated by 11～21° from $[001]_{\text{cub.}}$ axis. Unfiltered Fe radiation is used. Indices of split spots are to be referred to Table IV.

The alloy containing 28.5 % Pd gave quite similar diffraction patterns to those of the alloy of 27.3 % Pd and possessed the superstructure characterized by both kinds of step-shift with the periods $M_1 \simeq 3.8$ and $M_3 \simeq 3.5$.

In X-ray diffraction patterns of any specimen, there have never been found such satellites flanking the normal reflections as observed in electron diffraction patterns.

Next, the data obtained from the present study will be summarized as a function of composition. Fig. 7 gives the periods of anti-phase, domain M_1 and M_3, as a function of composition for four months annealed state. Both values of M_1 and M_3 seem to agree well with the results of Schubert *et al.*[3] rather than with those of the electron diffraction study[2]. The periods of anti-phase domain decrease continuously with the increasing concentration of Pd atoms. These values in atomic distances are in general not integers. This fractional property of M's values is considered to prove that the different periods of anti-phase domain are mixed uniformly but probably with some irregularity. On this point, detailed discussions and calculations were recently developed[10] in the course of study on the alloy Ag_3Mg in our laboratory.

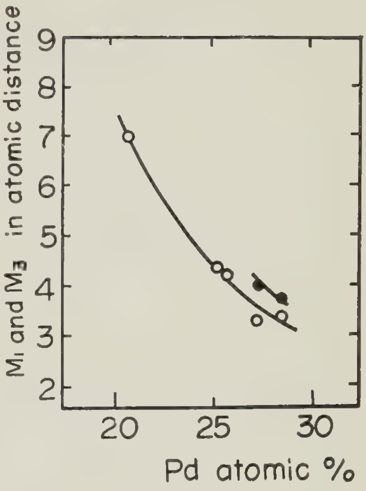

Fig. 7. Variation of the periods of anti-phase domain, M_1 and M_3, with composition. Open and full circles represent the values of M_3 and M_1 respectively.

Fig. 8(a) show the variation of lattice parameters with composition for the ordered and disordered states. The lattice parameters of the disordered alloys quenched from 600°C appear to be approximately linear with composition, but to deviate positively from Vegard's law. In this figure, $(a^2c)^{1/3}$ is also plotted, in addition to a and c, for the ordered tetragonal cell. These lattice parameters agree fairly well with the previous investigations [5],[6],[11]. The lattice contraction due to ordering is very

small, but it seems to reach a maximum value, about 0.08 %, in the vicinity of 25 % Pd. This value is greater than the value, 0.02 %, observed by Jaumot and Sawatzky[6], but agrees roughly with the result, 0.057 %, of dilatometric study by Sato[12]. In Fig. 8(b) it should be noticed that the c/a values have a minimum near the composition of Cu_3Pd rather than that of Cu_4Pd. The observed data plotted in Figs. 7 and 8 are summerized in Table VI.

The variation of the periods of anti-phase domain with temperatures was not completely examined, but it was found that the value of M_3 of the 25.2 % Pd alloy increases with temperature of annealing.

§ 5. Discussions

As already mentioned in § 1, Geisler and Newkirk[5] have proposed that the lattice of the fully ordered alloy Cu_4Pd has a "2-*hi* inverted Ni_4Mo-type" structure given in Fig. 3. Now, their data obtained from Debye-Scherrer patterns should be interpreted in terms of the present anti-phase domain model. In doing this, we assume that the ordered alloy of 20 % Pd possesses such a superstructure as characterized by the first kind of out-of-step with the period of 7 atomic distances, and that the dimensions of the elemental face-centered tetragonal cell are taken as $a=3.685$ Å $c=3.664$ Å according to Geisler and Newkirk. In Table V the first and the second columns list the values of $1/d^2$ and visual relative intensities of superlattice lines observed by them. The predicted positions, relative intensities and Miller indices of superlattice lines given by the present model are listed in the third, fourth and fifth columns of this table. The superlattice line positions and the relative intensities calculated by Geisler-Newkirk's model are also listed in the sixth and last columns. It is clearly seen that the experimental data, except two diffraction lines with VVW intensities, can quite well be explained on the basis of the one-dimensional anti-phase domain structure. The interpretation of Geisler and Newkirk is also good but not fully satisfactory, especially, two diffraction lines with W and

Table VI. Lattice parameters in the ordered and the disordered states of the copper-palladium alloys.

Composition Pd %	Disordered state	Ordered state (after 4 months annealing)				Period of aut-of-step

MW intensities, marked with*, can not be explained by their model. Therefore, it can be said that the agreement between the observed data and the calculated results is better for the present model than for their model. Furthermore, their model can not explain the diffraction patterns of single crystals represented in the present paper. And, in the present experimental study, there is no evidence to support the fact that the Cu_4Pd composition is the most favorable composition for ordering.

Thus, it is concluded that the superlattice in the vicinity of 25 % Pd possesses in equilibrium state the anti-phase domain structure characterized by the first kind alone or both the first and the second kinds of out-of-step. The latter type of the anti-phase domain structure was observed over the composition range from 21 to 30 % Pd according to the electron diffraction study in Part I, while in the present X-ray study this structure was found only at the composition of 27.3 and 28.5 % Pd*. If the two-dimensional anti-phase domain structure is the same as the "*Komplexe Verwerfungsstruktur*" called by Schubert *et al.*[3], the results of the present study seem to support the stable region of each type of anti-phase domain structures proposed by them. Taking the results of the electron diffraction study into consideration, however, the region of the two-dimensional anti-phase domain structure should extend to less content of Pd at higher temperatures. Hence it can safely be said that the two-dimensional anti-phase domain structure is stable at higher temperatures and at higher concentrations of Pd than the region of the one-dimensional one, although there seems to be no discrete boundary between the stable regions of both structures. The presence of a well marked maximum at about 400°C in the specific heat-*vs.*-temperature curve obtained by Jones and Sykes[1] might probably correspond to the transition from the one-dimensional to the two-dimensional anti-phase superstructure. Both types of anti-phase domains gradually fade away with decreasing Pd content and completely vanish at about 18 % Pd together with the tetragonality of the fundamental lattice. To determine unconfirmed points in the phase diagram of this alloy, more detailed and conclusive investigations seem to be necessary.

§ 6. Conclusion

According to the present X-ray diffraction study on the ordered Cu_3Pd crystals, it was confirmed that the two-dimensional anti-phase superstructure characterized by two kinds of step shift, proposed in Part I, exists stably in the compositions of 27.3 and 28.5 % Pd after slow cooling from 450°C to room temperature in four months. The alloys containing 20.8 to 25.8% Pd, which were also annealed for four months, have the one-dimensional anti-phase superstructure. This structure is entirely different from the "2-*hi* inverted Ni_4Mo-type" structure proposed for the alloy Cu_4Pd by Geisler and Newkirk, but agrees with the result of Schubert *et al.*.

The lattice parameters as well as the periods of anti-phase domains were obtained as functions of Pd concentration. It is pointed out that changes of physical properties accompanying the order-disorder transformation and cold-work of this alloy should be considered on the basis of such rather unusual superstructures as mentioned above.

The authors wish to express their sincere thanks to Mr. D. Watanabe for his kind discussions.

Proton Magnetic Resonance in Chain Polymers

By Akira ODAJIMA, Junkichi SOHMA
Research Institute of Applied Electricity, Hokkaido University
and Mitsuru KOIKE
Department of Physics, Hokkaido University

(Received August, 13, 1956)

Proton magnetic resonance absorptions have been studied for several chain polymers. The experimental second moments of the absorption lines in the glassy state were compared with the calculated ones for the model of $(\text{-}\mathbf{CH_2 \cdot CHX}\text{-})_n$ type.

The temperature variations of the line widths were observed from room temperature to about 160°C. For PMMA and Polystyrene having large side chains, the line widths were found to narrow in two steps as temperature was raised. The first step of narrowing occured in neighbor of the glassy transition temperature T_g and is assigned to the onset of the "hindered rotation" of the side chain. The second step of rapid narrowing started at the higher temperature than T_g and is assigned to the "segmental rotation" of the main chain.

In contrast with these cases, the line width transition of PVC and of PVAc occured in a single step narrowing at the higher temperature than T_g which is assigned to the onset of the segmental motion.

Referring to another observations information of the movements and of the configurations of the side chain which was obtained from the proton magnetic study was discussed in the last section.

§ 1. Introduction

During the past few years much work has been done in the field of proton magnetic resonance study of long chain polymers. The main object of these this researches was in the investigation of the molecular structures and, especially, of the molecular movements.

A number of polymeric materials have been found to show merely amorphous diagrams under X-ray and electron diffraction examinations[1]. Therefore, the knowledge of the molecular structure of these materials is obtained less exactly than in the case of crystalline substances. It seems possible, however, that the proton magnetic spectroscopy permit a further insight into the structure of polymeric systems, for example, the relative position of the side chains to the main chains which is determined by examining a resonance line width which is due to the interactions between the neighbouring nuclear spins.

On the other hand, it is well known that all polymers consisting of flexible long chains show the apparent second order transition which separates the soft "rubbery" state from the hard "glassy" state. An explanation of this characteristic property based on the assumption of "quasi-free rotation" in the long chain molecules. However, concerning the existence and the nature of such internal motions we have only unsatisfactory knowledge. Hitherto, in order to study the characteristics of polymers in the transition region, various physical methods were employed, such as thermal[2], dynamical[3], and dielectrical[4] measurements. Especially, the latter two are very useful in studying the molecular behaviors responsible for this transition.

While, the proton magnetic resonance method demonstrates directly internal motions of the main chains and the side chains[5], this method is one of the most useful means of studying various inner motions of linear polymers in the transition region. Concerning the polymers having large substituents the possibilities of diversity in the transition are expected, for example, the possibility of the rotation of the side chains under circumstances which prevent the segmental motion of the main chain. Thus, it seems to be interesting to investigate how the side chains in polymers relate to the onset of the rotation of the main chain, and how they behave with each other in the "glassy" to "rubbery" transition in polymers.

Taking into account the relations between the side chains and the main chain, we have studied the line width of the proton magnetic resonance absorption for several chain polymers of the vinyl compounds and acryl ones, which are of similar construction except for the different nature and the size of the side chains. Moreover, we have tried to obtain information concerning the relative position of side chains and the nature of their rotational motion more accurately than in the past, and the semi-quantitative investigation described in the following has been developed.

§2. Experimental Procedure

Apparatus

Autodyne detector was used for observing the proton magnetic resonance line. The detector used was a cathode follower type[6]) which has high sensitivity and is the most useful of those so far tried. A block diagram of the whole apparatus is shown in Fig. 1.

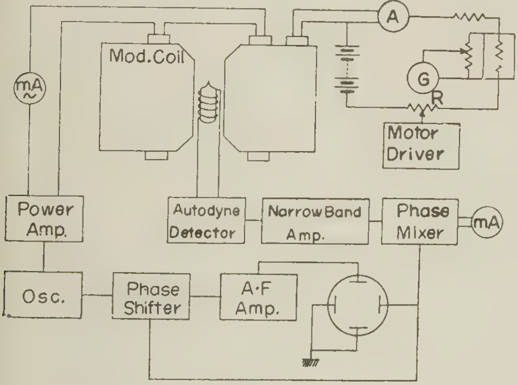

Fig. 1. Block diagram of apparatus.

The magnet used in this work was an electromagnet with 15 cm diameter pole face. The current to the magnet was supplied from storage batteries. The gap of the pole faces was 3 cm, and at this gap the inhomogeneity of the field was less than 0.3 gauss over the area of the sample used.

The experiments were performed at a fixed frequency with a variable applied magnetic field of about 3100 gauss. The linear variation of the magnetic field was accomplished through an electronic regulator extending over about 50 gauss range[6]). The magnetic field modulated at 50 cycles was applied and its intensity of less than 1.5 gauss was sufficient to obtain adequate signal strengths.

The narrow band amplifier and balanced mixer was used to observe the derivative of the absorption line as a function of the applied field. The line shapes were recorded by the automatic recording system.

Sample

The various samples used are shown in Table I. All samples have no plasticizer and are neither stretched nor orientated.

Table I.

Sample	Average Polymerization degree	Structure unit
Polyvinyl chrolide	1300	$-CH_2 \cdot CHCl-$*
Polystyrene	4200	$-CH_2 \cdot CHC_5H_5-$*
Polyvinyl Acetate	2000	$-CH_2 \cdot CHOCOCH_3-$*
Polymethyl Methacrylate		$-CH_2 \cdot CH_3$ $COOCH_3-$**
Polymethyl Acrylate		$-CH_2 \cdot CHCOOCH_3-$**

* These samples were manifactured by the Sekisui Kagaku and Co.

** These samples were supplied through the kindness of Dr. S. Iwayanagi and Mr. M. Hidejima, Scientific Research Institute.

These materials do not crystallize except PVC, and the crystallization of PVC is in such a small degree[1]) that it is not considered to affect the results of our experiment.

For the measurement, the powder or granular samples, of about 1 gram, were contained in a small glass tube of 1 cm inside diameter. And the radio frequency coil into which the glass tube was inserted was 1.1 cm inside diameter and 1 cm long, and was surrounded by a cylindical shield of 2.8 cm outside diameter. The temperature of the samples was measured with the copper constantan thermocouple embedded in the sample. The 3 cm gap of the available magnet prevented insertion of a heater, so heating was effected by conduction through the brass rod, the upper end of which was in contact with Ni–Cr heater placed too far above the magnetic pole to disturb the field homogeneity. And the shield tube containing the samples was thermally insulated from the surroundings. Thus the temperature of the samples was varied from room temperature to about 160°C. Within this extent satisfactory temperature control was obtained.

Hygroscopic samples were further desiccated in the vacuum desiccator for two days, and after this treatment they were desorbed by evacuating at 10^{-4} mmHg, having been kept in a heat bath of appropriately high temperature (100°C～160°C) for about 20 hours.

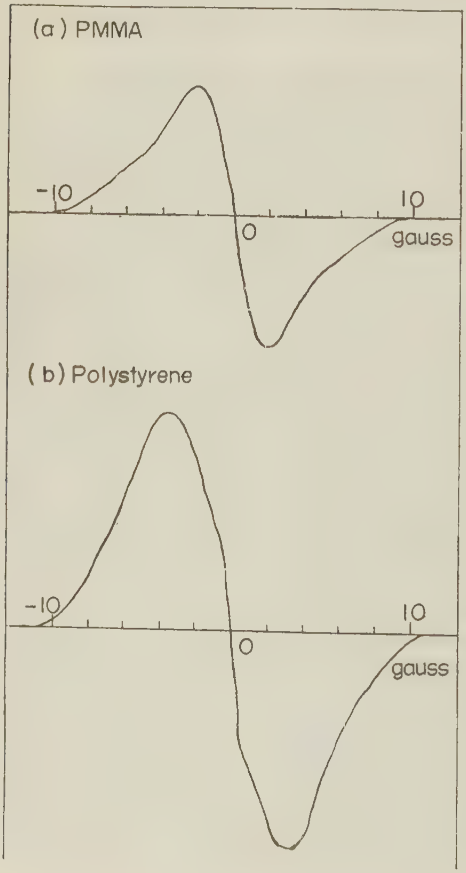
§ 3. Line Shapes and Line-width Changes

The derivatives of the absorption lines at room tempereture are shown in Fig. 2. All resonance lines are single-humped showing no fine structure. The second moments, half-widths and maximum slope widths are respectively listed in Table II. The experimental values of second moment $\langle\Delta H^2\rangle_{Av}$ and half-width $\Delta H_{1/2}$ of absorption lines are calculated through a graphical integration of the derivative curves replotted in a rectangular coordinate from the recording paper.

If the curve is the Gaussian type, there is the following well known relations⁷⁾.

$$\Delta H_{1/2}=2.35\langle\Delta H^2\rangle_{Av}^{1/2},\quad \Delta H_{m.sl.}=2\langle\Delta H^2\rangle_{Av}^{1/2}. \qquad (1)$$

Thus we obtain the ratio of $\Delta H_{1/2}$ to $\Delta H_{m.sl.}$



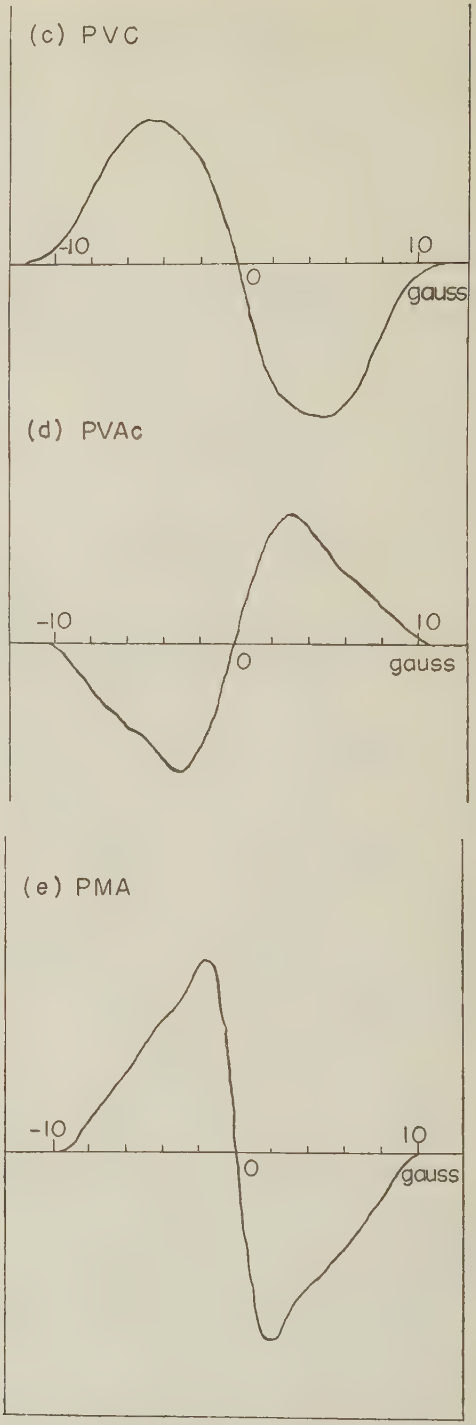


Fig. 2. Derivatives of the proton magnetic absorption line in PMMA, PS, PVC, PVAc and PMA at room temperature.

as 1.175. Referring to the experimental results, the line shapes for PVC and Polystyrene seem to be similar to the Gaussian type. On the other hand the line shapes for PMMA and

PVAc indicate sharper absorption line than the Gaussian type, in spite of the glass-like state at room temperature.

Table II.

	$\Delta H_{1/2}$	$\Delta H_{m.sl.}$	$\Delta H_{1/2}/\Delta H_{m.sl.}$	$\langle H^2\rangle_{Av}$	$\langle H^2\rangle_{Av}$ (narrowing)
	gauss	gauss		gauss^2	gauss^2
PMMA	6.2	3.8	1.6	9.0	6.9*
PS	8.9	7.3	1.2	11.9	9.1**
PVC	10.6	9.5	1.1	14.4	
PVAc	7.4	4.7	1.6	11.0	
PMA	6.8	3.5	2.0		

* at 103°C.

** at 105°C.

The line width behaviors as the temperature rises, are shown in Fig. 3 and 4. In each observation the values of the line width in the higher temperature region may be somewhat greater than the true ones because of the modulation broadening and the inhomogenity of the field.

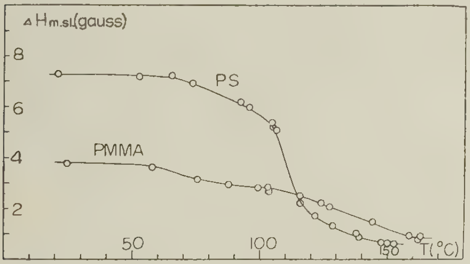

Fig. 3a. Max. Slope width vs. temperature curves for PMMA and PS.

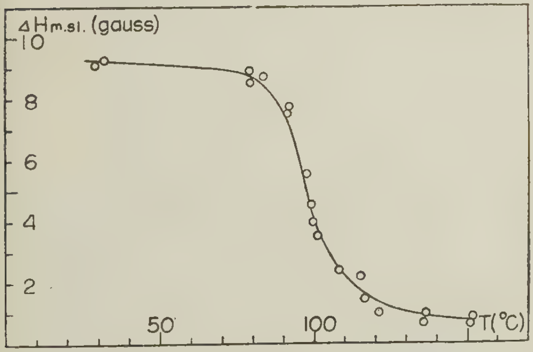

Fig. 3b. Max. Slope width vs. temperature curve for PVC.

Under the circumstances of thermal equilibrium, which was achieved by sufficiently slow variation of temperature, no hysteresis was apparent on the time scale of these experiments. The line width change for each material will be discussed in detail in a later part of this section.

(a) **PMMA.** The observed maximum slope width, $\Delta H_{m.sl.}$ of the absorption lines is plotted against temperature in Fig. 3a. The line width $\Delta H_{m.sl.}$ begins to narrow at about 60°C, which corresponds to the apparent second order transition temperature which is called, hereafter, T_g[2], and this result is consistent with that reported previously[9].

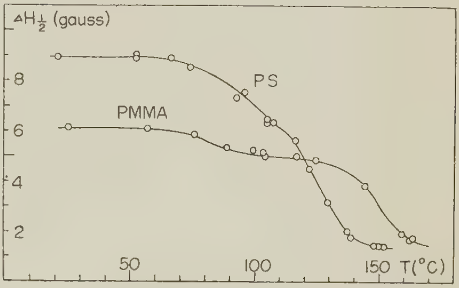

Fig. 4a. Half width vs. temperature curves for PMMA and PS.

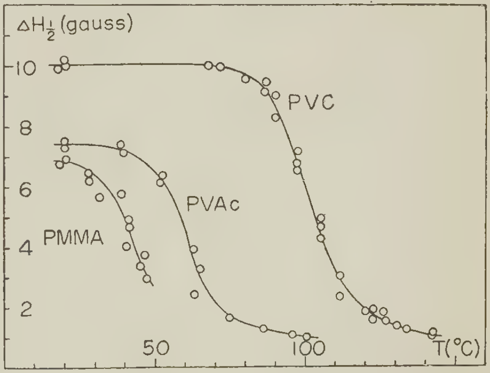

Fig. 4b. Half width vs. temperature curves for PVC, PVAc and PMA.

On the other hand, the observed half-width, $\Delta H_{1/2}$, vs. temperature curve is shown in Fig. 4a. In this case the line width transitions occur in two steps. At first step the narrowing of $\Delta H_{1/2}$ starts at about 65°C and is only 26% of the initial value of $\Delta H_{1/2}$ even at about 110°C, and after the first narrowing the curve enters into the second step of an abrupt decreasing at about 130°C, followed by the leveling off.

(b) **Polystyrene.** The maximum slope width and half-width vs. temperature curve are shown in Fig. 3a and Fig. 4a, respectively.

In this case the line width transitions also are shown to occur in two steps. The initial narrowing starts at about 80°C, which corresponds to the transition temperature T_g[2]. After this narrowing the curve enters into the second step of an abrupt decreasing at about 120°C followed by the leveling off.

(c) **PVC.** The line width vs. temperature curve for this material, given in Fig. 4b, shows typical one-step narrowing forming a contrast with those for the above two samples. That is, when the temperature rises the line width $\Delta H_{1/2}$ shows little change until about 85°C, which is higher than the transition temperature T_g, 75°C[2], and then it begins to fall rapidly to the leveling off.

(d) **PVAc.** The line width $\Delta H_{1/2}$ vs. temperature curve, given in Fig. 4b, begins to drop at about 50°C, and this temperature is higher than the transition temperature T_g of about 30°C[2].

Considering that PVAc has similar structure to PMMA, the line width transition might be supposed to occur in two steps as in the case of PMMA. Nevertheless the line width vs. temperature curve, shown in Fig. 4b, decreases not in two-steps but in one step.

(e) **PMA.** Although the unit of PMA is the isomer of that of PVAc, the line shape for this material at room temperature was a little different from those for PVAc and others. That is, even at room temperature the line shape, of which derivative curves are shown in Fig. 3, appears a little sharper than the shapes for PVAc, and the line width narrows at about 40°C being much higher than T_g of 3°C[2]. Considering that the transition temperature T_g of PMA is lower than room temperature, it seems not to be surprising that the above stated line shape appears for this material. For the purpose of studying whether the temperature variation of the line width shows another narrowing in the lower temperature region, the observation of the line width behavior in the lower temperature region seems to be interesting. Our results in this region, however, are not enough to draw any conclusion on this point.

§ 4. Second Moments for Rigid Chain Polymers

The second moment $\langle \Delta H^2 \rangle_{Av}$ of absorption line for the rigid lattice is given by Van Vleck. In case the chain axes in a material distribute at random in all directions, the second moment is given by the following equation[7]:

$$\langle H^2 \rangle_{Av} = \frac{6}{5}\frac{I(I+1)}{N}\frac{\mu^2}{I^2}\sum_{j>k} r_{jk}^{-6} + \frac{4}{15}\frac{1}{N}\sum_{j,f} I_f(I_f+1)\frac{\mu_f^2}{I_f^2} r_{jf}^{-6}. \qquad (2)$$

In this equation r is the distance between nuclei j and k, μ the magnetic moment of proton, I the proton spin and N the number of protons in the elementary cell over which the sum is taken. And the subscript f refers to all other nuclear species in sample. If the structure of a molecule is known and the lattice can be assumed rigid, **Eq.** (2) makes possible the calculation of the second ment.

The samples used in this experiment are the chain polymers of relatively simpl vinyl or acryl compounds of which chemical formulae are shown, respectively, in Table I. In the calculation of the second moment for the polymers in question $(-CH_2 \cdot CHX-)_n$, we consider two cases which are in the state of the planar zigzag chain and in the state of the randomly coiled chain respectively, as shown in Fig. 5. And we assume that the C–C and C–H distances are taken as 1.54 A and 1.094 A, respectively[9]. Then the intramolecular contributions to the second moment are found to be 12.64 gauss² in the case of the planar zigzag chain or 12.78 gauss² in the case of the randomly coiled chain, the necessary calculation for which being carried out in Appendix I.

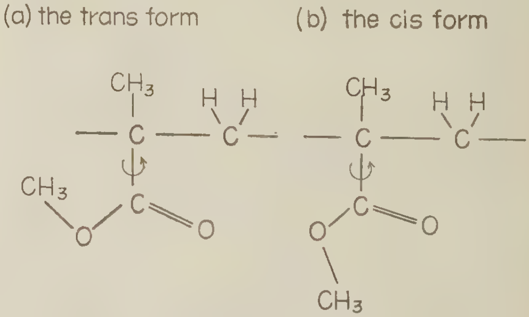

Fig. 5. Configurations of PMMA.

The chain molecules having large substituents are supposed not to be coiled up but to bend gradually on a scale of several bond lengths along the chain[1]. Therefore, in the following we will calculate the second moment based on the planar zigzag chain model.

The analysis[1)] of the X-ray and electron diffraction pattern for such polymers in stretched state suggests that steric hinderances are so great as to prohibit segments getting close to each other. Considering that the second moment is the inverse sixth power of the internuclear distances in **Eq.** (1) the contributions from the nuclei in external molecules are considered to be not sensitive to the intermolecular configuration.

This permits us to take the long chain molecule itself as the elementary cell in fairly good approximation, though the elementary cell should, in principle, include the neiboring molecules. Since all samples except PMA are glass-like at room temperature, they are supposed to be in a rigid state. Then a good estimate of their second moments can be obtained by adding up the contributions of each of the various structural groups in them.

(a) **PVC.** The monomer unit of PVC has 3 protons and a chlorine nucleus as the foreign nucleus. Considering the zigzag chain model, shown Fig. 5, **Eq.** (2) gives 12.7 gauss^2 as the second moment of PVC, of this only 0.1 gauss^2 is caused by chlorine nucleus.

The difference of 1.7 gauss^2 between the theoretical value and the experimental value, may come from the intermolecular interaction. This values would seem to be reasonable, though exact calculation of the intermolecular broadening is not possible.

(b) **Polystyrene.** Polystyrene shown in Fig. 6 contains 8 protons in its monomer unit, of these 5 are in the phenyl group of the side chain. CH_2 and CH groups in the main chain contribute 4.76 gauss^2 to the second moment. The phenyl group is a plane hexagon of carbon atoms, whose carbon-carbon length is known to be 1.39 A and the CH bond length is taken as 1.08 A[9)]. Thus the contribution to the second moment is obtained as $3.3\frac{4}{8}=1.65$ gauss^2. The experimental value is 11.9 gauss^2 being far larger than the sum of the contribution of the contribution of the above mentioned groups, 6.41 gauss^2. Moreover, it is neccesary to take account of the dipole interactions between the protons of the main chain and of the phenyl group, and between the protons of the different phenyl groups. In the Appendix II the broadening due to these interactions is calculated for the planar zigzag chain model and then $(3.97/8+1.87/4+1.27/4)=1.28$ gauss^2 is to be added to the second moment. However, the theoretical value which is combined with each of the above contributions is still less than the experimental value. This discrepancy seem to suggest that the planar structure does not represent the true picture of Polystyrene molecule[10)].

(c) **PMMA.** The monomer unit of PMMA has 8 protons, of these 6 are in 2 methyl groups which are found to rotate about their C_3 symmetry axis fast enough at room temperature. In the case of such rotation, the contribution of the methyl group to the second moment would be reduced by a factor of 1/4[11)].

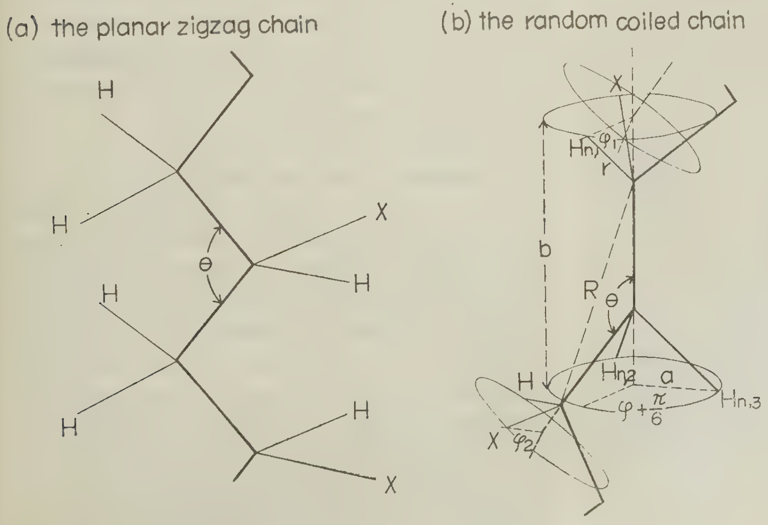

Fig. 6. The zigzag and random coiled chains.

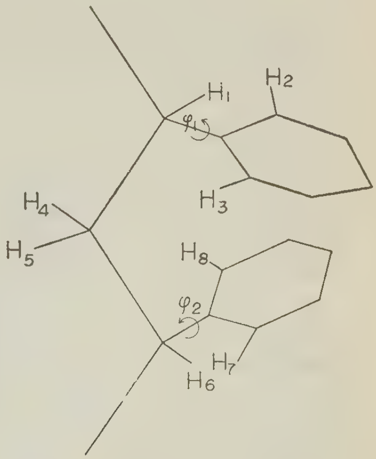

Fig. 7. The structure-model for Polystyrene.

Then the contribution of two methyl group to the second moment become $6/8\times(22.1/4)=4.14$ gauss². Combined with the contributions of the CH_2 group, we have an estimated second moment for PMMA of 6.90 gauss².

Another calculation can be obtained from the following consideration. The absorption line for PMMA can be interpreted to be a superposition of the line of the CH_2 group and the line of the CH_3 groups, because both groups are at a long distance from each other and because there is little interaction between the protons of each group. It is self-evident that the central part of the absorption line comes mainly from the line of the CH_3 group having the smaller second moment than the CH_2 group. Therefore, the maximum slope width of the line for PMMA is given by the broadening due to their external interactions. In the Appendix II, the relation of these broadenings to the meximum slope width of the CH_3 groups is calculated. As the result, we obtain $\alpha^2=3.35$ gauss² as the additional broadening of the CH_3 group, as shown in Fig. 8. We have then a predicated second moment for PMMA of $\langle\Delta H^2\rangle_{Av}=6.90+3.35\,\frac{6}{8}=9.41$ gauss². Comparing this theoretical value with the observed value agrees approximately with that predicted by adding the absorption of the various groups.

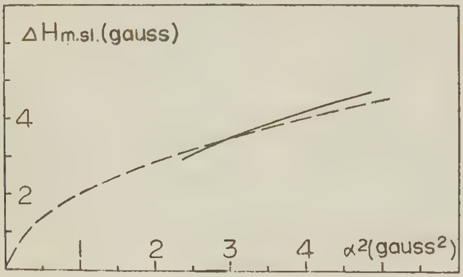

Fig. 8. Max. Slope width vs. external second moment for CH_3 group. The dashed line is the calculated curve based on the Eq. (9) of which the second term is neglected.

(d) **PVAc and PMA.** The each unit of PVAc and PMA has 6 protons, of these 3 belongs to the CH_3 group. The ambiguous distances of protons between those belonging to the side chain and main chain prohibit us to estimate the difference of the second moments for these materials.

The contribution from CH_3, CH_2 and CH are 2.76 gauss², 3.68 gauss² and 1.41 gauss², respectively. Adding up these values, the resultant value is 7.85 gauss². For PVAc, the difference 3.15 gauss² between the calculated value and experimental one comes presumably from the interactions between external protons.

For PMA in the rigid state, the accurate experimental value is not yet obtained. It is desirable to observe experimentally the difference of the second moments of PVAc and of PMA.

§ 5. Motional Narrowing

The line width of absorption is affected, in general, by both spin-spin relaxation time T_2 and spin-lattice relaxation time T_1.

But the effect of T_1 on the line width is considered to be negligible in the case of polymers[12], and we are able to confine our discussion to the effect of T_2 on the line width.

Bloembergen et al.[12] theoretically predicted how T_2 and the line width varies at the onset of the motion. It is pointed out, however, that as a measure of the line width, the maximum slope width or the root second moment are unable to be applied, since both quantities represent not exactly T_2 at the motional state. On the other hand Kubo and Tomita[14] derived the following equation predicting narrowing of half-width for motions.

$$(\Delta H_{1/2})^2=\frac{4\log 2}{\pi}\langle\Delta H_0^2\rangle_{Av}\tan^{-1}\left(\frac{\pi\tau}{4\log 2}\gamma\Delta H_{1/2}\right) \tag{3}$$

where $\langle\Delta H_0^2\rangle_{Av}$ stands for second moment of the rigid state, τ for the correlation time of the nuclear motion and γ for gyromagnetic ratio.

Therefore in this paper we adopt $\Delta H_{1/2}$ as the measure of the line width.

It is well known that motional narrowing of proton occurs when the correlation time of its Brownian motion is of the order of 10^{-5} sec[13]. Comparing narrowing temperature with the transition temperature T_g, given in Table II, it is found that the narrowing temperature are higher than the transition temperature T_g. This suggests that the segmental motion, of which rate is more rapid than 10^{-5} sec., occurs at the higher temperature than T_g. It is worthy to note, however, that apart from the narrowing to occur at the higher temperature both $\Delta H_{1/2}$'s of PMMA and of Polystyrene gradually narrow at first in the neighbourhood of T_g and show two-step narrowing, and that these polymers have large side chain containing several protons. The transition temperature T_g in the polymer could be associated with an increase of "free volume"[15]. And it is likely that in the vicinity of T_g, the free volume is too small to permit the rotation of the main chain as a whole, but may be sufficiently large to permit the localized rotation of the side chain itself.

If the correlation time of the latter rotation is of comparable order to the spin-spin relaxation time T_2, the line width of the absorption signal begins to narrow.

(1) Gradual Narrowing

(a) **PMMA.** For the sufficiently rapid rotation in the system containing a methyl group, the reduction of the second moment by this rotation is given by the following equation[11]

$$\langle \Delta H^2 \rangle_{Av} = \frac{9\mu^2}{10}(3\cos^2\psi - 1)^2\,, \qquad (4)$$

where ψ is the angle between the rotation axis of the side chain and C_3 symmetry axis of the methyl group. Referring to the structure of PMMA, shown in Fig. 5, two rotations about different axes except for C_3 axis, that is, C–O and C–C axis might be excepted to occur in a carboxyl group of the side chain as temperature is raised; there is however, evidence that the rotation about C–O axis is prohibited and that the only possible configuration of the carboxyl group in the side chain is approximately the cis form[16]. In this configuration the rotation of the side chain with increasing temperature is restricted to about C–C axis. As electron diffraction indicates that C–O–C plane is 25°±8° out of the cis planar configuration in methyl acetate[16], ψ becomes about 25° for this rotation axis, and then the reduction by this free rotation is estimated as 2.7 gauss² throug **Eq.** (4). The experimental value of narrowing is obtained as 2.1 gauss² at 103°C*. Since the actual motion seems to be a kind of oscillation, the reduction of this motion of the side chain is expected to be less than the above calculated value.

(b) **Polystyrene.** Following the similar procedure the reduction of the second moment for PS by the rotation of the phenyl group is theoretically expected to be 0.79 gauss² from **Eq.** (4), based on the assumption of the rapid, free rotation. The experimental value of narrowing is obtained as 2.8 gauss² at 105°C. In addition to the narrowing above calculated, the rotation also reduces the broadening contributed from the protons not in the same phenyl group but in the external group. However, the some part of narrowing must come from the reduction of the broadening contributed from the interaction of the protons in the main chain.

Simply speaking, the first narrowing may be closely related to the onset of the rotation of the side chain, and besides may be affected in some way by the motion of the main chain. That is, it is reasonable to assume that the rotation of the side chain is not completely independent of the motion of the main chain because of the steric hinderance, and that the rapid rotation of the side chain is accompanied by the localized motion of the main chain. Thus, this localized motion of the main chain is expected to contribute appreciably to the first narrowing.

(2) Rapid Narrowing

For PVC having a small side chain the narrowing as the temperature appears not in two steps but one rapidly narrowing due to the rotation of the segment in polymer. This fact supports quantitatively the above stated interpretation concerning the gradual narrowing.

On the other hand, the activation energy of the segmental rotation seems to be possibly estimated through **Eq.** (3) using the observed curve of the half-width. It should be noted, however, that in this equation the correlation time of the rotation is assumed to be only one kind, but for polymer the correlation time of the rotation is considered not to be one but to be distributed over some extent. Therefore, it is considered not to be correct way that the activation energy is estimated by **Eq.** (3) in which no distribution of the correlation times is included. We are now trying to estimate the activation energy assuming a reasonable distribution of the correlation times.

---

* For simplicity, we use the second moment as the measure of narrowing when we considere how the rotation of the side chain affect narrowing, though the second moment is known to represent narrowing not exactly.

Although PVAc has the larger side chain, this material alone shows one step narrowing. This exceptional line width transition for PVAc could be explained by assuming the hinderance of the independent motion of side chain. In this point we will discuss in the next section.

§ 6. Discussion

It is found that some polymers showing two-step transition of the line width, such as PMMA and PS, also show the secondary loss peak in the elastic[3)] or dielectric[4)] properties as temperature changes.

These anomalies would be interpreted by the movements of the side chain rather than the movement of the main chain. Concerning the details of the rotation of the carboxyl group, which is in the side chain of PMMA, some studies have been carried out with the substances containing the same group through the various experimental techniques. For example, it is known that for the carboxyl group in acetic ester two configuration (forms (a) and (b) of Fig. 5) are supposed to be possible in view of the possibility of resonance, though one has higher energy than the other[17)]. And the anomalous absorption and dispersion of the ultrasonics for the above substance[17)] suggest the existance of the transition to the higher energy state.

It is seen, however, from the infrared spectra study that the population of the higher energy level is very small for substances like these, because of the steric hinderance in the acetate. As a result it may be concluded that such a transition like this may not be detectable through the proton magnetic study. On the other hand, about the methyl methacrylate, that is the monomer of PMMA, the rotation about C–C axis is affirmed to be possible even in the crystalline state through the Raman spectra study[18)].

On the other hand, measureing the dielectric loss for PVAc and PMA, Mead and Fuoss[4)] found that the dielectric loss curve for PVAc is sharper and larger than that for PMA. And they pointed out that the side chain in PVAc may rotate more freely than PMA at the temperature higher than T_g.

The asymmetry of Cole-Cole diagram for PVAc also suggests the existance of the fast rotation of the side chain. Through our observation of the nuclear magnetic resonance line, the movements of the side chain and the main chain are in separable, and they are strongly coupled to each other and show rapid narrowing, as it was stated. It is worthy to note, however, that the large and sharp dielectric loss curve for PVAc would also seem to be interpreted to come from the simultaneous occurance of the rotations of the side and main chain.

For PMA, the line width vs. temperature curve shows one-step narrowing in the temperature region of our measurement. But the fact that the half-width appeared to reduce at room temperature suggests one more transition in the lower temperature region.

It is plausible from the molecular structure that steric hinderance for the rotation of the side chain in PMA may be smaller than that in PVAc, and that the rotation of the side chain is more independent from the motion of the main chain than in PVAc. These considerations lead us to the interpretation that the broad dielectric loss curve for PMA results from the rotation of the side chain under the circumstance of the hinderance of the movements of the main chain. And besides, this consideration may explain why the transition temperature T_g of PMA is lower than that of PVAc.

It is interesting to note that the line width transitions in proton magnetic resonance begin, in general, at a lower temperature than the temperature at which the dielectric or elastic anomaly occures in the same order of time scale.

This can be explained by the following consideration. Generally speaking, the temperature of the transition or of the anomaly in polymer is given the relation $\tau=\tau_0 \exp(E/RT)$ in which τ means the averaged correlations time.

In the case of dielectric properties the correlation time should belong to the resultant motions of each dipole vector.

On the other hand, in the case of the nuclear magnetic resonance it is known that the short range interaction is predominant for the line width. Therefore, the correlation time τ for the nulear magnetic resonance is supposed to be smaller than the dielectric relaxation time, and then the transition of the line width occurs at the lower temperature. The detailed discussion concerning these problems will be published later.

Acknowledgment

We wish to express our sincere thanks to Assistant Professor Y. Yokozawa of the Institute for his helpful advice. Moreover we would like to express gratitude for the encouragement given by Prof. J. Furuichi of Hokkaido University. We are also indebted to Mr. M. Nagai for his assistance in carrying out the measurements.

APPENDEX I.

For the chain polymer of $(\text{-CH}_2\cdot\text{CHX-})_n$ type, the contribution of the intramolecular interaction to the second moment is readily obtained in the following two cases.

(1) **Planar Zigzag Chain**

In the case of the planar zigzag chain, that is the configuration of the stretched out chain polymer, distances between each proton in a chain are estimated by assuming the tetrahedral distribution of the chain skelton. Taking into account the interaction of the protons, each distance of which is less than about 3.5 A, the intramolecular contribution is found to be $\langle \varDelta H^2\rangle_{Av}=12.62-3.97/n$ gauss² from the equation of the second moment (2). But it is possible to neglect the second term in the above expression because of the large n for polymer. Therefore $\langle \varDelta H^2\rangle_{Av}$ is assumed to be 12.62 gauss².

(2) **Randomly Coiled Chain**

We shall now discuss the case of the randomly coiled chain, in which chain segments orientate at random with the tetragonal bond angle. In this case, the distances between each proton have to be statistically averaged, excepting the constant distance of the proton pair in CH_2 group.

The distance r_{12} between the proton $H_{n,1}$ and the proton $H_{n,2}$ and the distance r_{13} between the proton $H_{n,1}$ and $H_{n,3}$, as it is illustrated in Fig. 6(b) are determined by the following relations, respectively,

$$r_{12}^2=b^2+2a^2\left(1-\frac{1}{2}\cos\varphi-\frac{\sqrt{3}}{2}\sin\varphi\right) \qquad \text{(A1)}$$

$$r_{13}^2=b^2+2a^2(1+\cos\varphi)$$

where a is 1.03 A and b is 2.20 A.

Using these two equation, we get in the average

$$\left\langle \frac{1}{r_{12}^6}+\frac{1}{r_{13}^6}\right\rangle_{Av(\varphi)}=0.673\,A^{-6}\,. \qquad \text{(A2)}$$

The distance $r_{n,n\pm1}$ between the proton $H_{n,2}$ or $H_{n,3}$ and the proton $H_{(n\pm1),2}$ or $H_{(n\pm1),3}$ belonging to the next monomer is determined by following equations,

$$r_{n,n\pm1}^2=2\{(X_1-x)^2+(Y_1-y)^2+(Z_1-z)^2\}\,, \qquad \text{(A3)}$$

$$\begin{aligned} &X_1=R\cos\theta\cos\varphi_1+r\sin\theta \quad \begin{cases} x=R\cos\varphi_2 \\ y=R\sin\varphi_2 \end{cases} \\ \text{and}\quad &Y_1=R\sin\varphi_1\,, \\ &Z_1=-R\cos\varphi_1\sin\theta+r\cos\theta+r\,. \end{aligned} \qquad \text{(A3')}$$

Therefore, we get

$$\left\langle \frac{1}{r^6}\right\rangle_{Av(\varphi)}=0.366\,A^{-6}\,. \qquad \text{(A4)}$$

In the case of the randomly oriented chain, the proton, that is to say $H_{n,n\pm m}$, belonging to the monomer labelled $(n\pm m)$ being far from the monomer n in question, it is possible for the proton $H_{(n\pm m),i}$ to get close to the proton $H_{n,i}$ in question. Thus we have to take this into account. If the m is large enough, the statistics of the random flights chain[19] with fixed bond lengths and fixed valence angles, tells us that the distribution of $r_{n,n\pm m}$ is Gaussian, and is given by the following equation

$$f(r)=\left(\frac{3}{2\pi R^2}\right)^2\exp\left(-\frac{3r^2}{2R^2}\right), \qquad \text{(A5)}$$

were R^2, the average of r^2, is,

$$R^2=N_q^2(1+\cos\theta)/(1-\cos\theta)\,. \qquad \text{(A5')}$$

Using this distribution, one can approximately evaluate through

$$\left\langle \frac{1}{6}\right\rangle_{Av}{}_{r_{n,n\pm m}}=\int_{r_0}^{r_{max}}\frac{1}{r^6}f(r)dr\,. \qquad \text{(A6)}$$

Table III.

	Planar zigzag (gauss²)	Random coil (gauss²)	Gaussian (gauss²)	
$\langle \varDelta H_{11}^2\rangle$	3.85	4.85		
$\langle \varDelta H_{12}^2\rangle$	3.63	2.64		
$\langle \varDelta H_{132}\rangle$			1.43	$(r_{max.})$ (5.0 A)
$\langle \varDelta H_{14}^2\rangle$			0.90	(6.8 A)

Actually, the lower limit of the integral in the above equation is somewhat arbitary. It may be reasonably assumed, however, that the proton is not possible to come close together within its Van der Waals redius and then the lower limit it taken as 2.4 A[20]. The values of the second moment for $m=3, 4$ as well as the previous results are listed in Table III.

APPENDEX II.

The Interaction Between Side Chain and Main Chain.

(1) **Polystyrene**

At first we assume that the main chain is fully stretched and it is in the state of polanar zigzag. The proton pairs which are consisted of protons in the phenyl group, protons in the main chain and a proton in a neighbouring phenyl group are H_1-H_2, H_3-H_6 and H_3-H_8, as it is shown in Fig. 7. We can certainly object to this assumption on physical grounds: however, it leads to the equations which given us the characteristic of the configuration in the rigid state. As protons in the phenyl groups are not possible to come close together within their Van der Waals radius 1.2 A, the groups do not orientate freely but presumably within the range of about 30°, thus the value of φ should be taken within this extent. For each proton pair H_i-H_j the distance r_{ij} is given respectively as follows.

$$\left.\begin{aligned} r_{12}^2 &= 9.92-4.26\cos\varphi \\ r_{36}^2 &= 11.29-10.78\sin\varphi \\ r_{38}^2 &= 23.14-3.05\cos\varphi_1\cos\varphi_2 \\ &\quad +4.28\sin\varphi_1\sin\varphi_2 \\ &\quad +10.79(\sin\varphi_1+\sin\varphi_2) \\ &\quad -6.85(\cos\varphi_1+\cos\varphi_2) \\ &\quad +4.95(\sin\varphi_1+\sin\varphi_2)^2 . \end{aligned}\right\} \qquad (A7)$$

Therefore we get in the average,

$$\begin{aligned} \langle \varDelta H_{12}^2\rangle_{Av(\varphi)} &= 3.94 \ \text{gauss}^2 \\ \langle \varDelta H_{36}^2\rangle_{Av(\varphi)} &= 1.87 \ \text{gauss}^2 \\ \langle \varDelta H_{38}^2\rangle_{Av(\varphi)} &= 1.27 \ \text{gauss}^2 . \end{aligned} \qquad (A8)$$

(2) **PMMA**

The absorption line for the triangular group is given by Andrew et al[21]. For the rotating triangular group the absorption line is given by the following expression

$$f(x)=\frac{1}{2\sqrt{2\pi\alpha}}\exp\left(-\frac{x^2}{2\alpha}\right) + \int_{-\infty}^{\infty} P_{\pm}(x_0)\exp\{-(x-x_0)^2/2\alpha^2\} , \qquad (A9)$$

where α^2 means the additional second moment due to the external broadening, and $P_{\pm}(x)$ of the shape function of the triangular group is

$$P_{\pm}(x)=\frac{1}{8\sqrt{3}\beta}(1\pm x/\beta)^{-1/2} \qquad (A10)$$

for

$$-\beta<\pm x\leqslant 2\beta .$$

As a result the second moment due to the external broadening is determined by obtaining the maximum slope width of the absorption line (A9). This relation is given by the solid line shown in the Fig. 8. For example, α^2 is 3.35 gauss² at $\varDelta H_{m.sl.}=3.8$ gauss for CH_3 group ($\beta=4.4$ gauss).

Nuclear Magnetic Resonance in Some Crystalline Polymers

By Atsuo NISHIOKA
Electrical Communication Laboratory, Musashino, Tokyo
Hachiro KOMATSU and Yoshinobu KAKIUCHI
Institute of Science and Technology, Tokyo University

(Received November 27, 1956)

Nuclear magnetic resonance absorption was studied for some linear crystalline polymers in the temperature range from liquid air temperature to the neighbourhood of the melting points of the samples. The second moments of the absorption curve observed for the rigid samples were in well accordance with the calculated moments about their assumed crystalline forms.

Recently the line width transitions of crystalline linear polymers such as polyethylene (P.E.) and polytetrafluoroethylene (P.T.F.E.) have been studied using the nuclear magnetic resonance technique by several workers.[1-3)

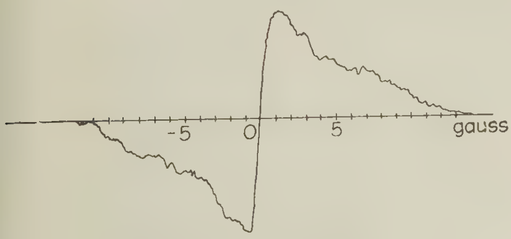

Fig. 1 (a). P.E., 1.2°C.

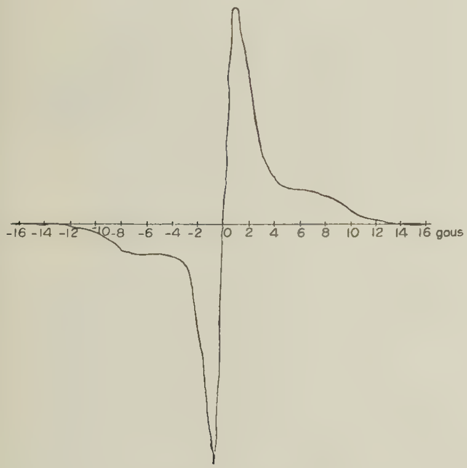

Fig. 1 (b). Polyethylene annealed for 30 min. at 100C°

We have studied these polymers and polytrifluorochloroethylene (P.T.F.C.E.) in further detail by nuclear magnetic resonance in wider temperature range from liquid air temperature to the neighbourhood of their melting points. Preliminarily, the polyvinylchloride (P.V.C.) has also been studied.

The derivatives of the absorption curves at room temperature are shown in Fig. 1~3 which show the composite structure with the sharp peak and long tail for P.E. and P.T.F.E., and broad bell shape for P.T.F.C.E. and P.V.C. Temperature dependences of the line widths defined as the separation between the maximum slopes ΔH_p, and the half maximum height width, $\Delta H_{1/2}$, of the absorption curves are shown in Fig. 4~6.

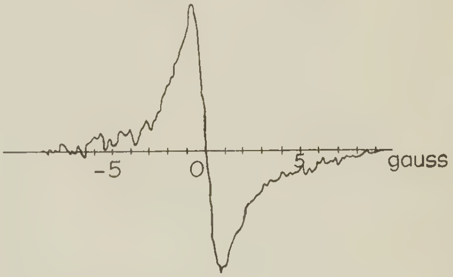

Fig. 2. P.T.F.E., 1.6°C.

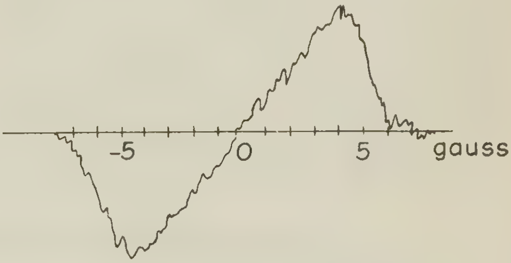

Fig. 3. P.T.F.C.E., 6°C.

The magnitude of ΔH_p or $\Delta H_{1/2}$ of the annealed samples of P.E. are comparable to those of the quenched specimen. In some cases, we observed the shoulder part pointed out by Wilson and Pake[2] in the annealed specimen as shown in Fig. 1 (b), whereas not in the quenched ones. With increasing temperature, the difference between ΔH_p and $\Delta H_{1/2}$ becomes larger. This is assumed to be due to the onset of the segmental motions of chain molecules. The tendencies of the changes of the line widths are very similar in P.E. and P.T.F.E. According to the results of Fig. 4, the "freezing temperature" of the segments, where the thermal motion of the segments begin to be stopped, is assumed around −100°C for both samples. With increasing temperature above this critical region, the line width decreases gradually in certain temperature range of −100°C∼0C°, and then drops markedly to a small value in the room temperature. Then the width continuously decreases with temperature from the room temperature to the melting point. On the other hand, P.T.F.C.E. has relatively monotonous decreasing curve as seen from Fig. 6 and the segments are frozen in about −30°C, but this temperature would depend upon the crystallinity of polymer. The behavior of P.V.C. are in well accordance with the results reported by Odajima.[4]

The observed second moment at the rigid state are shown in Table I. Assuming paraffine-like structure of plane zigzag molecule and further assuming that the expantion coefficient and axial ratio a/b of P.T.F.E. and P.T.F.C. are equal to that of P.E., we calculated the intra- and inter-molecular contribution to the second moment on the basis of the data of P.E. at liquid air temperature, and obtained the results shown in Table I, which are in well accordance with the observed values. These results may be considered to suggest that the chain molecules of these crystalline polymers have short range order in their rigid state.

Self-consistent Field without Exchange for Doubly Ionized Cobalt

By Masataka ARIYAMA, Kunihusa KAYAMA and Masayoshi SUGIMOTO

Department of Physics, University of Tokyo

(Received December 7, 1956)

A self-consistent field without exchange for Co^{++} ion has been calculated and the tables of the results are given. Preliminary calculations were carried out with the aid of the differential analyzer, and the final results were obtained by the numerical integration. In the final approximation, the difference between estimated and calculated values of the contribution to Z_p from each subshell does not exceed 0.01 at any radius.

§ 1. Introduction

For the analysis of the atomic spectra, for the quantitative discussion of the properties of the fluoride, oxide, complex salts and intermetallic compounds of cobalt, and further for the calculation of the electronic structure of the metallic cobalt, it is desirable to know the atomic wave functions for Co as accurately as possible. The rough estimates of these atomic wave functions may be obtained by the interpolation between the wave functions for the atoms for which the calculations of the self-consistent field have already been carried out. The self-consistent field for Fe[1] and Cu^{+} [2] are available, and they may be used for the interpolation for Co. However, the interpolated wave functions are not sufficient for some applications. Therefore, it seems to be worth while to carry out a complete calculation of the self-consistent field without exchange for the paticular ion Co^{++}. The results of this calculation are reported in this paper, and they may be used for some applications which are mentioned above. Further, if it is found necessary to obtain the self-consistent field for the other electron configuration or the self-consistent field with exchange for this atom, the results for the Co^{++} ion will provide useful starting estimates of the wave functions.

In the present calculation, the electron configuration of the Co^{++} ion was assumed to be $(1s)^2\ (2s)^2\ (2p)^6\ (3s)^2\ (3p)^6\ (3d)^7$. Simultaneous integro-differential equations for six radial functions have been solved by the well known iterative method devised by Hartree[3]. Numerical work has been carried out partly with desk machines and partly with the diffferentical analyzer, which was recently designed and constructed in the Institute for Industrial Science, University of Tokyo. In using the differential analyzer, we followed in the technique used by Manning and others, who worked out several self-consistent field calculations with the aid of the differential analyzer in M.I.T.[1],[4],[5]

§ 2. Method and Procedure

As the detail of the practical procedure of calculating the Hartree field is reported in many literatures[3],[6],[7], only the outline of the method will be described here. In this paper, atomic units are used for all quantities except the eigenvalue for which the Rydberg unit is used.

The total wave function of the many electron atom is written as a product of one electron wave function of the type

$$\psi_{nl}=\frac{P_{nl}(r)}{r}\phi(\theta,\varphi)\,. \qquad (1)$$

The radial factor $P_{nl}(r)$ is the solution of the wave equation

$$\frac{d^2P_{nl}}{dr^2}+\left[2v^{(nl)}-\mathcal{E}_{nl}-\frac{l(l+1)}{r^2}\right]P_{nl}=0 \qquad (2)$$

where $\mathcal{E}_{nl}$ is the eigenvalue and $v^{(nl)}$ is the effective potential which is due to the nuclear charge and averaged charge distribution of that atom:

$$v^{(nl)}=\frac{1}{r}\left\{1+c+\sum_{n'l'}^{\text{all occupied subshells}}Z_p(n'l';r)-\frac{Z_p(nl;\ r)}{N_{nl}}\right\} \qquad (3)$$

where c is the degree of ionization and N_{nl} is the number of electrons in the subshell (nl). $Z_p(nl;\ r)$ is determined by the following relations.

$$\frac{dZ_p(nl;\ r)}{dr}=\frac{Z_p(nl;\ r)-Z(nl;\ r)}{r}, \qquad (4)$$

$$Z(nl;\ r)=N_{nl}\left\{1-\int_0^r P_{nl}^2\,dr\Big/\int_0^\infty P_{nl}^2\,dr\right\}. \qquad (5)$$

$Z(nl;\ r)$ is the contribution to the effective charge from N_{nl} electrons in the subshell (nl) and the corresponding positive charge on the nucleus. $Z_p(nl;\ r)$ is the contribution to the effective charge for potential, from N_{nl} electrons in the subshell (nl) and the corresponding positive charge on the nucleus.

It is convenient to start the self-consistent calculation from the estimated $Z_p(nl;\ r)$'s for each subshell. Then, $v^{(nl)}$ is calculated by (3) and the set of equations of the type of (2) is solved. The eigenvalue is determined by integrating the wave equation outwardly from $r=0$ and inwardly from large r with a trial values of $\mathcal{E}_{nl}$, and adjusting the value of $\mathcal{E}_{nl}$ so as to make the logaritymic derivatives of the solutions fit at a certain intermediate radius.

For the integration of Eq. (2), it is convenient to introduce a new independent variable $\rho=\log 1000r$ and new dependent variables $Y_{nl}=P_{nl}r^{-1/2}$ and $Q_{nl}=-\frac{1}{Y_{nl}}\frac{dY_{nl}}{d\rho}$, as has been suggested by Hartree5). With these variables, Eq. (2) is transformed into the following forms:

$$\frac{d^2Y_{nl}}{d\rho^2}+\left[2rZ_p^{(nl)}-\mathcal{E}_{nl}r^2+\left(l+\frac{1}{2}\right)^2\right]Y_{nl}=0, \qquad (6)$$

$$\frac{dQ_{nl}}{d\rho}=\left[Q_{nl}^2+2rZ_p^{(nl)}-\mathcal{E}_{nl}r^2-\left(l+\frac{1}{2}\right)^2\right], \qquad (7)$$

where $Z_p^{(nl)}=rv^{(nl)}$. Eq. (6) is used for the outward integration from $r=0$, and Eq. (7) is suitable for the inward integration from larger r.

When $P_{nl}(r)$'s are known, $Z(nl;\ r)$'s are calculated by (5) and the $Z_p(nl;\ r)$'s are obtained by solving Eq. (4) subject to the condition that $Z_p(nl;\ r)\rightarrow 0$ at large values of r. These calculated $Z_p(nl;\ r)$'s are compared with the estimated $Z_p(nl;\ r)$'s which are used to construct $v^{(nl)}$'s. The difference between the calculated and the estimated $Z_p(nl;\ r)$ for each subshell will be denoted by $\Delta Z_p(nl;\ r)$, and it is considered to be the measure of the consistency. These procedures form the one cycle of the interative process of our self-consistent field calculatirn, and it must be repeated until an estimate of the set of $Z_p(nl;\ r)$'s which makes the resulting $\Delta Z_p(nl;\ r)$'s sufficiently small is found.

In the present calculation, the consistency aimed at was 0.01 in $Z_p(nl;\ r)$, i.e. $\Delta Z_p(nl;r) < 0.01$ at any radius and for any subshell. The initial estimates of $Z_p(nl;\ r)$'s for Co^{++} were obtained by an interpolation4) between $Z_p(nl;\ r)$'s of Fe1) and those of Cu^{+} 2). To find the eigenvalue and eigenfunction for a paticular subshell, Eq. (2) was integrated for five different trial values of $\mathcal{E}_{nl}$ which were spread about the expected eigenvalue of that subshell.*) For a chosen value of $\mathcal{E}_{nl}$, integration was carried out by the following procedure.

For small values of r, $\frac{dY_{nl}}{d\rho}\Big/Y_{nl}$ can be expanded into a power series of r**). The value of $\frac{dY_{nl}}{d\rho}\Big/Y_{nl}$ at $\rho=0$ $(r=0.001)$ was found by this power series expansion, and from $\rho=0$, Eq. (6) was integrated outwardly with the aid of the differential analyzer. On the other hand, Eq. (7) was integrated inwardly with the aid of the differential analyzer. The starting point of this integration was taken well outside the range in which P_{nl} is appreciable, and the initial values were determined by the expansion of Q_{nl} in the power series of $1/r$.**)

---

*) This estimation was made from the X-ray term values for neutral Co. See, Manne Siegbahn; Spektroskopie der Röntgen strahlen, Berlin, 1931, p. 348.

**) As to the power series expansion, see Reference 1).

The eigenvalue was determined by graphical interpolation as follows. At a certain radius ρ_1, both $\left[\frac{dY_{nl}}{d\rho}\Big/Y_{nl}\right]_{\rho=\rho_1}$ obtained from outward integration and $Q_{nl}(\rho_1)$ obtained from inward integration are smooth functions of $\mathcal{E}_{nl}$. Thus $\left[\frac{dY_{nl}}{d\rho}\Big/Y_{nl}\right]_{\rho=\rho_1}$'s for each of the five values of $\mathcal{E}_{nl}$ were plotted and a curve of $\left[\frac{dY_{nl}}{d\rho}\Big/Y_{nl}\right]_{\rho=\rho_1}$ vs. $\mathcal{E}_{nl}$ was drawn. Similarly a curve of $-Q_{nl}(\rho_1)$ vs. $\mathcal{E}_{nl}$ was drawn. The value of $\mathcal{E}_{nl}$ with which $\left[\frac{dY_{nl}}{d\rho}\Big/Y_{nl}\right]_{\rho=\rho_1}=-Q_{nl}(\rho_1)$, was found from the intersection of those two curves. This procedure was carried out at two different values of the radius to check the accuracy of the determination, and it was confirmed that the eigenvalue can be determined to four or five significant figures by this crude graphical method, if trial values of $\mathcal{E}_{nl}$'s were chosen properly.

The eigenfunction was determined by an interpolation, with respect to the value of $\mathcal{E}_{nl}$, between the solutions which had already been obtained for several trial values of $\mathcal{E}_{nl}$. From the obtained eigenfunctions, $Z(nl;\,r)$'s and $Z_p(nl;\,r)$'s were caclulated. Using ρ as the independent variable, we have the explicit representation of the solution of Eq. (4) as follows,

$$Z_p(nl;\,\rho)=e^{\rho}\int_{\infty}^{\rho} Z(nl;\,\rho)\,e^{-\rho}\,d\rho\,.$$

These calculations were carried out with desk machines.

The maximum value of $\Delta Z_p(nl;\,r)$ was not less than 0.4 in the first approximation, and eight approximations were needed to obtain the consistency aimed at.

In the second and the third approximations, the calculated $Z_p(nl;\,r)$ of the preceding approximation was used as the estimate of $Z_p(nl;\,r)$ for the next approximation. This simple iterative process converged for inner shells, but oscillated for 3*s* and 3*p* shells, and diverged for 3*d* shell. Therefore, a revised estimate of $Z_p(nl;\,r)$ for 1*s*, 2*s*, 2*p*, 3*s*, and 3*p* electrons were made by averaging the results of 1st and 2nd approximations, and fixing these $Z_p(nl;\,r)$'s, $Z_p(3d;\,r)$ which was consistent with these revised estimates of $Z_p(nl;\,r)$ for other subshells was sought by the trial and error method. As had been reported by Manning and Goldberg,[1] once this approximate self-consistent field was found, the iterative process converged rapidly. From the 4th approximation, the average of the estimated and the calculated $Z_p(nl;\,r)$'s of the preceding approximation was used as the estimate of $Z_p(nl;\,r)$'s for the next approximation. This method of estimation

quickens the convergence, and at the same time, has a merit of preventing the divergence which is apt to occur for the outer subshells.

In the 7th approximation, the consistency aimed at was obtained. The 8th approximation was carried out entirely by desk machines to refine the results and to check the systematic error of the differential analyzer. The systematic error was found to be very small, and if careful set-up is used, relative error of the solution will be less than 1% except at some singular points. The schematic diagrams for the set-up of the differential analyzer for the solution of the Eqs. (6) and (7) are shown in Fig. (1) and (2).[8]

§ 3. Results

Tables are given of the values of Y, $2Z$, and $2Z_p$ for each type of electrons as a function of ρ. Tables of ε_{nl}, $\int_{-\infty}^{\infty} Y^2 e^{2\rho}\,d\rho$, $-2v_0(nl)$, and the maximum value of $\Delta Z_p(nl; r)$ are also given. In the actual integrations, one or two more significant figures have been retained in the calculations than are tabulated. Slater Intetegrals F_2, F_4,[9] spin-orbit separation parameter ζ_{3d}[10] and several intermultiplet separations are calculated from the values tabulated in Tables II and IV, and are compared with those values estimated from optical data.[11] These results are tabulated in Table VI. The discrepancy between the calculated and estimated values is less than 5% of the magnitude of each of these quantities, but ^4P and ^2G levels are obtained in wrong order. These discrepancies would not be reduced even if more convergent solutions of Hartree equations were used for the calculation.

Table V. Values of ε_{nl}, $\int_{-\infty}^{\infty} Y_{nl}^2 e^{2\rho}\,d\rho$, $-2v_0(nl)$ and $2\Delta Z_p(nl; r)$

	$(1s)$	$(2s)$	$(2p)$	$(3s)$	$(3p)$	$(3d)$
ε_{nl}	567.07	67.357	59.558	8.7897	6.2520	2.1216
$\int_{-\infty}^{\infty} Y_{nl}^2 e^{2\rho}\,d\rho$	13869	15502×10	31552×10	10636×10^2	23205×10^2	39143×10^2
$-2v_0(nl)$	106.1	22.4	67.3	7.04	19.66	17.14
$2\Delta Z_p(nl; r)$	≤ 0.001	≤ 0.006	≤ 0.007	≤ 0.006	≤ 0.014	≤ 0.002

$v_0(nl)$ is the contribution from N_{nl} electrons in the subshell (nl) to the potential at the position of nucleus.

Table VI. F_2, F_4, ζ_{3d} and intermultiplet separations

	Calculated	Estimated from observation
F_2	1685.2 cm^{-1}	1598.8 * cm^{-1}
F_4	115.32	123.81*
ζ_{3d}	519.8	527.4 **
$^4P-{}^4F$	16630.5	14697.2
$^2G-{}^4F$	16541.3	16918.9
$^2H-{}^4F$	22084.8	21817.9

* The values of F_2 and F_4 are estimated by the least square method.

** The value of ζ_{3d} is estimated from the average of fine structure separations of ^4F levels.

§ 4. Acknowledgements

The authors would like to express their sincere gratitude to Prof. Kotani and the members of his laboratory for their helpful discussions and to Dr. Watanabe and Dr. Miita of Institute for Industrial Science for their instruction as to the use of the differential analyzer. They also wish to express their indebtedness to Misses S. Maniwa, J. Matsuoka and K. Murata for their assistance in carrying out the numerical work.

The Forces Experienced by Two Circular Cylinders in a Uniform Flow at Small Reynolds Numbers

By Shinji KUWABARA

Department of Physics, Faculty of Science, University of Tokyo

(Received December 7, 1956)

Using Imai's general method of solving two-dimensional Oseen's equations, the drag and lift coefficients for one of two parallel circular cylinders in a uniform flow at small Reynolds numbers have been calculated. The general expressions for these coefficients become very simple when the two cylinders are placed symmetrically with respect to the uniform flow. Numerical calculations have been carried out in several cases for various values of the parameters.

§1. Introduction and Summary

As is well known, the motion of an incompressible viscous fluid past obstacles at small Reynolds numbers can be described by Oseen's approximate equations. With the aid of these Oseen's equations the viscous flow past a single obstacle such as a sphere, a circular cylinder, etc. has been studied by several authors, but there have been few works concerning the case of two obstacles. Here, the case of two circular cylinders placed in general configurations in a uniform flow, will be investigated with a, d, α and R as parameters, where a is the radius of the second circular cylinder (the radius of the first circular cylinder is normalized as unity), d the distance between the centres of the two cylinders, α the angle between the direction of the uniform flow and the vector drawn from the centre of the first cylinder to that of the second and R the Reynolds number based on the diameter of the first cylinder.

Prof. Imai proposed an elegant general method of solving Oseen's equations by introducing complex variables [1], and we shall make use of his method in our study. We calculate the drag and the lift coefficients of one of the two circular cylinders and then the resultant drag, lift and moment coefficients of the system of the two circular cylinders are related to these coefficients of each cylinder.

Numerical calculations were carried out in the following cases; (i) $a=1$; $d=5$, 10, 20; $\alpha=0°$, 90°, 180°; $R=0.04-1.0$. (ii) $a=1$; $d=5$; $\alpha=0°-180°$; $R=0.4$, 0.8 and (iii) $a=0-3.0$; $d=10$; $\alpha=0°$, 90°, 180°; $R=0.4$, 0.8. The qualitative results obtained from these calculations are as follows: (i) the drag coefficients for one of the two cylinders are smaller than that for a single cylinder at the same Reynolds numbers; (ii) the mutual interaction is attractive when the central line is parallel to the uniform flow and is repulsive when it is perpendicular; (iii) the force acting on the first cylinder is roughly in the direction of the flow induced when the second cylinder alone is in the uniform flow and (iv) if the two cylinders of the same radius connected rigidly are falling in a viscous fluid, there exists a tendency that the central line becomes perpendicular to the direction of fall.

§ 2. Imai's Method of Solving Oseen's Equations

Oseen's approximate equations and the equation of continuity for the two-dimensional steady motion of an incompressible viscous fluid can be written as

$$U\frac{\partial u}{\partial x}=-\frac{1}{\rho}\frac{\partial p}{\partial x}+\nu\Delta u\,, \qquad (2.1)$$

$$U\frac{\partial v}{\partial x}=-\frac{1}{\rho}\frac{\partial p}{\partial y}+\nu\Delta v\,, \qquad (2.2)$$

and

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\,, \qquad (2.3)$$

where $\Delta=\partial^2/\partial x^2+\partial^2/\partial y^2$, (x, y) are the cartesian co-ordinates, (u, v) the velocity components, U the velocity at infinity of a uniform flow in the direction of the x-axis, p the pressure, ρ the density and ν the kinematic viscosity.

Eliminating p from (2.1) and (2.2), we have

$$\Delta\omega-2k\frac{\partial\omega}{\partial x}=0\,, \qquad (2.4)$$

where ω is the vorticity defined by

$$\omega=\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}\,, \qquad (2.5)$$

and $2k=U/\nu$.

Introducing complex variables

$$z=x+iy,\quad z=x-iy\,, \qquad (2.6)$$

and

$$W=u-iv\,, \qquad (2.7)$$

we obtain from (2.3) and (2.5)

$$\frac{\partial W}{\partial\bar{z}}=-\frac{1}{2}i\omega\,. \qquad (2.8)$$

The general solution of (2.4) satisfying $\omega=0$ at infinity can be expressed as

$$\omega=\Re\sum_{n=0}^{\infty}C_n e^{kx}K_n(kr)e^{ni\theta}\,, \qquad (2.9)$$

where (r, θ) are polar co-ordinates, K_n is the modified Bessel function of the second kind, C_n is a complex coefficient and $\Re$ signifies "the real part of".

Inserting (2.9) into (2.8) and integrating with respect to $\bar{z}$, we have

$$W=\frac{i}{2k}e^{kx}\Big\{A_1K_0(kr)+\sum_{n=1}^{\infty}(A_{n+1}e^{ni\theta}-\bar{A}_n e^{-ni\theta})K_n(kr)\Big\}+\frac{df}{dz}\,, \qquad (2.10)$$

where $A_n=\sum_{p=n}^{\infty}C_p$ is a new complex coefficient and $f(z)$ is an arbitrary analytic function of z. In Oseen's approximation, $f(z)$ can be expressed in general as

$$f(z)=Uz+\frac{m+i\Gamma}{2\pi}\ln z+O\Big(\frac{1}{z}\Big)\,, \qquad (2.11)$$

where m and Γ are constants.

§ 3. Application of Imai's Method to the Case of Two Circular Cylinders

Since Oseen's equations are linear, the sum of the complex velocities (2.10) is also their solution. In the case of two circular cylinders we assume the following form for the complex velocity

$$W(z_1, z_2)=W_1(z_1)+W_2(z_2)+U\,, \qquad (3.1)$$

$$W_1=\frac{i}{2k}e^{kx_1}\Big\{A_1^{(1)}K_0(kr_1)+\sum_{n=1}^{\infty}(A_{n+1}^{(1)}e^{ni\theta_1}-\bar{A}_n^{(1)}e^{-ni\theta_1})K_n(kr)_1\Big\}+\frac{m_1+i\Gamma_1}{2\pi}\frac{1}{z_1}+\cdots\,, \qquad (3.2)$$

$$W_2=\frac{i}{2k}e^{kx_2}\Big\{A_1^{(2)}K_0(kr_2)+\sum_{n=1}^{\infty}(A_{n+1}^{(2)}e^{ni\theta_2}-\bar{A}_n^{(2)}e^{-ni\theta_2})K_n(kr_2)\Big\}+\frac{m_2+i\Gamma_2}{2\pi}\frac{1}{z_2}+\cdots\,, \qquad (3.3)$$

where

$$z_1=x_1+iy_1=r_1e^{i\theta_1},\quad z_2=x_2+iy_2=r_2e^{i\theta_2} \qquad (3.4)$$

are vectors drawn from the centres of the circular cylinders C_1 and C_2 to a point P in question respectively. The radius of the cylinder C_1 is normalized as unity and that of the cylinder C_2 is a. $de^{i\alpha}$ is a vector connecting the centres of C_1 and C_2 (*cf.* Fig. 1).

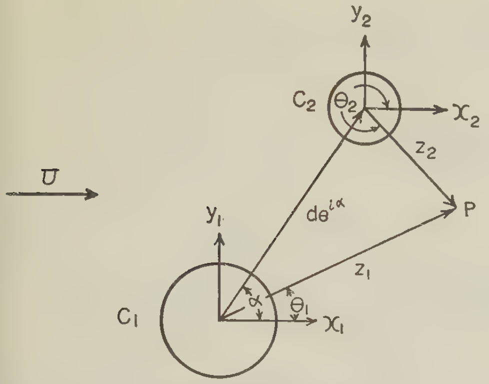

Fig. 1. The general configuration of two circular cylinders.

The boundary conditions are

$$W=0$$

at the surfaces of the cylinders C_1 and C_2, or

$$W_1(e^{i\theta})+W_2(-de^{i\alpha}+e^{i\theta})+U=0\ , \qquad (3.5)$$

$$W_1(de^{i\alpha}+ae^{i\theta})+W_2(ae^{i\theta})+U=0\ . \qquad (3.6)$$

Expanding these equations (3.5) and (3.6) with respect to $e^{i\theta}$, we have

$$\begin{aligned}\cdots&+e^{i\theta}\{A_2^{(1)}I_0(k)K_1(k)+O(k^2)\}\\ &+A_1^{(1)}I_0(k)K_0(k)-\bar{A}_1^{(1)}I_1(k)K_1(k)\\ &+e^{-kd\cos\alpha}I_0(k)^2\{A_1^{(2)}K_0(kd)+\bar{A}_1^{(2)}K_1(kd)e^{-i\alpha}\}\\ &+ik\frac{m_2+i\Gamma_2}{\pi}\frac{e^{-i\alpha}}{d}+O(k^2)\\ &+e^{-i\theta}\left\{-\bar{A}_1^{(1)}I_0(k)K_1(k)-ik\frac{m_1+i\Gamma_1}{\pi}+O(k^2)\right\}\\ &+\cdots=2ikU\ , \qquad (3.7)\end{aligned}$$

$$\begin{aligned}\cdots&+e^{i\theta}\{A_2^{(2)}I_0(ka)K_1(ka)+O(k^2)\}\\ &+e^{kd\cos\alpha}I_0(ka)^2\{A_1^{(1)}K_0(kd)-\bar{A}_1^{(1)}K_1(kd)e^{-i\alpha}\}\\ &+A_1^{(2)}I_0(ka)K_0(ka)-\bar{A}_1^{(2)}I_1(ka)K_1(ka)\\ &-ik\frac{m_1+i\Gamma_1}{\pi}\frac{e^{-i\alpha}}{d}+O(k^2)\\ &+e^{-i\theta}\left\{-\bar{A}_1^{(2)}I_0(ka)K_1(ka)\right.\\ &\left.-ik\frac{m_2+i\Gamma_2}{\pi}\frac{1}{a}+O(k^2)\right\}+\cdots=2ikU\ . \qquad (3.8)\end{aligned}$$

Here we have assumed that $k\ll 1$, $a\doteqdot 1$, $kd=O(1)$ and therefore $A_n=O(k^n)$. Retaining the terms of the order 1 and k and neglecting those of higher order in (3.7) and (3.8) as the first approximation, we have six algebraic equations for the complex numbers $A_1^{(1)}$, $A_2^{(1)}$, $A_1^{(2)}$, $A_2^{(2)}$, $m_1+i\Gamma_1$ and $m_2+i\Gamma_2$;

$$A_2^{(1)}I_0(k)K_1(k)=0\ , \qquad (3.9)$$

$$\begin{aligned}&A_1^{(1)}I_0(k)K_0(k)-\bar{A}_1^{(1)}I_1(k)K_1(k)+e^{-kd\cos\alpha}I_0(k)^2\\ &\quad\times\{A_1^{(2)}K_0(kd)+\bar{A}_1^{(2)}K_1(kd)e^{-i\alpha}\}\\ &\quad+ik\frac{m_2+i\Gamma_2}{\pi}\frac{e^{-i\alpha}}{d}=2ikU\ , \qquad (3.10)\end{aligned}$$

$$-\bar{A}_1^{(1)}I_0(k)K_1(k)-ik\frac{m_1+i\Gamma_1}{\pi}=0\ , \quad (3.11)$$

$$\bar{A}_2^{(2)}I_0(ka)K_1(ka)=0\ , \qquad (3.12)$$

$$\begin{aligned}&e^{kd\cos\alpha}I_0(ka)^2\{A_1^{(1)}K_0(kd)-\bar{A}_1^{(1)}K_1(kd)e^{-i\alpha}\}\\ &\quad+A_1^{(2)}I_0(ka)K_0(ka)-\bar{A}_1^{(2)}I_1(ka)K_1(ka)\\ &\quad-ik\frac{m_1+i\Gamma_1}{\pi}\frac{e^{-i\alpha}}{d}=2ikU\ , \qquad (3.13)\end{aligned}$$

$$-\bar{A}_1^{(2)}I_0(ka)K_1(ka)-ik\frac{m_2+i\Gamma_2}{\pi}\frac{1}{a}=0\ . \qquad (3.14)$$

Now the drag coefficients $C_D^{(1)}, C_D^{(2)}$ and the lift coefficients $C_L^{(1)}, C_L^{(2)}$ for the cylinders C_1, C_2 are respectively defined as

$$C_D^{(1)}=\frac{X_1}{\frac{1}{2}\rho U^2\times 2}\ , \qquad C_L^{(1)}=\frac{Y_1}{\frac{1}{2}\rho U^2\times 2}\ , \qquad (3.15)$$

$$C_D^{(2)}=\frac{X_2}{\frac{1}{2}\rho U^2\times 2a}\ , \qquad C_L^{(2)}=\frac{Y_2}{\frac{1}{2}\rho U^2\times 2a}\ , \qquad (3.16)$$

where X_1, X_2 and Y_1, Y_2 are the drags and the lifts for the cylinders C_1, C_2 respectively.

As is well known, the drag X and the lift Y of a cylinder are given by

$$X=\rho Um\ , \quad Y=\rho U\Gamma\ , \qquad (3.17)$$

where m and Γ are constants which appeared in (2.11).

If $C^{(1)}$ and $C^{(2)}$ are defined as

$$C^{(1)}=C_D^{(1)}+iC_L^{(1)}, \quad C^{(2)}=C_D^{(2)}+iC_L^{(2)}\ , \qquad (3.18)$$

we have, by (3.15), (3.16) and (3.17),

$$m_1+i\Gamma_1=UC^{(1)}, \quad m_2+i\Gamma_2=aUC^{(2)}\ . \qquad (3.19)$$

Since $k\ll 1$ and $ka\ll 1$, we can make use of the following approximate formulae;

$$\begin{aligned}K_0(k)=&-\ln(\tfrac{1}{2}k)-\gamma-(1/4)k^2\{\ln(\tfrac{1}{2}k)+\gamma-1\}\\ &+O(k^4), \qquad (3.20)\end{aligned}$$

$$K_1(k)=\tfrac{1}{2}(\tfrac{1}{2}k)^{-1}+\tfrac{1}{2}k\{\ln(\tfrac{1}{2}k)+\gamma-\tfrac{1}{2}\}+O(k^3)\ , \qquad (3.21)$$

and similar formulae as obtained by putting ka in place of k in (3.20) and (3.21), where

$\gamma=0.57721\cdots$ is Euler's constant. Then we can rewrite (3.10)–(3.14) as follows:

$$\tfrac{1}{2}C^{(1)}+S_1\overline{C}^{(1)}-a\left(K_1e^{-(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)e^{-i\alpha}C^{(2)}$$
$$+aK_0e^{-(Rd/4)\cos\alpha}\overline{C}^{(2)}=\frac{8\pi}{R}, \qquad (3.22)$$

$$\left(K_1e^{(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)e^{-i\alpha}C^{(1)}+K_0e^{(Rd/4)\cos\alpha}\overline{C}^{(1)}$$
$$+\tfrac{1}{2}aC^{(2)}+aS_2\overline{C}^{(2)}=\frac{8\pi}{R}, \qquad (3.23)$$

where

$$S_1=\ln\frac{8}{R}-\gamma, \quad S_2=\ln\frac{8}{Ra}-\gamma, \qquad (3.24)$$

$R=4k=2U/\nu$ is the Reynolds number based on the diameter of the cylinder C_1 and the argument $kd=Rd/4$ of the modified Bessel function $K_n(kd)$ is omitted for brevity in (3.22), (3.23) as well as in the following lines. (3.22), (3.23) and their complex conjugate equations determine $C^{(1)}, \overline{C}^{(1)}, C^{(2)}$ and $\overline{C}^{(2)}$. And then we obtain the drag and the lift coefficients by means of taking their real and imaginary parts of these coefficients. We consider, for example, only the coefficients of the first cylinder C_1 for brevity:

$$C_D^{(1)}=\frac{8\pi}{R}\frac{\Delta_X^{(1)}}{J}, \qquad (3.25)$$

$$C_L^{(1)}=\frac{8\pi}{R}\frac{\Delta_Y^{(1)}}{J}, \qquad (3.26)$$

with

$$J=o_1o_2o_3o_4+(p_1p_2-q_1^2)(p_3p_4-q_2^2)-o_1o_3p_2p_3$$
$$-o_2o_4p_1p_4+o_1o_4q_1q_2+o_2o_3q_1q_2, \qquad (3.27)$$

$$\Delta_X^{(1)}=o_2o_3o_4+p_2(p_3p_4-q_2^2)-o_3p_2p_3$$
$$-o_2o_4p_4+o_4q_1q_2, \qquad (3.28)$$

$$\Delta_Y^{(1)}=-q_1(p_3p_4-q_2^2)+o_3p_3q_1+(o_1-p_1)o_4q_2 \qquad (3.29)$$

where

$$o_1=S_1+\tfrac{1}{2}, \qquad (3.30)$$

$$o_2=S_1-\tfrac{1}{2}, \qquad (3.31)$$

$$o_3=S_2+\tfrac{1}{2}, \qquad (3.32)$$

$$o_4=S_2-\tfrac{1}{2}, \qquad (3.33)$$

$$p_1=K_0e^{(Rd/4)\cos\alpha}+\left(K_1e^{(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\cos\alpha, \qquad (3.34)$$

$$p_2=K_0e^{(Rd/4)\cos\alpha}-\left(K_1e^{(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\cos\alpha, \qquad (3.35)$$

$$p_3=K_0e^{-(Rd/4)\cos\alpha}+\left(K_1e^{-(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\cos\alpha, \qquad (3.36)$$

$$p_4=K_0e^{-(Rd/4)\cos\alpha}-\left(K_1e^{-(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\cos\alpha, \qquad (3.37)$$

$$q_1=\left(K_1e^{(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\sin\alpha, \qquad (3.38)$$

$$q_2=\left(K_1e^{-(Rd/4)\cos\alpha}-\frac{4}{Rd}\right)\sin\alpha. \qquad (3.39)$$

Making use of the asymptotic form of $K_n(kd)$:

$$K_n(kd)=\left(\frac{\pi}{2kd}\right)^{1/2}e^{-kd}\left(1+\frac{4n^2-1}{1!8kd}+\cdots\right),$$

we have the limiting form of (3.25) and (3.26) for $kd\to\infty$ $(k\ll 1)$ as

$$C_D^{(1)}=\frac{8\pi}{R}\frac{1}{S_1+\frac{1}{2}}, \quad C_L^{(1)}=0 \qquad (3.40)$$

which are the same in the case of a single circular cylinder.

(3.25) and (3.26) can be simplified in a few special cases, that is;

(i) $a=1$ (two circular cylinders of the same radius); $\alpha=90°$ (*cf.* Fig. 2a).

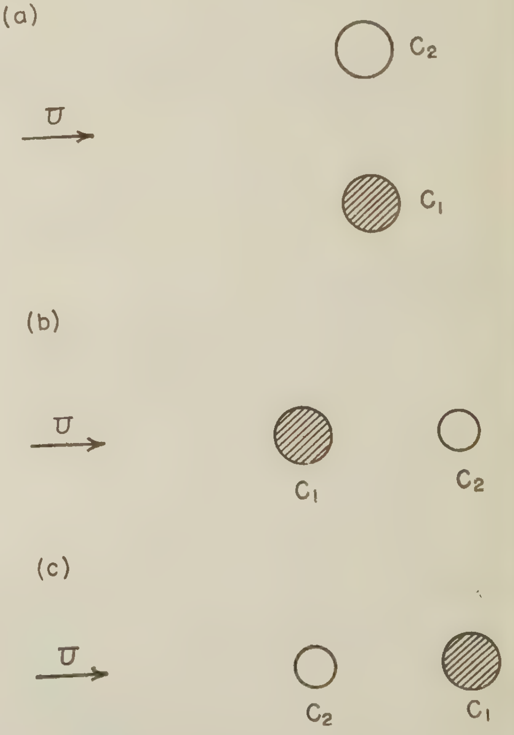

Fig. 2. Special configurations. (a) $a=1$, $\alpha=90°$; (b) $a\doteqdot 1$, $\alpha=0°$; (c) $a\doteqdot 1$, $\alpha=180°$. The drag and lift coefficients are concerned with the hatched cylinders.

$$C_D^{(1)}=\frac{8\pi}{R}\frac{S_1-\frac{1}{2}-K_0}{(S_1+\frac{1}{2}+K_0)(S_1-\frac{1}{2}-K_0)+\{K_1-(4/Rd)\}^2}\,, \qquad (3.41)$$

$$C_L^{(1)}=\frac{8\pi}{R}\frac{K_1-(4/Rd)}{(S_1+\frac{1}{2}+K_0)(S_1-\frac{1}{2}-K_0)+\{K_1-(4/Rd)\}^2}\,. \qquad (3.42)$$

(ii) $a\doteqdot 1$; $\alpha=0°$ (*cf.* Fig. 2b).

$$C_D^{(1)}=\frac{8\pi}{R}\frac{S_2+\frac{1}{2}-(K_0-K_1)e^{-(Rd/4)}-(4/Rd)}{(S_1+\frac{1}{2})(S_2+\frac{1}{2})-\{(K_0+K_1)e^{(Rd/4)}-(4/Rd)\}\{(K_0-K_1)e^{-(Rd/4)}+(4/Rd)\}}\,, \qquad (3.43)$$

and no lift.

(iii) $a\doteqdot 1$; $\alpha=180°$ (*cf.* Fig. 2c).

$$C_D^{(1)}=\frac{8\pi}{R}\frac{S_2+\frac{1}{2}-(K_0+K_1)e^{(Rd/4)}+(4/Rd)}{(S_1+\frac{1}{2})(S_2+\frac{1}{2})-\{(K_0+K_1)e^{(Rd/4)}-(4/Rd)\}\{(K_0-K_1)e^{-(Rd/4)}+(4/Rd)\}}\,, \qquad (3.44)$$

and no lift.

(iv) If $a=1$ and $k\ll kd\ll 1$, we can make use of (3.20) and (3.21) with respect to kd instead of k so that we have

$$C_D^{(1)}=\frac{8\pi}{R}\frac{2S_1-\frac{1}{2}-\ln d-\cos^2\alpha}{(2S_1+\frac{1}{2}-\ln d+\cos^2\alpha)(2S_1-\frac{1}{2}-\ln d-\cos^2\alpha)-\cos^2\alpha\sin^2\alpha}\,, \qquad (3.45)$$

$$C_L^{(1)}=-\frac{8\pi}{R}\frac{\cos\alpha\sin\alpha}{(2S_1+\frac{1}{2}-\ln d+\cos^2\alpha)(2S_1-\frac{1}{2}-\ln d-\cos^2\alpha)-\cos^2\alpha\sin^2\alpha}\,. \qquad (3.46)$$

Especially, for $\alpha=0°$, 90°, 180°, we have:

$$\alpha=90°; \qquad C_D^{(1)}=\frac{8\pi}{R}\frac{1}{2S_1+\frac{1}{2}-\ln d}\,, \qquad C_L^{(1)}=0\,, \qquad (3.47)$$

$$\alpha=0° \text{ and } 180°; \qquad C_D^{(1)}=\frac{8\pi}{R}\frac{1}{2S_1+\frac{3}{2}-\ln d}\,, \qquad C_L^{(1)}=0\,, \qquad (3.48)$$

which may also be obtained by expanding (3.41)–(3.44) in terms of kd.

If we are interested in the resultant drag X, lift Y and moment M of the system of the two circular cylinders with respect to the (geometrical) centre of gravity, we have

$$X=X_1+X_2\,, \qquad (3.49)$$

$$Y=Y_1+Y_2\,, \qquad (3.50)$$

$$M=d_1(X_1\sin\alpha-Y_1\cos\alpha)-d_2(X_2\sin\alpha-Y_2\cos\alpha)\,, \qquad (3.51)$$

where

$$d=d_1+d_2\,, \quad \frac{d_1}{d_2}=\frac{\pi a^2}{\pi}=a^2\,,$$

so that

$$d_1=\frac{a^2d}{1+a^2}\,, \qquad d_2=\frac{d}{1+a^2}\,. \qquad (3.52)$$

If we define the resultant drag, lift and moment coefficients of the system of the two circular cylinders as:

$$C_D=\frac{X}{\frac{1}{2}\rho U^2d}\,, \qquad (3.53)$$

$$C_L=\frac{Y}{\frac{1}{2}\rho U^2d}\,, \qquad (3.54)$$

$$C_M=\frac{M}{\frac{1}{2}\rho U^2 2d}\,, \qquad (3.55)$$

we can relate these resultant coefficients to those coefficients of each cylinders as follows:

$$C_D=\frac{2}{d}C_D^{(1)}+\frac{2a}{d}C_D^{(2)}\,, \qquad (3.56)$$

$$C_L=\frac{2}{d}C_L^{(1)}+\frac{2a}{d}C_L^{(2)}\,, \qquad (3.57)$$

$$C_M=\frac{a^2}{1+a^2}\{C_D^{(1)}\sin\alpha-C_L^{(1)}\cos\alpha-(1/a)(C_D^{(2)}\sin\alpha-C_L^{(2)}\cos\alpha)\}\,. \qquad (3.58)$$

In case when $a=1$, we have

$$C_D=\frac{2}{d}(C_D^{(1)}+C_D^{(2)})\,, \qquad (3.59)$$

$$C_L=\frac{2}{d}(C_L^{(1)}+C_L^{(2)})\,, \qquad (3.60)$$

$$C_M=\tfrac{1}{2}\{(C_D^{(1)}-C_D^{(2)})\sin\alpha-(C_L^{(1)}-C_L^{(2)})\cos\alpha\}. \qquad (3.61)$$

Since, in this case,

$C_D^{(2)}(\alpha)=C_D^{(1)}(\pi-\alpha),\ C_L^{(2)}(\alpha)=-C_L^{(1)}(\pi-\alpha),$

we have

$$C_D(\alpha)=C_D(\pi-\alpha)\ , \qquad (3.62)$$

$$C_L(\alpha)=-C_L(\pi-\alpha)\ , \qquad (3.63)$$

$$C_M(\alpha)=-C_M(\pi-\alpha)\ , \qquad (3.64)$$

that is, C_D is symmetric about $\alpha=\pi/2$, while C_L and C_M are antisymmetric about it.

§ 4. Numerical Discussions

Numerical calculations have been carried out for the cases: (i) $a=1$; $d=5$, 10, 20; $\alpha=0°$, 90°, 180°; $R=0.04$—1.0 by using (3.41)—(3.44), (ii) $a=1$; $d=5$; $\alpha=0°$—180°; $R=0.4$, 0.8 by using (3.25)—(3.39) and (3.59)—(3.61) and (iii) $a=0$—3.0; $d=10$; $\alpha=0°$, 90°, 180°; $R=0.4$, 0.8 by using (3.25)—(3.39), (3.41) and (3.42). They are shown in Figs. 5—7 and tabulated in Tables I—III.

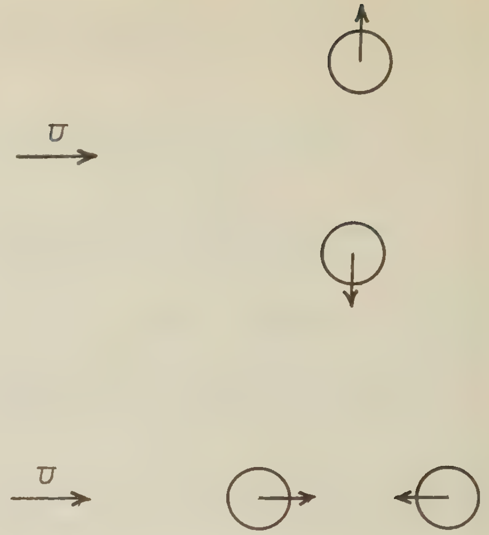

Fig. 3. The mutual interaction of the two circular cylinders in the case of a viscous fluid.

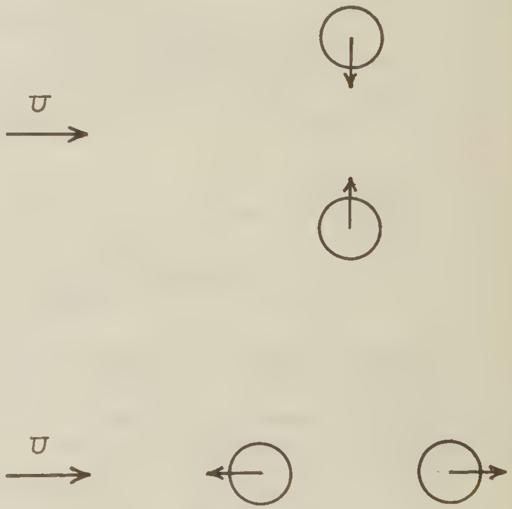

Fig. 4. The mutual interaction of the two circular cylinders in the case of an ideal fluid.

The qualitative results obtained from the numerical calculations are summarized as follows:

(1) The drag coefficient of the first cylinder is smaller than that for a single cylinder at the same Reynolds numbers. The greater or the nearer the second cylinder is, the smaller becomes the drag coefficient of the first cylinder (*cf.* Figs. 5 and 7).

(2) Comparing three cases when (i) the second cylinder is downstream of the first (*cf.*

Theory of the Ultrasonic Absorption in Aqueous Solutions (II) Aqueous Solutions of Some Alcohols*

By Otohiko NOMOTO

Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received May 31, 1956)

Anomalous parts of the ultrasonic absorption coefficient have been calculated for aqueous solutions of methanol, ethanol and *n*-propanol as functions of the concentration by employing the result of the general theory described in part (I) of this paper (J. Phys. Soc. Japan **11** (1956) 827), which is based on the assumption that the pressure change of the sound wave accompanies a change in the existence ratio between the single and the associated molecules of water, that there takes place a molecular rearrangement among the single and the associated molecules of water and the solute molecules, accompanying changes in configurational entropy of the system, and that the irreversible entropy production takes place in the stage of energy transfer from the thermal motion to the configurational degree of freedom and vise versa. Calculations have been performed for two simplified model cases: (a) ignoring the difference in sizes of the single water molecule and the solute molecule, and (b) taking into account the difference in sizes of these molecules by approximating them by linear polymers each consisting of one kind of atoms. The value of the absorption peaks and the location of them have been found to be in semi-quantitative agreement with experiments, the agreement being somewhat better in case (b) as compared with (a).

§ 1. Introduction

Anomalous parts of the ultrasonic absorption coefficient are to be calculated in aqueous solutions of three sorts of alcohols (methanol, ethanol and *n*-propanol) by employing the result of the general theory developed in Part I (cited as (I) in the following) of this paper[1]. It becomes necessary for this purpose to estimate various quantities involved in theoretical formulas. These estimations are preformed in § 2 ~ § 5. By employing the values of the constants evaluated, we have calculated the values of the function f of the entropy of molecular rearrangement, apparent specific heat C_m, and the sound absorption coefficient (α/ν^2) as functions of the concentration. These calculations are executed in § 6~§ 8.

§ 2. Ratio Between the Numbers of Moles of the Associated and the Single Water-Molecules in Pure Water

According to Hall's theory[3] on ultrasonic absorption in pure water, the ratio between the number of moles of the associated water molecules n_{a0} and that of the single water molecules n_{s0} in pure water is given by

$$n_{s0}/n_{a0}=\exp(-\Delta F/RT) \qquad (2.1)$$

(cf. (I), eq. (3.5)), where ΔF means the difference in free energies (per mole) of the single and the associated molecules of water, R the universal gas constant and T the absolute temperature.

The value of ΔF is to be obtained from the expression given by Hall for the relaxational compressibility of pure water:

$$\beta_r=\beta_0-\beta_\infty=\frac{(v_a-v_s)^2}{2vRT\{1+\cosh(\Delta F/RT)\}}, \qquad (2.2)$$

where β_0 and β_∞ mean the static and the instantaneous compressibility respectively, v the molar volume and v_a and v_s the molar volumes of the associated and the single molecules of water respectively. This equation is easily to be obtained from (I), eq. (3.12).

Hall has estimated the value of ΔF to be 500 cal/mole. It depends, however, also on the temperature and on the assumed values of Δv and β_∞. Hall has determined the values of the constants so as to afford the ultrasonic absorption coefficients in agreement with experiment, the values at 20° being as follows:

---

* The text in Japanese of this paper will be published in "Bulletin of the Kobayasi Institute of Physical Research" somewhat in detail.

$$\left.\begin{array}{l}\beta_0=45.8\times10^{-12}\ \mathrm{cm^2/dyne}\ ,\\ \beta_\infty=(15\sim18)\times10^{-12}\quad\text{″}\quad ,\end{array}\right\}\begin{array}{l}\beta_r=(30.8\sim27.8)\\ \times10^{-12}\ \mathrm{cm^2/dyne};\end{array}$$

$$\left.\begin{array}{l}v_s=10.4\ \mathrm{cm^3}\ ,\\ v_a=18.0\sim19.6\ \mathrm{cm^3}\ ,\end{array}\right\}\ \Delta v=7.6\sim9.2\ \mathrm{cm^3}\ .$$

By employing various values for β_∞ and v_a, the values of ΔF were computed. These values are tabulated in Table I, together with the existence ratio

$$n_s/n_w=\frac{n_s}{n_a+n_s}=\frac{1}{1+\exp(\Delta F/RT)}\ . \qquad (2.3)$$

We have calculated the absorption coefficients corresponding to various values of the existence ratio tabulated, but adopted the value $n_s/n_w=0.175$ (the smallest one) for final calculation, because this gives the greatest absorption coefficients, i.e., the nearest to experimental results.

Table I. Difference in free energies per mole (ΔF) between the single and the associated molecules of water, and the existence ratio n_s/n_w of the single molecules as functions of v_a and β_∞ (20°C).

	$v_a=18.0\mathrm{cm^3}$		$v_a=18.8\mathrm{cm^3}$		$v_a=19.6\mathrm{cm^3}$	
β_∞	ΔF cal/mole	n_s/n_w	ΔF cal/mole	n_s/n_w	ΔF cal/mole	n_s/n_w
15×10^{-12}	296	0.376	613	0.259	808	0.200
16.5 ″	397	0.336	671	0.241	856	0.187
18 ″	482	0.305	728	0.223	904	0.175

Hall has assumed the associated molecules of water to be in a state of lower free energy, while the single molecules are in a state of higher free energy. On the contrary, Litovitz and Carnevale[4)] have recently deduced from the pressure dependence of the ultrasonic absorption in pure water that the associated molecules are in the state of higher free energy and the single molecules are of lower free energy. If we adopt this latter view, the existence ratio of $n_s:n_a$ becomes reversed and we have $n_s/n_w=0.825\sim0.624$. For example, $n_s/n_w=0.759$ for average value of β_∞ and that of v_a. This however, gives an absorption maximum only about 1/3 the experimental value for the ethanol-water mixture, when the magnitude of the associated molecule is so assumed as to give a relaxation time in agreement with the experiment. Also the estimation of n_s/n_a from the molar volumes of water, solute and the solutions deviates widely from the estimation from Litovitz-Carnevale's theory. The existing various estimations are not in accord with this, too.

So we have assumed, after Hall, the single water molecules to be in a state of higher free energy and the associated molecules to be of lower free energy, and adopted the following values of the parameters (at 20°C) in the following:

$$\left.\begin{array}{l}v_s=10.4\ \mathrm{cm^3}\ ,\\ v_a=19.6\ \mathrm{cm^3}\ ,\end{array}\right\}\ \Delta v=9.2\ \mathrm{cm^3}; \qquad (2.4)$$

$$\Delta F=904\ \mathrm{cal/mole}\ , \qquad (2.5)$$

and

$$n_{s0}/n_{w0}=0.175\ , \qquad n_{a0}/n_{w0}=0.825\ , \qquad (2.6)$$

where the suffix zero indicates the values at zero concentration of the solvent, i.e., the values for pure water.

§ 3. Concentration Dependence of the Number of Moles of the Associated Water-Molecules in Solvent Water

The number of moles of the associated water-molecules in aqueous solutions is to be estimated from the concentration dependence of the adiabatic compressibility in aqueous solutions. The procedure was described elsewhere (Nomoto[2)]) and we will employ the result in the following. The number of moles of the associated water-molecules (n_a) and that of the single water-molecules (n_s) in one mole of the aqueous solutions, of methanol, ethanol and n-propanol are represented as functions of the concentration (molar fraction of the solute n_F) in Fig. 1. As is to be seen in the figure, the value of n_a in aqueous methanol solution decreases monotonously with increasing concentration, while in ethanol-solution the decrease of n_a with increasing n_F becomes slow in the intermediate concentration, and the n-propanol solution shows even a slight minimum and a nearly flat region in the curve of n_a.

Although it may be supposed from these curves that the slowing down of the reduction of n_a in aqueous solutions of ethanol and n-propanol with increasing concentration may be due to the mutual association between water and alcohols, this idea must be rejected because the absorption curves, and especially, the relative heights of the absorption peaks and the concentrations for the absorption peaks, widely deviates from experiments if this view is adopted.

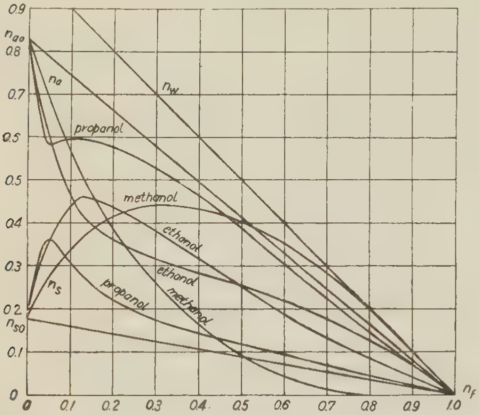

Fig. 1. Number of moles of the associated water-molecules (n_A) and that of the single water-molecules (n_s) in aqueous solutions of methanol, ethanol and n-propanol as functions of the concentration (20°C).

§ 4. Physical Constants of the Aqueous Alcohol Solutions

All calculations were performed for 20°C.

(a) density ρ

Jacobson's data[5] were employed for the values of the density. The values of the density are represented in Fig. 2 for the three alcohol solutions here considered as functions of the concentration.

As the data of Jacobson, however, are represented as functions of the volume fraction ϕ (ratio between the volumes of the solute and the solution), we have to transform the volume fractian into molar fraction. First we obtain the weight fraction p by

$$p=\phi\rho_2/\rho\ , \tag{4.1}$$

where ρ_2 means the density of the solute and ρ the density of the solution, and then obtain the molar fraction n_F by

$$n_F=m_F/(m_w+m_F)\ , \tag{4.2}$$

where

$$m_w=(1-p)/M_w;\quad m_F=p/M_F\ . \tag{4.3}$$

Here M_w and M_F mean the molecular weight of water and that of the solute respectively.

(b) thermal expansion coefficient ϑ

This was computed from the density data of ICT (=International Critical Tables) and also shown in Fig. 2. As is to be seen in the figure, the methanol solution shows an irregular behaviour with respect to the thermal expansion coefficient, and it seems that the smoothed values indicated by arrows are the more reliable ones. Also the computed values of γ and c_v become irregular by this effect, although the influence on the values of C_m, c_p and (α/ν^2) are not large, being masked by other irregularities due to the estimation of n_a, n_s, etc.

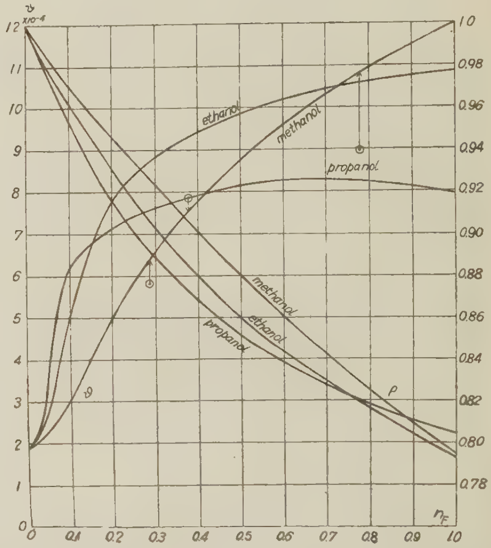

Fig. 2. Density and the thermal expansion coefficient in aqueous alcohol solutions in dependence on the concentration (20°C).

(c) sound velocity V

Jacobson's data were employed.

(d) specific heat at constant pressure c_p **and the ratio of the specific heats** γ

c_p was obtained from ICT by interpolation. Fig. 3 shows the concentration dependence of c_p and γ. The interpolation, however, is presumably not so exact because of the non-monotonous variation of c_p with temperature, c_p at lower concentration having a maximum at a certain temperature. C_p involved in the absorption formulars (I), (6.7) and (6.8) mean the molar specific heat at constant pressure, given by

$$C_p=Mc_p\ , \tag{4.4}$$

where M means the average molecular weight of the solution given by

$$M=(1-n_F)M_w+n_FM_F\ . \tag{4.5}$$

The ratio of the specific heats γ is to be calculated by (I), (5.8) from the known values of V, ϑ and c_p. Then we have c_v from c_p and γ. The values of γ are also shown in Fig. 3. As is to be seen, the calculated values of γ in methanol-solutions are scatterd by the influence of the scattered values of ϑ.

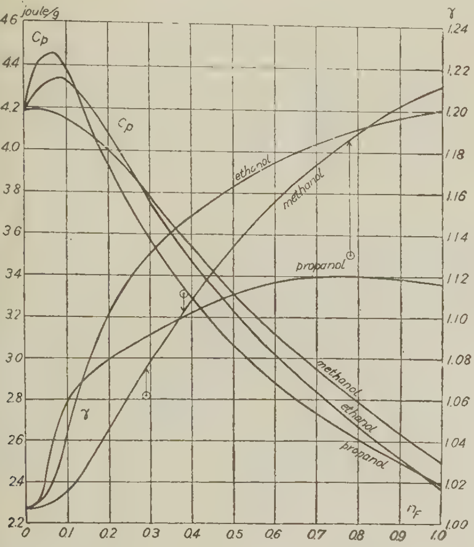

Fig. 3. The values of c_p and γ in aqueous solutions of methanol, ethanol and n-propanol as functions of concentration (20°C).

(e) **diffusion coefficient D**

The values of the diffusion coefficient are not so well investigated. Concerning the three alcohol solutions here considered, ICT gives the concentration dependence of D only for the ethanol solution at 10°C. The tabulated values are as follows (with indicated errors ±10%):

c (mole)	3.75	0.75	0.25	0.05	(0)
D (in 10^{-5} cgs)	0.50	0.70	0.78	0.83	($D_0=0.87$)

The value at zero (=infinitesimal) concentration D_0 was obtained here by extrapolation. By reducing the molarity c into the weight fraction by

$$p=M_F c/1000\rho\ , \qquad (4.6)$$

and then transforming p into the molar fraction n_F by (4.2) and (4.3), we can obtain the concentration dependence of D as indicated in Fig. 4, where D/D_0 is represented *vs.* n_F. Although this corresponds to the ethanol solution at 10°C, we have assumed that this curve is also valid for the aqueous solutions of methanol, ethanol and n-propanol at 20°C.

Now the ICT gives the diffusion coefficient at zero (=infinitesimal) concentration for the aqueous solutions of three sorts of alcohols at 15°C. This is reproduced in the third column of Table II (accuracy ±7%).

Table II. Diffusion coefficient at zero concentration (D_0 in 10^{-5} cgs) for aqueous alcohol solutions.

Solute	10° (extrapolated)	15° (ICT)	20° (estimated) (a)	20° (estimated) (b)
methanol		1.28	1.47	1.46
enthanol	(0.87)	1.00	1.16	1.14
n-propanol		0.87	1.01	0.99

Two estimations were made from this for the values of D_0 at 20°C. In the first place, if we assume the theoretical formula

$$D=kT/6\pi\eta a\ , \qquad (4.7)$$

where η means the viscosity coefficient of the solvent, a the molecular radius of the solute, and k the Boltzmann constant, we have $D\infty T/\eta$. This gives the values tabulated in column (a). In the second place, if we make graphical extrapolation from the extrapolated value of D_0 at 10° (for ethanol solution) and the ICT value at 15°, we obtain column (b). As both estimations are nearly in accord, we employed the results of (b) in the following. The diffusion coefficients at any concentration were obtained by multiplying this value by D/D_0 obtained from Fig. 4.

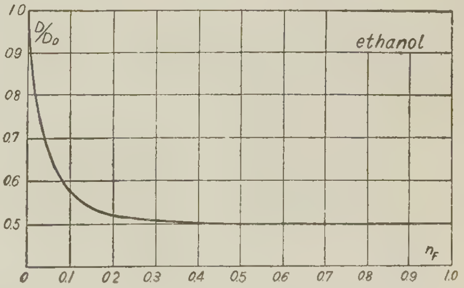

Fig. 4. Concentration dependence of the diffusion coefficient in aqueous ethanol solutions (10°C).

§ 5. Concentration Dependence of the Size of the Associated Molecules of Water in Aqueous Solutions

The only parameter in our theory to be determined directly from acoustic absorption experiment is the size of the associated water-molecules in aqueous solutions. This is to be estimated from the relaxation time by the relation, $\tau=0.783r^2/D$ (cf. (I) (7.14)), where D means the diffusion coefficient and r the radius of the groups of single water molecules produced under excess pressure by the collapse of the associated molecules. This radius is given by $r=s(3v_s/4\pi N_L)^{1/3}$ (cf. (I) (7.27)), where N_L means the Loschmidt number and s the ratio between the radius of the associated water molecules and the effective radius of the monomers constituting the associated molecules.

By employing the value of (2.4) for v_s, we have

$$r=s\times1.60\times10^{-8}\,\mathrm{cm} \qquad (5.1)$$

and accordingly

$$\tau=2.005\times10^{-16}\,\mathrm{cm}^2\,s^2/D\,. \qquad (5.2)$$

The relaxation frequencies are known experimentally in the neighbourhood of the absorption maximum for aqueous solutions of ethanol, n-propanol and phenol, as cited in (I), (1.2), (1.3) and (1.4). In the first place, we have for aqueous ethanol solution from Storey's measurements (cf. (I), (1.2)) by interpolation:

$$\nu_m=137\,\mathrm{Mc/sec} \quad \text{at } 20°\mathrm{C},\ 25\%\ (n_F)\,,$$

and accordingly by

$$\tau=1/2\pi\nu_m \qquad (5.3)$$

the experimental value of the relaxation time:

$$\tau_{\mathrm{exp}}=1.16\times10^{-9}\,\mathrm{sec}$$
$$\text{(ethanol solution, } 20°\mathrm{C},\ n_F=0.25) \qquad (5.4)$$

Then we have from Sette's absorption data at 24.5°C and 13.9% (n_F) the relaxation frequency $\nu_m=53.6$ Mc (cf. (I), (1.3)), for propanol-solution, and this gives $\tau=2.85\times10^{-9}$ sec (24.5°C). The value of τ at 20° was estimated from this by employing (5.2) and assuming the diffusion coefficient D to be proportional to T/η and ignoring the temperature dependence of s. This was calculated to be

$$\tau_{\mathrm{exp}}=3.23\times10^{-9}\,\mathrm{sec}$$
$$(n\text{-propanol solution, } 20°\mathrm{C},\ n_F=0.13 \qquad (5.5)$$

Finally, we have from Cevolani and Petralia's absorption data at 70°C for aqueous phenol solutions $\nu_m=35$ Mc (cf. (I), (1.4)). This gives

$$\tau=4.55\times10^{-9}\,\mathrm{sec}\ (70°\mathrm{C})\,.$$

Correcting for the temperature dependence of D, but not for s as before, we have from this

$$(\tau^*_{\mathrm{exp}}=13.2\times10^{-9}\,\mathrm{sec}) \quad \text{(hypothetical phenol solution, } 20°\mathrm{C},\ n_F=0.06) \qquad (5.6)$$

Then the values of s were calculated by (5.2) corresponding to these values of τ_{exp} at 20°C, and found to be

$$\left.\begin{array}{ll} s=5.92 & \text{(ethanol solution, } n_F=0.25)\,. \\ s=9.36 & (n\text{-propanol solution, } n_F=0.13)\,, \\ (s^*=19.1) & \text{(hypothetical phenol solution,} \\ & \qquad n_F=0.06) \end{array}\right\} \qquad (5.7)$$

The phenol solution, however, is known to separate into two phases below the critical mixing temperature at about 68°C, and there is no solution of the concentration $n_F=0.06$ at 20°C. So the values with asterisks are only extrapolated values corresponding to hypothetical solution. (The value of s^* was computed by employing $D_0=0.84$ (at 20°C) and assuming $D=(2/3)D_0$ at $n_F=0.06$.)

Also the mechanism of sound absorption may be somewhat different for critical mixtures. The mechanism is certainly different for non-aqueous mixtures near the critical point, the cluster formation playing an important role in this case. The mechanism, however, may not be so widely different for aqueous critical mixtures, from that for ordinary aqueous solutions. These points must be investigated in a separate research. Here we assumed the mechanism of the excess sound absorption in aqueous phenol solution near the critical solution temperature to be the same as in ordinary aqueous solutions.

Although it is not clear as yet what are the quantities which determine the seize (s) of the associated water molecules, it is to be seen from the above result that s decreases rapidly with increasing value of n_F. As we have no sufficient data to investigate the dependency of s on concentration in each of the aqueous solutions, we have assumed s to be a function of n_a, but not dependent on other quantities, and obtained the relation as indicated in Fig. 5. As the data for phenol solution is not exact, we assumed the curve a rather arbitrarily. The curve connecting ethanol and n-propanol gives straight line b. Here we adopted the curve a for further calculations because the experimental absorption curves at different frequencies seem to indicate that the concentration dependence of the relaxation time is only slight, at least in the neighbourhood of the absorption peak. The coincidence of the calculated absorption curves with experiments is also better for curve *a* than for curve *b*.

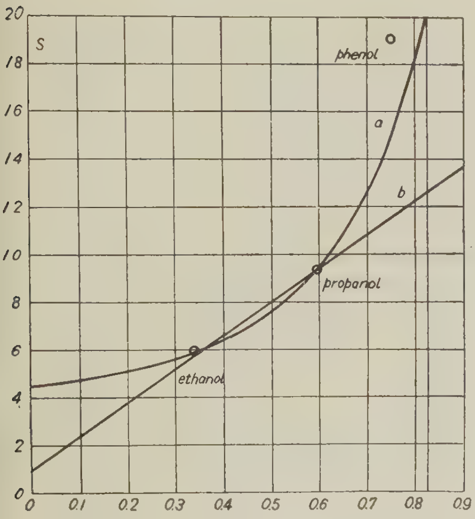

Fig. 5. Relation between s, the quantity proportional to the radius of the associated water molecules in aqueous solutions, and the molar fraction of the associated molecules (20°C).

As is to be seen in the figure, the value of s for pure water is comparatively large, becoming

$$s_0=20 \tag{5.8}$$

n case of curve *a*. Accordingly, the number of monomers constituting an associated molecule becomes

$$Z=8000 \tag{5.9}$$

by (I) (7.15).

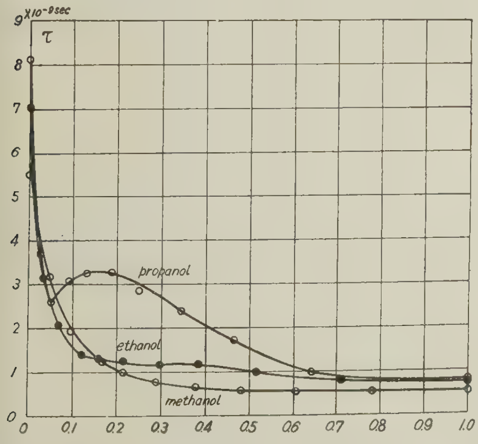

Fig. 6. Relaxation time of the molecular rearrangement in aqueous solutions of methanol, ethanol and n-propanol as functions of the concentration (20°C).

In order that a molecular diffusion may take place, it is necessary that the diameter ($2r$) of the groups of single water molecules produced by the sudden collapse of the associated water molecules under excess pressure are larger than the mean distance of the solute molecules in the solution (l_F), i.e.,

$$l_F<2r \tag{5.10}$$

This, condition, however, is always satisfied except at extremely low concentrations.

Fig. 6 shows the values of the relaxation time as functions of the concentration, calculated by (5.2) for the three sorts of alcohol solutions here considered.

§ 6. Entropy Change Due to the Molecular Rearrangement (Functions *f* and *f**)

Now we have all the quantities required to calculate the function $f=T\Delta S/\Delta p$ (cf. (I), (4.6)) proportional to the entropy change of the molecular rearrangement. In case when the difference in seizes of the various kinds of molecules are ignored, this function is given by (I), (4.7), i.e.,

$$f=\frac{(v_a-v_s)n_a\log(1+n_F/n_s)}{\{1+\exp(\Delta F/RT)\}} \tag{6.1}$$

Fig. 7 shown the values of f as functions of n_F for the three sorts of alcohol solutions here considered.

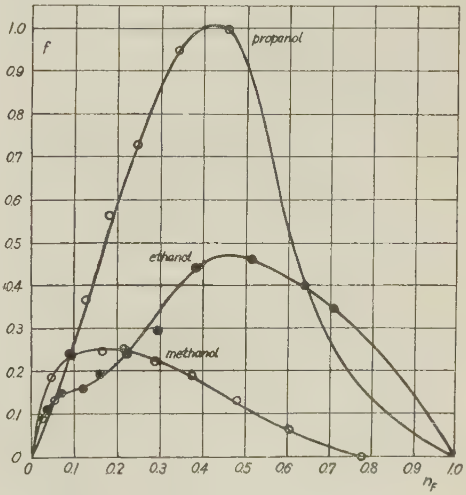

Fig. 7. Entropy function f in aqueous solutions of methanol, ethanol and n-propanol as functions of the concentration (20°C).

In case the effect of the difference in magnitudes of the molecules are taken into account, by regarding the single molecule of water and the solute molecule as linear polymers, each consisting of one kind of atoms, the entropy function becomes f^* given by (I), (4.13),

There may be problems as to the number of the nearest neighbours z surrounding an atom in an aqueous alcohol solutions. The number, however, cannot exceed 12. The number z may be also dependent on the kind of the atoms, and there are reasons to suppose that z is presmuably far smaller than 12 for carbon atoms in alcohol molecules. The increment of the configurational entropy ΔS, however, is not so largely dependent on the value of z, increasing slightly with increase in z. So we assumed

$$z=12 \tag{6.2}$$

in this calculation. The calculation gives, therefore, the upper limit of the entropy change under this liquid model.

The values of the constants r_s, q_s and r_F, q_F in eq. (I) (4.13), become by (I) (4.9) and (4.10) as follows:

$$\left.\begin{array}{lll} \text{water:} & r_s=3\,, & q_s=8/3; \\ \text{methanol:} & r_F=6\,, & q_F=31/6; \\ \text{ethanol:} & r_F=9\,, & q_F=23/3; \\ n\text{-propanol:} & r_F=12\,, & q_F=61/6. \end{array}\right\} \tag{6.3}$$

Here r_s and r_F mean the number of atoms constituting the molecules. By employing these values we obtain from (I) (4.13) the following expressions of the entropy function for the aqueous solutions.

methanol solution:

$$f^*=\frac{(v_a-v_s)n_a}{1+\exp(\Delta F/RT)}\left\{16\log\left(1+\frac{31}{16}\frac{n_F}{n_s}\right)-15\log\left(1+2\frac{n_F}{n_s}\right)\right\} \tag{6.4}$$

ethanol solution:

$$f^*=\frac{(v_a-v_s)n_a}{1+\exp(\Delta F/RT)}\left\{16\log\left(1+\frac{23}{8}\frac{n_F}{n_s}\right)-15\log\left(1+3\frac{n_F}{n_s}\right)\right\} \tag{6.5}$$

n-propanol solution:

$$f^*=\frac{(v_a-v_s)n_a}{1+\exp(\Delta F/RT)}\left\{16\log\left(1+\frac{61}{16}\frac{n_F}{n_s}\right)-15\log\left(1+4\frac{n_F}{n_s}\right)\right\}\,. \tag{6.6}$$

§7. Apparent Specific Heat Due to Molecular Rearrangement C_m

Once f is known, we can calculate C_m by (I), (5.9), i.e.,

$$C_m=\rho c_p f/T\vartheta\,. \tag{7.1}$$

Fig. 8 shows the values of C_m as functions of the concentration, for the three alcohol solutions here considered. The dependence of C_m on concentrations is widely different according to the kinds of the alcohols, methanol solution exhibiting higher values of C_m at low concentration as compared to other solutions.

In case the difference in sizes of the molecules are taken into account we have

$$C_m^*=\rho c_p f^*/T\vartheta\,. \qquad (7.2$$

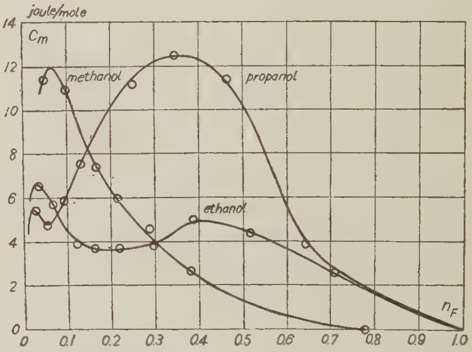

Fig. 8. Relaxational specific heat C_m due to the molecular rearrangement in aqueous solutions of methanol, ethanol and propanol in dependence on the concentration (20°C).

§8. Ultrasonic Absorption Coefficient

The ultrasonic absorption coefficient at sufficiently low frequency is to be calculated by (I), (6.7), i.e.,

$$\left(\frac{\alpha}{\nu^2}\right)_0=\frac{2\pi^2\rho\vartheta V}{C_p}\frac{C_v}{C_v-C_m}f\tau\,. \tag{8.1}$$

In case we take into account the difference in seizes of the molecules, we have to replace f with f^* and C_m with C_m^*. The corresponding value of α is to be written as α^*. The relaxation time being of the order of 10^{-9} sec, the equation (8.1) holds true within an error of 1% up to about 20 Mc/sec.

Fig. 9 shows the values of $(\alpha/\nu^2)_0$ for the three sorts of alcohol solutions here considered, and Fig. 10 shows $(\alpha^*/\nu^2)_0$. Table III summarizes the experimental and the theoretical results concerning the height and location of the absorption peaks.

Table III. Experimental and theoretical values of the height and location of the ultrasonic adsorption peaks in aqueous alcohol solutions.

Solute		methanol		ethanol		n-propanol	
		n_F	$(\alpha/\nu^2)_0$ (in 10^{-17})	n_F	$(\alpha/\nu^2)_0$ (in 10^{-17})	n_F	$(\alpha/\nu^2)_0$ (in 10^{-17})
Experiments	25∼27°C	(—)	(—)	0.27	190	0.14	960
	−10°C	0.3	110	—			
Calculation 20°C							
(a) point molecules		0.05	60	0.39	125	0.28	435
(b) linear polymer molecules		0.05	85	0.38	155	0.27	640

As seen in the table, the theoretical result is in qualitative agreement with the experiments. The tendency that the absorption peak increases in height with increase in seize of the solute molecules, is in agreement with experiment. The values of the absorption peaks, however, are not in agreement with the observed ones, being about half the experimental value for propanol solution, 2/3 for ethanol solution and somewhat heigher for methanol solution, in case of Fig. 9 (calculation (a)). Also the positions of the absorption maxima are somewhat displaced, the calculated absorption peaks being located at somewhat higher alcohol concentrations than observed ones in case of n-propanol and ethanol solutions, and at lower concentration for methanol solution. In case of Fig. 10 (calculation (b)) the agreement with experiment is somewhat improved, especially concerning the height of the absorption peaks, though the location of the absorption peaks remains nearly the same.

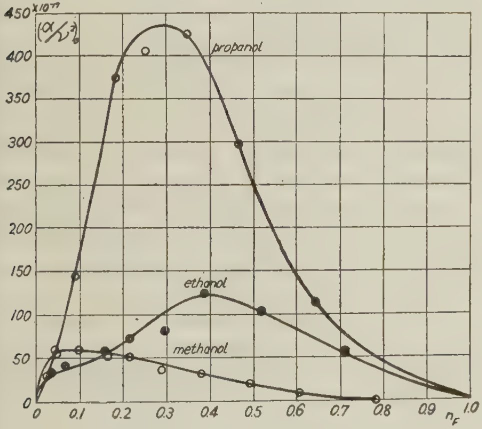

Fig. 9. Absorption curve of sound for aqueous solutions of methanol, ethanol and n-propanol (20°C).

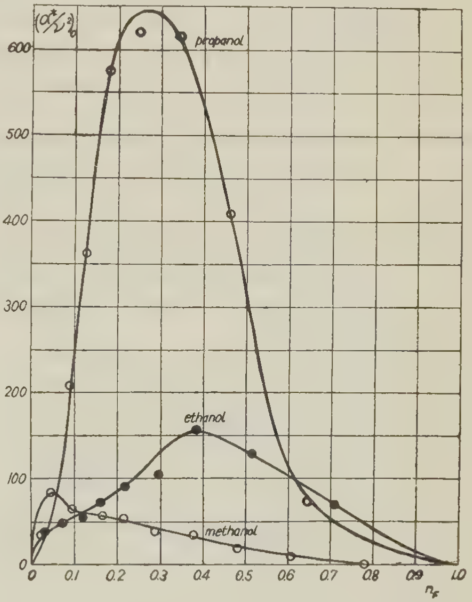

Fig. 10. Absorption curve of sound for aqueous solutions of methanol, ethanol and n-propanol (20°C). Calculation by taking into account the effect of the difference in magnitudes of the molecules.

An Empirical Regularity of Energy Gap in Semiconductors

By Takeshi MIYAUCHI

Junior College of Engineering, University of Osaka Prefecture, Neyagawa, near Osaka

(Received January 8, 1957)

Fundamental properties of a semiconductor that determine its characteristics are width of energy gap and mobilities of electrons and holes. If their regularities could be known, these would be very useful and convenient to the study of semiconductors, specially, in the field of their applications. According to Goodman¹⁾, the energy gap of the compound with the zincblende structure increases with the increase in melting point and also with the increase in electronegativity difference between elements. However, this method has numerous exceptions in practice. For example, the melting point of GaSb (720°C) is lower than of InAs (936°C), but the gap of the former (0.8 ev) is greater than of the latter (0.47 ev).

In this paper, a trial will also be made for this purpose. The method is almost empirical as follows. A ratio (r_1/r_2) is dopted, where r_1 is half of the distance between the neighbouring elements in the crystal lattice and r_2 is average of the positive ionic radii of elements. For example, in the case of InSb, the distance between neighbours is 2.80A, the ionic raddii are: In^{+3} 0.81A, Sb^{+5} 0.62A, and therefore the ratio (r_1/r_2) becomes 1.96. When we examine dependence of the energy gap to this ratio, an unexpected simple relation results.

The results for several groups of compounds are shown in Fig. 1, where values of ionic radii are those by Pauling²⁾. The relation is satisfactorily linear, if it is taken into consideration that the values of gaps used in the figure are gathered from many literatures³⁾ and that they show small differences even in the similar measuring methods. Besides, they have temperature coefficients of the order of -10^{-4} to -10^{-3} ev/deg. It is interesting to get such a simple regularity although the physical reason is not known to the author.

In the figure, Si deviates from Sn-Ge line. A similar phenomenon also occurs in the case of Mg_2Si of the antifluorite lattice type group. This may be due to a chemical peculiarity of silicon. This method essentially involves that in the same group the band structures, as well as chemical properties, have resemblances to each other, and it may be desirable that the deviation is associated with their considerable variation. In fact, some workers⁴⁾ have pointed out remarked differences between band structures of germanium and silicon.

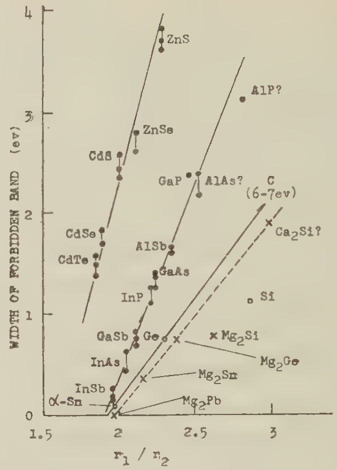

Fig. 1. Energy gap vs r_1/r_2. Dots, zincblende type; circles, diamond type; crosses, antifluorite type.

As to the zincblende type family including the diamond type the slope of the curve increases and the curve shifts to the left from the Group IV elements through the $A^{III}B^{V}$ group to the $A^{II}B^{VI}$ group with the increasing ionic character of bonding, corresponding to the electronegativity difference between elements mentioned by Goodman.

The utility of this regularity is to presume the energy gaps for several compounds, whose properties are unknown or uncertain. It seems that this method can be applied to other groups of compounds, but no systematic study in this field has been carried out up to now.

Nuclear Magnetic Resonance in Solid Solutions of Transition Metals in Copper and Aluminum

By Tadashi SUGAWARA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, Japan

It is known that the magnetic properties of the dilute solide solutions of transition metals in non-transition metals can be interpreted in terms of the localized 3d-state picture of the solute atoms[1]. When the localized $3d$-electrons have unpaired spins, the nuclear magnetic resonance absorption of the solvent nucleus will have the following characteristics. (1) *The line width.* At low temperatures each nucleus will be subjected to a local field arising from the magnetization of the solute atoms which is given by[2]

$$H_{\mathrm{loc}}=\sum_k g_k{}^2\mu_\beta{}^2 H_0 \frac{S_k(S_k-1)}{3k(T-\Theta)}(1-3\cos^2\theta_{ik})r_{ik}{}^{-3}\,. \tag{1}$$

The line shape and the width will be determined by the distribution of the local field. (2) *The Knight shift.* The Knight shift of the alloy will be expressed by

$$(\delta H/H)_l=(\chi_l/\chi_0)(\delta H/H)_0\,, \tag{2}$$

where χ_l is the spin susceptibility of conduction electrons in the alloy, χ_0 and $(\delta H/H)_0$ is the spin susceptibility and the Knight shift of the pure metal. (3) *The spin-lattice relaxation time.* The relaxation time T_1 will be given by

$$1/T_1=(1/T)_{ce}+(1/T_1)_S\,, \tag{3}$$

where $(1/T_1)_{ce}$ and $(1/T_1)_S$ are the contributions arising from the interaction of the nuclear spins with the conduction electron spins and with the localized $3d$-spins, respectively. Explicit expression for $(1/T_1)_S$ is given by Bloembergen[2].

The experiments were made on fine powders of Cu-Mn, Al-Mn, Cu-Fe and Cu-Ni at frequencies of about 8 Mc/sec. Variations of the line width, the Knight shift and T_1 with temperature are shown in Figs. 1, 2 and 3. The line widths in Cu-Fe and Cu-Mn showed the behavior expected from eq. (1). Temperature dependence of the Knight shift of Cu-Mn seems to support the prediction made by Owen et al[3]. T_1 at helium temperatures in Cu-Mn was smaller than that of pure Cu, showing the effect considered above. In Al-Mn, the width, the shift and T_1 did not show appreciable changes as compared with Al. T_1 in Cu-Ni with 1.5. and 3.5% Ni could not be determined owing to the anomalous saturation behaviors of these alloys, though T_1 in 0.07% alloy was the same as that of pure Cu.

Multiplication of Charge Carriers and Breakdown in Ge p-n Junction I

By Chiyoe Yamanaka and Tokuo Suita

Department of Electrical Engineering,
College of Engineering,
Osaka University

(Received November 26, 1956)

We have studied the relation between the current multiplication[1] and the breakdown voltage of Ge p-n junction at various temperatures. The junctions were prepared by alloying indium at 550°C on n type Ge, doped with arsenic, the resistivity of which was 5 Ω cm. The crystallographic direction of specimens was [100].

The drift of the current with time is shown in Fig. 1. At low voltage the collector current did not show any drift. At the voltage of about seventy percent of the breakdown value, the current decreased to a certain lower value in a period of ten minutes. At ninety percent, this drift disappeared. A little increase of voltage across this critical point provoked a current rise with time which turned itself to the breakdown.

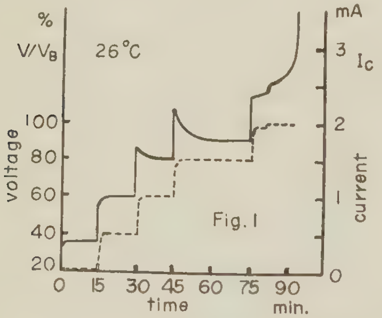

Fig. 1. The time dependent collector current. The real line indicates the collector current. The dotted line indicates the applied voltage.

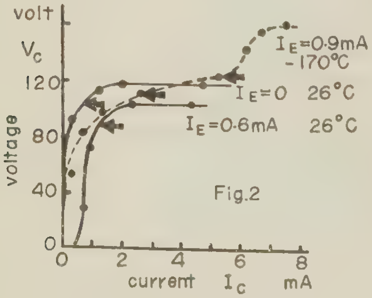

Fig. 2. Voltage-current characteristics. The arrows show the decrease in current with time.

As for the effect of temperature, at lower temperatures the breakdown voltage was higher and the current jumped more sharply at this critical point than in the case of higher temperature. In fact, the junctions were restorative at room temperature by a prompt cut of the after-current, but at −170°C they were non-restrative. In Fig. 2, we show the characteristics of current and voltage where the arrows indicate the drift with time. These results seem to show that at higher temperature the current multiplication and the breakdown process are much more influenced by the thermal effect. The mechanism of time dependent creep is not clear, but a possible interpretation might be as follows. As the applied field is increased, the surface current begins to appear. As the surface state is so changeable by the current, the surface leakage tends to decrease with time. Near the breakdown voltage, the avalanche current has a dominant role and masks the behavior of surface component.

The distribution of current pulses was measured by using an amplifier and a discriminator. Fig. 3 shows these results. At lower current density the distribution obeys the Furry-Wijsman's[2] formula which is observed in gasous ionization. But at higher current density the distribution was quite flat. This means the intermittent discharges which consists of rather large pulses of the same magnitude are prevailing. These phenomena may be the same ones as those observed by McKay[3] The mechanism of them may be the on-off process in the different discharge paths in junction which have nearly the same firing voltage.

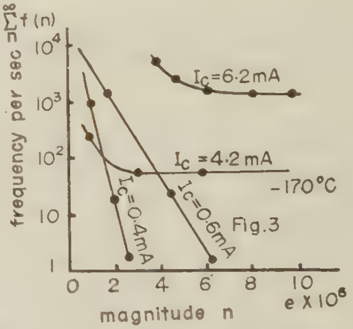

Fig. 3. The distribution of current pulses.

More experiments concerning the directional effect by using impulse voltages are being carried out.

Molecular Sound Velocity of Aqueous Sugar Solutions

By Otohiko NOMOTO and Tadashi KISHIMOTO
Kobayasi Institute of Physical Research, Kokubunzi, Tokyo

(Received January 10, 1957)

One of the authors[1] has reported that Rao's molecular sound velocity[2] $R=(M/\rho)V^{1/3}$ becomes a linear function of the molar fraction (n) in most of the liquid mixtures. Here M is the mean molecular weight, ρ the density and V the sound velocity. Deviation from linearity has been observed in aqueous solutions, R becoming higher than the value corresponding to the straight line connecting the R-values of the both component liquids. This was attributed to the breaking of the bydrogen bonds of water in aqueous solutions by the influence of the solute molecules[3]. As some of the aqueous solutions show deviation from linearity rule of R, while others do not, we intended to investigate the behaviour of R also in other aqueous solutions than hitherto investigated.

Sound velocity (at 1.43 Mc/sec, by ultrasonic interferometry) and density were measured for some aqueous sugar solutions at various concentrations (0～20% weight) and temperatures (5°～30°C), and the values of R were computed. R was found to be a linear function of n for all the sugar solutions investigated within the accuracy of the experiments (cf. Fig. 1.).

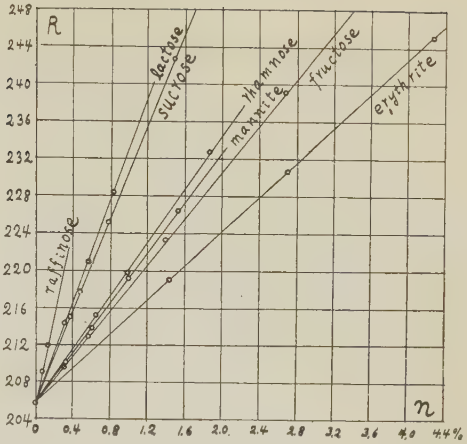

Fig. 1. Molecular sound velocity *vs.* molar fraction of the solute for aqueous sugar solutions (20°C).

When the linear relationship is extrapolated to $n=100\%$ we obtain the values of R for the pure solutes (corresponding to the supercooled liquid state). These values (average values over the temperature range 5°～30°) are indicated by R_{exp} in Table I, while R_{cal} indicates the values computed by assuming the additivity rule of R for the atomic increments and employing Rao's values[4] of the atomic increments (C=10, H=92.5, and O=74). As is to be seen in the table, R_{exp} is always lower than R_{cal}. This may presumably be due to the branching of the sugar molecules.

If the linear relationship of R holds true up to 100% concentration, we may conclude that the state of association of water molecules are effectively nearly the same as in pure water. This may presumably be due to the fact that the effect of the solvation (combination by hydrogen bonds of water molecules to the sugar molecules) on compressibility nearly compensates the effect of the partial destruction of the associated water molecules (destruction of hydrogen bonds) by the influence of the solute.

Table I. Molecular sound velocity of saccharides obtained by extrapolation from aqueous solutions and that calculated by employing the atomic increments

Sugars	Chemical formula	Molecular weight	R_{exp}	R_{cal}	$R_{\mathrm{exp}}/R_{\mathrm{cal}}$
erythrite	$C_4H_{10}O_4$	122.08	1129	1261	0.895
fructose	$C_6H_{12}O_6$	180.09	1452	1614	0.900
mannite	$C_6H_{14}O_6$	182.11	1553	1799	0.862
rhamnose	$C_6H_{12}O_5\cdot H_2O$	182.11	1644	1799	0.914
sucrose	$C_{12}H_{22}O_{11}$	342.17	2692	2969	0.907
lactose	$C_{12}H_{22}O_{11}\cdot H_2O$	360.19	2883	3228	0.893
raffinose	$C_{18}H_{32}O_{16}\cdot 5H_2O$	594.33	4540	5619	0.808

Phase Transition of In_2Se_3

By Hisao Miyazawa and Suezo Sugaike
Matsuda Research Laboratory,
Tokyo-Shibaura Electric Co.,
Kawasaki-shi, Kanagawa-ken

(Received December 15, 1956)

Fairly large single crystals of In_2Se_3 grown by means of the double furnace techniques[1] in this laboratory were confirmed by X-ray examination to have the hexagonal lattice at room temperature, where $a=4.01$ Å, $c=19.2_4$ Å, and $c/a=4.80$, in good agreement with those reported by Hahn[2]. This is one exception among III_2VI_3 type compounds almost crystalizing in wurtzite, zincblende or their related structure, where the symbol III represents one of the third-B metals from aluminium to indium in Periodic Table, and VI one of the chalcogene elements that is sulphur, selenium or tellurium. It is therefore expected that the material shows different features from other families.

In the course of observations of several properties about these crystals, it was found at nearly 200°C that In_2Se_3 has a remarkable phase transition which might be first order. As shown in Fig. 1, electrical conductivity along (0001) plane of the crystal abruptly decreases by two orders of magnitude at the transition temperature T_c, while Hall constant* which is nearly constant up to T_c increases about sixfold discontinuously. Though it is not illustrated, thermoelectric power also jumps at T_c from 150~200 μV/deg to 600~700 μV/deg.

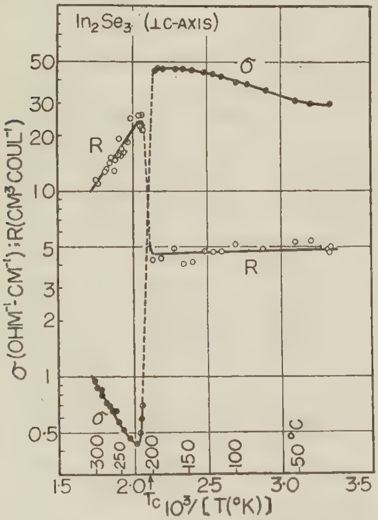

Fig. 1. Discontinuous changes of conductivity and Hall constant due to phase transition of In_2Se_3.

These changes are accompanied by extraordinary volume contraction of the crystal. This is obvious from Fig. 2, where thermal expansion measured in the direction perpendicular to the c axis is shown. One can see that the specimen does shorten by 0.5 percent in its length at T_c. Meanwhile, the thermal expansion appeared to be anisotropic and it was disclosed that in one case the rate of contraction along the c axis was about four times larger than that along (0001) plane.

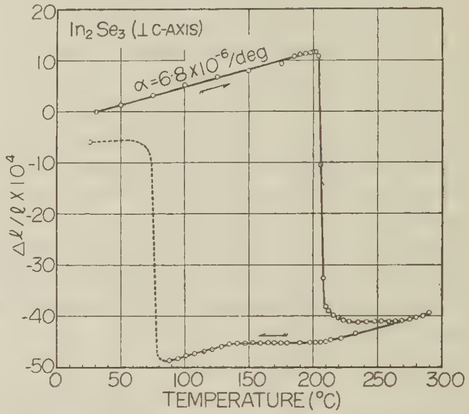

Fig. 2. Thermal expansion of In_2Se_3 characterized by marked contraction at T_c with increasing temperature and by striking supercooling with decreasing temperature.

Differential thermal analysis carried out on powdered sample, provided that temperature is slowly increased, indicates a sharp heat absorption process at T_c which may correspond to the latent heat. Supercooling is always characteristic to all quantities observed. As for the thermal expansion, for example, recovery to the lower temperature phase, when temperature is decreased, takes place below 100°C as seen in Fig. 2. Of course, simultaneous recovery of electrical quantities is confirmed.

Since the crystals easily cleave along (0001) plane somewhat like a mica sheet, it is difficult to cut out a specimen along the c axis which is long enough to set probes for electrical anisotropy measurements. However, it appears that current-voltage characteristics observed along the c axis suggest large anisotropy in conductivity, which is especially striking at the lower temperature phase and slightly diminishes at the higher temperature phase.

Further results and discussions will be published later.

The Generation of EMF During Melting and Freezing of Ionic Crystalline Substances

By Kiyoshi Azuma and Hiroshi Kametani

Department of Metallurgy, Faculty of Engineering, Tokyo Univ.

(Received September 20, 1956)

The emf studies on ionic crystals during melting and freezing were carried out with the apparatus illustrated in Fig. 1. In a silica tube two platinum electrodes are placed 20 mm apart. A pre-heating coil is wound around the silica tube. This set is put in an electric furnace which is movable at a constant velocity. The pre-heating coil raised the temperature of the salt and maintained it at least over 660°C. This pre-heating method reduced the error due to the internal resistance of the KCl system to below 10%, and minimized the possibility of the damage to the tube by the expansion-contraction of the salt accompanying melting and freezing.

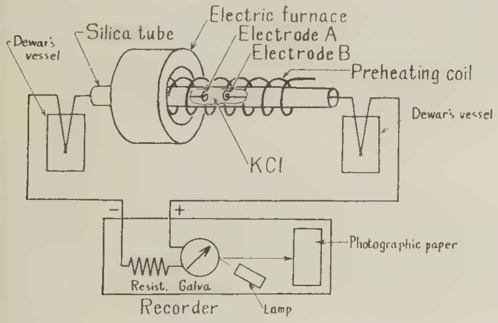

Fig. 1.

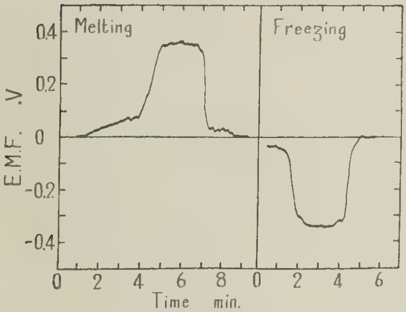

Fig. 2.

The KCl (Guaranteed Reagent) in the tube was melted and allowed to solidify. The furnace was moved from left to right, melting the salt. When the melting phase reached the electrode A, the emf appeared. The emf persisted as long as the solid phase existed between the electrodes A and B and disappeared when the melting phase reached the electrode B and only molten material remained between the electrodes. A freezing phase followed the passage of the furnace. When this freezing phase reached the electrode A, the oppositely polarized emf was developed which continued as long as molten salt remained between the electrodes. Fig. 2 illustrates the development and magnitude of the emf in the above sequence. The maximum emf obtained for KCl and similar substances are listed in Table I. A similar phenomenon has been noted for silicates such as glass, ferrous silicates etc$^{1)}$.

Table I.

Substance	EMF V	Substance	EMF V
KCl	0.33±0.03	NaCl	0.36±0.03
KBr	0.31±0.03	AgCl	0.29±0.03
KI	0.28±0.02		

The solid generally had a positive charge against the melt. Futher experiments show that the magnitude of the emf is independent of the shape of the electrodes, the distance between them and the rate of movement of the melting and freezing phases in the range of 0.3 to 3.4 cm/min., assuming that they travelled at the same velocity as the furnace. This was also true when the cooling rate was increased to 30 cm/min. by quenching the tube with water.

In another experiment the electrode B was maintained at 740°C and the electrode A at 830°C. When the temperature gradient was kept constant between the solid at one electrode and the melt at the other, the measured emf was negligible. It appears, then, that the emf is generated only when a phase change is taking place.

Workman and Reynolds$^{2)}$ and Gill$^{3)}$ have noted that the potential difference as great as 230 V accompany the freezing of dilute aqueous solutions. This phenomenon may be analogous to the one we have studied. However, there is a difference in the bonding nature of the water solution and the ionic crystals, and at high temperatures the determining factor is not "structure-sensitive lattice defects" but thermal vibration of atoms or ions. Taking into account the Schottky defects existing on the surface of the NaCl crystal in contact with its vapor, Lehovec$^{4)}$ calculated the surface potential to be −0.28 V. Though we are dealing with the solid-melt interface, it may be of some meaning that his calculated value is comparable to our result.

Frequency Shift in Ammonia Absorption due to Self-broadening

By Kiyokata MATSUURA, Yoshikazu SUGIURA and G. M. HATOYAMA
Electrotechnical Laboratory, Nagata-cho, Tokyo

(Received December 25, 1956)

Although it is well known that the resonance frequencies of molecules in visible and infrared regions vary with pressure, and the amount of the shift is proportional to the line width, the corresponding shift in microwave region has not yet been observed. Theoretically, the shift due to collision broadening is expected to be much smaller in microwave region than in visible or infrared region. For example, Towness[1] estimates a shift of less than 5×10^{-2} Mc per Mc width.

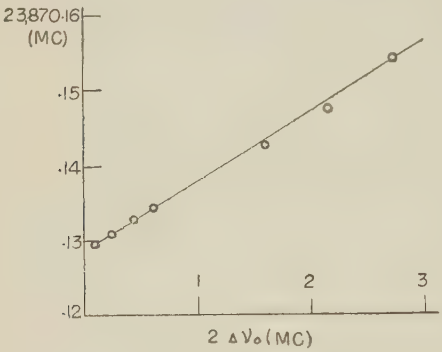

Fig. 1.

We have observed during the course of researches on atomic clock the shift in resonance frequency of ammonia (3,3) line with pressure.

An example of the measurements is shown in Fig. 1, where the apparent resonance frequency is plotted against the line width between half-power points. If the line-shape is assumed as

$$\gamma=\frac{\gamma_0}{(\nu-\nu_0-a\Delta\nu_0)^2+\Delta\nu_0^2},$$

where,

$1-e^{-\gamma}\approx\gamma$: absorption per cm for a plane wave,
$2\Delta\nu_0$: line width between half-power points,
ν: frequency of the incoming wave,
ν_0: resonance frequency of an isolated molecule,

we can estimate the value of a from the above measurement as

$$a=(1.8\pm0.1)\times10^{-2}.$$

The error given includes those coming from the uncertainties in the measurements of the resonance frequency and the line width. Errors from other sources such as coming from the purity of the gas should also be considered.

It has also been observed that the apparent resonance frequency varies with the foreign gases contained. Studies on such effects are now going on. The frequency shift reported previously[2] may come from either or both of these effects.

Crystal Structure and Phase Transition of Some Metallic Halides (IV)

On the Anomalous Structure of α-AgI

By Sadao HOSHINO*

Department of Physics, Tokyo Institute of Technology,
Oh-Okayama, Meguro-ku, Tokyo

(Received September 22, 1956)

Intensities of X-ray diffraction from α-AgI at various temperatures were measured in the absolute scale by using a G-M counter spectrometer with the crystal monochromated Cu $K\alpha$ radiation. Measurements of the specific heat and the thermal expansion were also performed. A drastic temperature dependence of the intensities of Debye lines and the presence of a comparatively strong diffuse background were detected. The observed intensities of the Debye lines could be explained well by the disordered structure model (or the "averaged structure") proposed by Strock (Z. Physik. Chem., **B31** (1936) 132.), assuming fairly large Debye factors for silver and iodine atoms. The intensity of the diffuse background from such an averaged structure was calculated in the similar way as in the case of binary alloys having short range order, assuming appropriate probability functions for the presence of atoms in different sites. It was confirmed that the intensity curves of the diffuse background measured at 250° and 400°C were in fair agreements with the theoretical ones. The nature of the "averaged structure" having the random arrangement of silver atoms and the origin of the large displacements of atoms from their equilibrium positions were discussed.

§ 1. Introdution

Silver iodide (AgI) has three solid phases α, β and γ. The crystal structure of the α-phase for the highest temperature range, from 148°C to the melting point 555°C, was investigated by Strock¹⁾, and is famous as a typical example of the "averaged structure". According to his X-ray study, α-AgI has a cubic unit cell in which two silver atoms are distributed statistically over fourty two sites around the body centered arrangement of iodine atoms. He considered that the silver atoms may behave almost liquid-like, in accordance with the remarkably high ionic conductivity of this phase. However, since his result is still qualitative, further studies of the structure of this phase seems to be desirable.

The present author has studied α-AgI by thermal and X-ray methods, in which the intensity of Debye lines and also of the diffuse background of the Debye lines have been accurately measured in absolute scale by the use of a G-M counter spectrometer. Results of the intensity measurements have been compared with some possible models of the α-AgI structure.

§ 2. Experimental

1. *Preparation of Specimen*

The sample was prepared by the following chemical reaction.

$$AgNO_3aq.+KI\,aq.\rightarrow KNO_3aq.+AgI\downarrow$$

As was reported by Bloch and Möller²⁾, AgI samples prepared by this method at room temperature contain sometimes coexisting phases γ and β. When the amount of $AgNO_3$ in the solution is in excess over the stoichiometric proportion the solution tends to precipitate the cubic γ-phase of ZnS type. On the other hand, when the amount of KI is in excess the hexagonal β-structure of ZnO type tends to precipitate. The cubic γ-phase is stable at room temperature, while the hexagonal β-phase is only metastable since the stable range of the β-phase is from 136° to

---

* Now at Department of Physics, The Pennsylvania State University, University Park, Pennsylvania, U.S.A

148°C. In fact, the metastable hexagonal state at room temperature was found to transform readily to the cubic γ-phase by grinding the samples. It was confirmed that the structure of the α-phase is not affected by the forms of the precipitate at room temperature. We used, however, the sample obtained from the solution containing slightly excessive KI, because the sample prepared with excessive $AgNO_3$ showed a tendency to separate gradually free metallic silver at the surface of specimen.

2. *Specific Heat Measurement*

In order to confirm the transition temperature and to obtain some information about the phase transition of AgI, the temperature change of the specific heat was measured. AgI sample (14 gr. in weight) sealed in a hard glass vessel (3 gr. in weight) was set in an adiabatic calorimeter of modified Sykes's type[3]. The heat input given to the specimen was about 0.05 cal/sec. The specific heat vs. temperature curve (Fig. 1) shows only one transition peak at 148°C corresponding to the $\beta \rightarrow \alpha$ transition, wanting the peak corresponding to the $\gamma \rightarrow \beta$ transition at 136°C. This is because the sample was used for which the hexagonal β-phase was metastable at room temperature. The transition energy ΔQ and the entropy change ΔS obtained for the $\beta \rightarrow \alpha$ phase change are as follows:

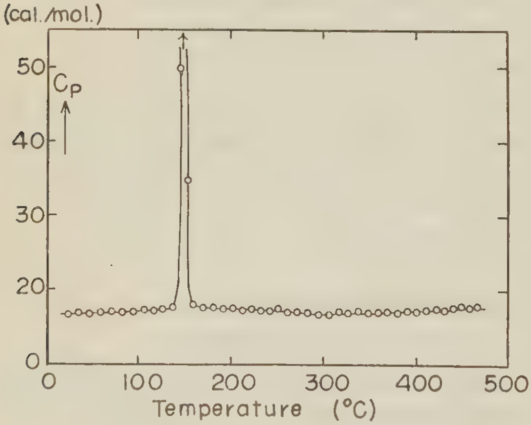

Fig. 1. Specific heat vs. temperature curve.

$$\Delta Q = 1.53 \text{ Kcal/mol.}$$
$$\Delta S = 3.6 \text{ cal/mol. degree.}$$

3. *Thermal Expansion*

The measurement of the lattice constant a_0 of cubic α-AgI at various temperatures was performed by the analysis of X-ray photographs from AgI powder coated on a Pt wire. Because the intensities of the reflexion lines of α-AgI decrease rapidly with diffraction angle especially at high temperatures, we were obliged to use the line (321) at a comparatively low angle of reflexion. The Pt wire served as the standard specimen. The result of this measurement is shown in Fig. 2.

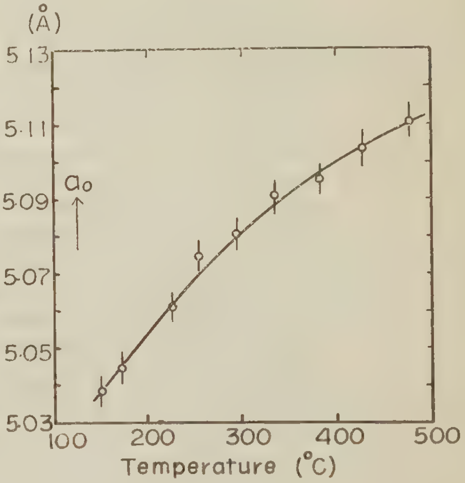

Fig. 2. Change of lattice constant a_0 with temperature.

In addition to the measurement of the lattice constant by X-ray method, we measured the thermal expansion by the ordinary dilatometric method. The sample used in the dilatometry was shaped to a cylinder of diameter 10 mm and length 35 mm by four ton weight press. As the crystal of α-AgI is highly plastic, we must avoid the deformation at the top of the sample caused by the weight of the silica tube touching there. To prevent this influence a very thin and light silica tube was used and a thin mica plate was inserted between the sample and the silica tube. The change of the linear expansion with temperature obtained by this method is shown in Fig. 3, where black circles show the values by the X-ray method. The results by the two methods show general agreement except for high temperatures.

4. *X-ray Intensity Measurement*

In the X-ray measurement a rotating copper anode X-ray tube[4] having a fine focus was used as the X-ray source, because the X-ray diffraction intensities from powdered specimen of α-AgI, especially the intensity of diffuse background, are very weak and, moreover, it was desired to use monochromatic beam in the present study. The tube was opetated with electron current about 70～80 mA and voltage 20～25 kV. Cu K radiation generated from this tube was momochromated by the (200) reflexion from a LiF crystal monochromator. Comparatively low tube voltage was applied in order to prevent the participation of higher harmonic terms.

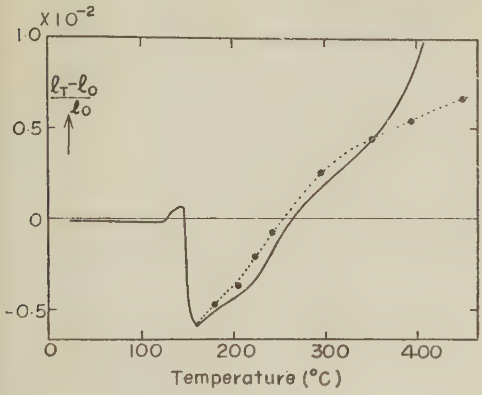

Fig. 3. Thermal expansion vs. temperature curve.

Measured values were standardized by using a monitor counter whicn detects the change of incident intensities by measuring a reflexion from Al foil set behind the first slit. Scheme of the measurement is shown in Fig. 4.

By pressing slightly the powder specimen in a metal case, a plate shape sample of 15 mm × 10 mm × 1 mm was made, and was set in a furnace made of isolite. Temperature of the sample was measured by an alumel-chromel thermocouple. The accuracy of temperature measurements was within about ±5°C even at high temperatures.

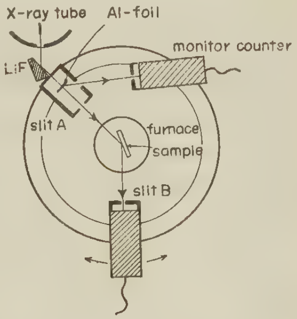

Fig. 4. Schematic diagram of X-ray intensity measurement.

Values of the height l and the breadth b of the slit B and the distance R from the center of the sample to the slit were chosen as inscribed in the following figures explaining each measurement. The slit breadth b was taken sufficiently wide to cover the whole

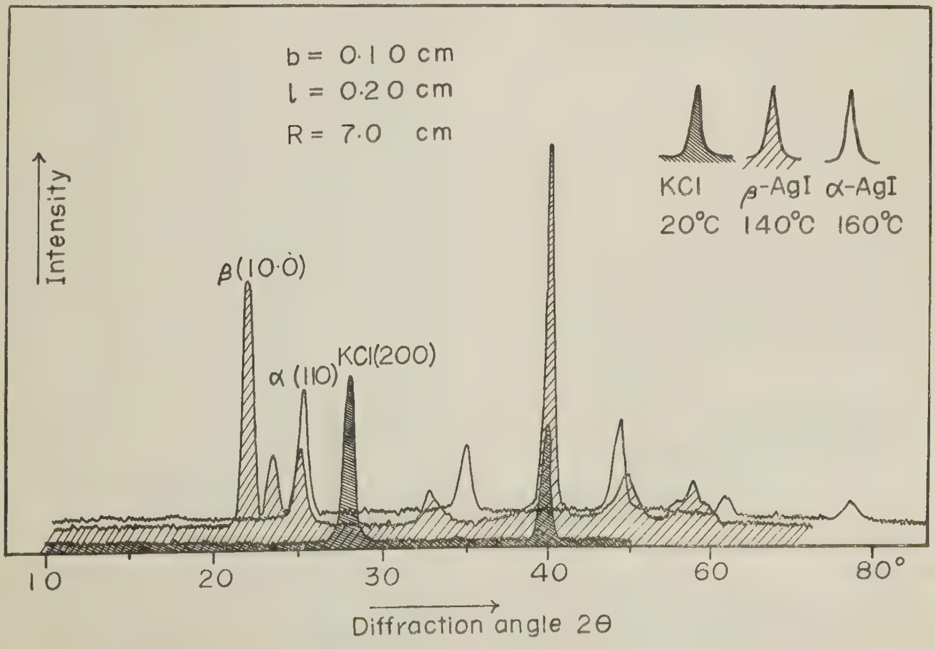

Fig. 5. Intensity curves with monochromated CuKα radiation.

width of each line so as to obtain the integrated intensity of the Debye lines.

Fig. 5 is the intensity curves obtained by the ordinary self recording method. The curves from β-AgI at 140°C and KCl at room temperature are also shown for comparison. It is readily seen in this figure that the diffuse background of α and β-AgI is considerably prominent compared with that of KCl.

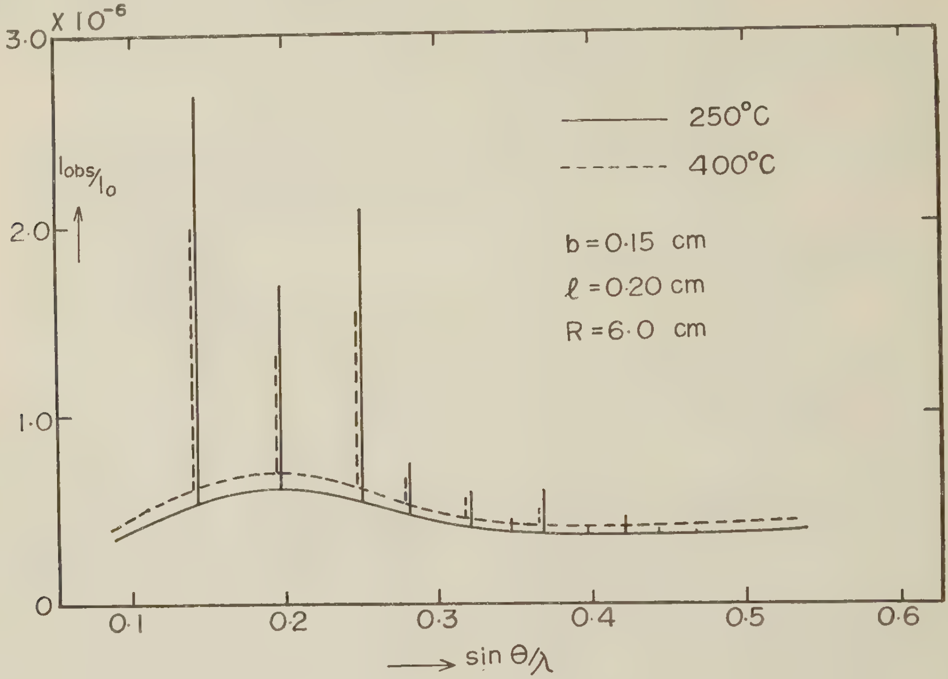

Fig. 6. Intensity curves at 250°C and 400°C measured by counting with monochromated CuKα, as functions of $\sin\theta/\lambda$.

More precise intensity measurement was performed by measuring the counts in a constant time-interval for the diffraction angle 2θ from 10° to 110°. Intensity curves obtained were transformed into an absolute intensity scale by the measurement of line intensities from standard specimens such as KCl, NaCl and CuI powdered crystals. The background proper to the apparatus, such as the scattering from air and the slit A and natural counts of the counter tube was subtracted. The intensity curves thus obtained for 250° and 400°C are shown in Fig. 6, in which the length of vertical lines represents the integrated intensity of Debye lines.

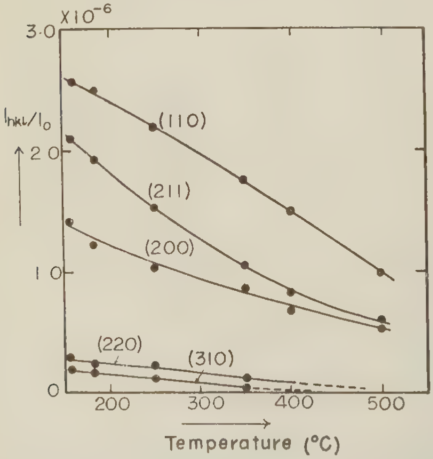

Fig. 7. Intensity change of Debye lines with temperature.

The integrated intensities of several Debye lines were measured at various temperatures. The result is shown in Fig. 7.

§ 3. Structure Model and Temperature Effect

1. *Intensities of Debye Lines and Structure Model*

In the structure model of α-AgI proposed by Strock (which is referred to as Model A), two silver atoms in the unit cell occupy the the following fourty sites of the space group $Im3m$ with an equal probability:

(0 0 0, 1/2 1/2 1/2)+
6(*b*) 0 1/2 1/2 ↺;
12(*d*) 1/4 0 1/2 ↺, 3/4 0 1/2 ↺;
24(*h*) 0 1/8 1/8 ↺, 0 7/8 7/8 ↺;
0 1/8 7/8 ↺, 0 7/8 1/8 ↺.

Strock showed that the relative intensities of Debye lines can be well explained by this model. On the other hand, the present author[5)] has previously proposed an alternative model of α-AgI which, referred to as Model B, is also in accordance with the observation so far as the relative intensities are concerned.* This circumstance implies the fact that in the case of α-AgI, for which only several lines are observable on account of a rapid intensity decrease with scattering angle, the relative intensties of the Debye lines can not supply a deciding information for the structure determination. However, the difficulty of finding the correct structure may be much reduced when the comparison of calculated and observed values is performed with respect to the absolute intensity.

The intensities of Debye lines, $I(hkl)$, reflected by a powdered block is calculated by the formula

$$I(hkl) = I_0(e^2/mc^2)^2 N_0 \frac{l}{2\mu} \frac{\lambda^3 j}{32\pi R a_0{}^3} \frac{1+\cos^2 2\theta \cos^2 2\mathcal{E}}{\sin^2\theta\cos\theta} |\overline{F^2}|, \tag{1}$$

where I_0 is the total intensity flux of the incident beam, N_0 the number of the unit cell in unit volume, l the height of the slit B, μ the linear absorption coefficient, a_0 the lattice constant, R the distance from the sample to the slit B, j the multiplicity, and $\mathcal{E}$ the Bragg angle for the monochromator crystal. $\overline{F}$ is the mean structure amplitude of the satistical structure, which is expressed as

$$\overline{F} = \Big< \sum_i f_i \exp[-B_i(\sin\theta/\lambda)^2] \exp[2\pi \boldsymbol{i}/\lambda(\boldsymbol{s}-\boldsymbol{s}_0\cdot\boldsymbol{r}_i-\boldsymbol{r}_{i'})] \Big> \tag{2}$$

where B_i is the Debye factor for the ith atom in a unit cell.

The results of calculations for the intensities of several lines are shown in Fig. 8 in comparison with the observed values. In this figure the solid curve corresponds to the observation at 250°C, and the broken curves *a* and *b* show the calculated values for the structures of Model A and B respectively. In these calculations the Debye factors, B_i, were chosen so as to bring the best agreement between the calculated and the observed relative intensities of the lines. They were put

$B_{Ag}=8$, $B_I=8$ for Model A, and
$B_{Ag}=3$, $B_I=2$ for Model B.

In Fig. 8, it is seen that the intensity values of Model A are in a good agreemenl with observation (with the reliability index $R=0.09$*) not only in the relative values but also

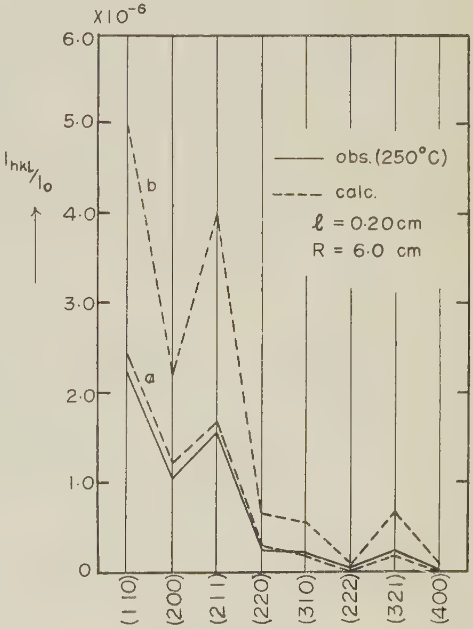

Fig. 8. Observed and calculated values of Debye line intensities.

---

* The proposed model is a partially disordered structure between a perfectly ordered and a perfectly disordered structure. The perfectly ordered structure has the tetragonal unit cell with the axial ratio $c/a=1$ and the space group $I\bar{4}m2$; iodine stoms are at (0 0 0), (1/2 1/2 1/2), and sliver atoms at (0 1/2 1/4), (1/2 0 3/4). The perfectly disordered structure has a cubic symmetry and belongs to the space group $Im3m$; iodine atoms are in the same positions as in the ordered structure, whereas the two silver atmos are distributed statistically over the 12(*d*) sites. The relative intensities of Debye lines could be explained well when the parameter of the degree of order S was put as 0.8 and values of the Debye factors were appropriately assumed.

* The index adopted here is defined as

$$R = \frac{\sum|I_{\rm obs}-I_{\rm calc}|}{\sum I_{\rm obs}}.$$

in the absolute values. On the other hand, Model B fails decidingly with respect to the absolute intensity.**

2. *Temperature Dependence of Line Intensity*

In the previous section we found that Model A is a more favourable model than model B for the structure of α-AgI. To get this agreement, however, we had to assume the anomalously large Debye factors in the calculation. Moreover, as seen in Fig. 7, the line intensities decrease drastically with increasing temperature, so that far larger Debye factors should be taken into account at higher temperatures. These facts seem to show that in α-AgI crystal the displacements of atoms from their mean positions are very large.

The Debye factor B_i in the equation (2) was introduced formally without accounting for its physical implication, assuming only the statistical displacements of atoms from their mean positions. It is natural to consider that the thermal vibration of atoms is the most important cause for the statistical displacements of atoms. However, since the anomalously large Debye factor assumed for α-AgI is in the outside of the scope of the ordinary theory of thermal vibration, we can not exclude some other origins of the statistical displacements. For instance, irregularities of the atomic positions associated with the disordered structure supposed for α-AgI might contribute to the large Debye factors.

The experimental result shows that the B-factor is the function of temperature whatever its implication may be. The change of the *mean* Debye factors, $\overline{B}$, can be deduced by the relation

$$\ln [I_F \exp(-2\overline{B}_{T_1}[\sin\theta/\lambda]^2)$$
$$\div I_F \exp(-2\overline{B}_{T_2}[\sin\theta/\lambda]^2)]$$
$$=2(\overline{B}_{T_2}-\overline{B}_{T_1})(\sin\theta/\lambda)^2\,,$$

where I_F corresponds to the intensity for a hypothetical state of crystal in which atoms are frozen in their equibrium positions, and $\overline{B}_{T_1}$ and $\overline{B}_{T_2}$ are the mean Debye factors at temperatures T_1 and T_2 respectively. Fig. 9 shows the temperature dependence of $(\overline{B}_{T_2}-\overline{B}_{T_1})$ calculated from the intensity change of (110), (200) and (211) shown in Fig. 4; T_1 is fixed at 160°C. If the origin of the ordinate in Fig. 9 is displaced so as the value at 250°C becomes 8 in accordance with the result in the previous section, we can find $\overline{B}$ value at any temperature. The calculations for the Debye line intensities with these $\overline{B}$ values at various temperatures showed fair agreements with observations up to the temperature of about 350°C. Above this temperature the deviation begins to appear, indicating the inadequacy of the use of the mean factor $\overline{B}$ for the two kinds of atoms.

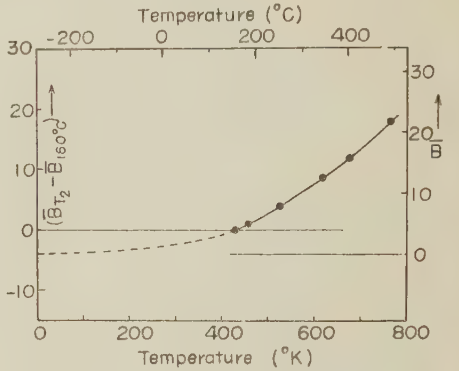

Fig. 9. $(\overline{B}_{T_2}-\overline{B}_{160°C})$ vs. temperature curve.

§ 4. Interpretation of Diffuse Background

In addititon to the absolute intensity measurement of the Debye lines, another helpful information is available for the structure determination of α-AgI. That is the measurement of the diffuse background due to the disordered structure supposed for α-AgI.

The intensity of the diffuse background I_B scattered by a crystal of a disordered structure may be written as

$$I_B=I_D+I_S+I_{\text{incoh.}}\,, \tag{3}$$

where I_D is the diffuse term due to the disordered structure, I_S the term due to the statistical displacements of atoms from their mean positions caused by thermal vibration and other origins, and $I_{\text{incoh.}}$ the term due to the incoherent scattering.

Since the first term in (3) is most important one in the present study, let us obtain a general expression of I_D for the "averaged

---

** Model B fails also in explaining the absolute intensity of the diffuse scattering (§ 4).

structure" in which the number of atomic sites is more abundant than that of atoms and the atoms are distributed statistically over these sites. It is conceived that in the structure of α-AgI only one kind of atom, silver atom, has the statistical arrangement. If this is the case, the disordered term I_D is solely due to the scattering from silver atoms, and may be expressed as

$$I_D=I_0k\sum_s\sum_{s'}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_s-\boldsymbol{R}_{s'})\right]\Delta f_s\cdot\Delta f_{s'},\tag{4}$$

where k is a constant depending on the experimental conditions, $\boldsymbol{R}_s$ is the position vector of the sth site in the crystal and summation is taken over the unit volume of the crystal. Δf_s is defined as the deviation of the scattering amplitude f_s at the sth site from the mean scattering amplitude $\overline{f}$, namely

$$\Delta f_s=f_s-\overline{f}\,.$$

If all the sites are equivalent, the probability of finding the atom in any sites, W, is equal to the ratio of the number of atoms to the number of sites in the crystal, and we obtain

$$\overline{f}=Wf_{Ag}$$

and

$$\Delta f_s=f_s-Wf_{Ag}\,,\tag{5}$$

where f_{Ag} is the atomic scattering factor of silver atom and f_s is either f_{Ag} or 0.

The equation (4) can be treated in the similar way as in the case of binary alloy having short range order. The equation (4) in written as

$$I_D=I_0k\Big[\sum_s(\Delta f_s)^2+\sum_s\sum_{s'}{}'\Delta f_s\cdot\Delta f_{s'}\times\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_s-\boldsymbol{R}_{s'})\right]\Big],\tag{6}$$

in which the prime added to the summation symbol in the second term means to omit the term of $s=s'$. Since, from (5), Δf_s is $(1-W)f_{Ag}$ or $-Wf_{Ag}$, thus

$$(\Delta f_s)^2=(1-W)^2f_{Ag}^2\quad\text{or}\quad W^2f_{Ag}^2\,.$$

The probabilities for the two cases are W and $(1-W)$ respectively, so we have

$$\langle(\Delta f_s)^2\rangle=W(1-W)^2f_{Ag}^2+W^2(1-W)f_{Ag}^2=W(1-W)f_{Ag}^2\,.$$

Thus the first term of the summation in (6) is given as

$$\sum_s\langle(\Delta f_s)^2\rangle=pN_0W(1-W)f_{Ag}^2\tag{7}$$

where p is the number of sites in a unit cell.

In order to calculate the second term in (6), let us introduce the probability functions $\alpha(r)$ and $\beta(r)$ as follows: $\alpha(r)$ gives the probability of finding an atom at a site apart by a distance r from a site occupied by an atom, and $\beta(r)$ the probability of finding an atom at a site apart by r from a vacant site. By the use of these two functions we can obtain

$$\langle\Delta f_s\cdot\Delta f_{s'}\rangle=W(1-W)[\alpha(r_{s,s'})-\beta(r_{s,s'})]f_{Ag}^2\,,\tag{8}$$

where $r_{s,s'}$ denotes the distance between the sth and the s'th sites. Thus, by the use of atomic scattering amplitudes taking account of Debye factors, the disordered term of the diffuse scattering may be expressed as

$$I_D=I_0kN_0pW(1-W)f_{Ag}^2\exp\left[-2B_{Ag}(\sin\theta/\lambda)^2\right]\left[1+\frac{1}{pN_0}\sum_s\sum_{s'}{}'(\alpha-\beta)_{r_{s,s'}}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_s-\boldsymbol{R}_{s'})\right]\right]\tag{9}$$

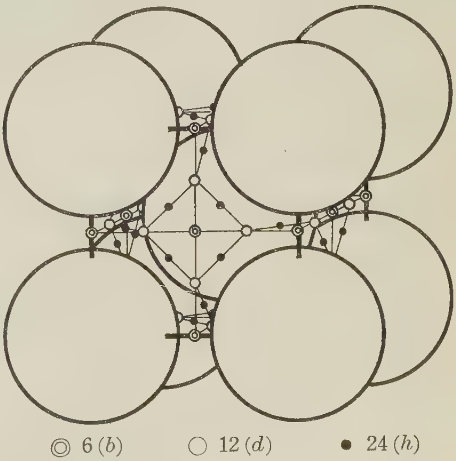

Fig. 10. Structure of α-AgI.

As mentioned in a previous section, the fourty two sites for silver atoms in Model A are classified into three kinds of positions (b), (d) and (h) (Fig. 10). Thus the summation in (9) for Model A is given by the three terms as follows:

$$\frac{1}{pN_0}\sum_{s}\sum_{s'}{}'(\alpha-\beta)_{r_{s,s'}}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_s-\boldsymbol{R}_{s'})\right]=\frac{1}{pN_0}\Big[\sum_{s(b)}\sum_{s'}{}'(\alpha-\beta)_{r_{s(b),s'}}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_{s(b)}-\boldsymbol{R}_{s'})\right]$$

$$+\sum_{s(d)}\sum_{s'}{}'(\alpha-\beta)_{r_{s,s'}}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_{s(d)}-\boldsymbol{R}_{s'})\right]+\sum_{s(h)}\sum_{s'}{}'(\alpha-\beta)_{r_{s(h),s'}}\exp\left[2\pi i(\boldsymbol{b}\cdot\boldsymbol{R}_{s(h)}-\boldsymbol{R}_{s'})\right]$$

$$=\frac{1}{pN_0}\Big[p_bN_0\sum_{s'}{}'(\alpha-\beta)_{r_{s(b),s'}}\exp\left[2\pi i\,\boldsymbol{b}\cdot\boldsymbol{R}_{s(b),s'}\right]+p_dN_0\sum_{s'}{}'(\alpha-\beta)_{r_{s(d),s'}}\exp\left[2\pi i\,\boldsymbol{b}\cdot\boldsymbol{R}_{s(d),s'}\right]$$

$$+p_hN_0\sum{}'(\alpha-\beta)_{r_{s(h),s'}}\exp\left[2\pi i\,\boldsymbol{b}\cdot\boldsymbol{R}_{s(h),s'}\right]\Big] \tag{10}$$

where the index $s(b)$ specifies the sth of the (b) type sites and p_b is the number of the (b) type sites per unit cell, and so forth.

Expression (10) can be simplified in the case of powder samples. If we write $\frac{\sin(4\pi r\sin\theta/\lambda)}{4\pi r\sin\theta/\lambda}=S_r$, then the disordered term of the diffuse scattering from a powder sample is given by

$$I_D=I_0kN_0n(1-W)f_{Ag}{}^2\exp\left[-2B_{Ag}(\sin\theta/\lambda)^2\right]\Big[1+p_b/p\sum_{s'\neq0}Z_{s(b),s'}(\alpha-\beta)_{r_{s(b),s'}}S_{r_{s(b),s'}}$$

$$+p_d/p\sum_{s'\neq0}Z_{s(d),s'}(\alpha-\beta)_{r_{s(d),s'}}S_{r_{s(d),s'}}+p_h/p\sum_{s'\neq0}Z_{s(h),s'}(\alpha-\beta)_{r_{s(h),s'}}S_{r_{s(h),s'}}\Big] \tag{11}$$

where $n(=pW)$ corresponds to the number of silver atoms per unit cell and $Z_{s(b),s'}$ is the number of sites belonging to the s'th neighbor around a (b) type site.

The factor $(\alpha-\beta)_{r_{s,s'}}$ is an analogous function to the distribution function of the short range order in alloys. Let us consider two sites s and s' which are apart by the distance r. The probability of finding an atom in s and a vacancy in s' simultaneously is $W(1-\alpha_r)$, while the probability of finding a vacancy in s and an atom in s' is $(1-W)\beta_r$. Since these two probabilities should be equal, we find a relation

$$W(1-\alpha_r)=(1-W)\beta_r\,. \tag{12}$$

This equation gives a relation between α_r and β_r and will be used later for the calculation of I_D.

The kind and the number Z of neighboring sites around each kind of positions and the neighboring distances are as listed in Table 1, in which the distance is expressed by a fraction of the lattice constant, namely, by r_s/u, where $u=a_0/8$. The values of r_s at 160°C are given in Table 2.

The possibility of the simultaneous presence of silver ions in closer neighboring sites should be excluded on account of the finite radius of the siver ion. The ionic radius of Ag⁺ has been given by Goldschmidt and by Pauling and their values are 1.13 Å and 1.26 Å respectively. In our consideration Goldschmidt radius was adopted, though Pauling

radius gave almost the same result. By the mutual interference due to the ionic radius, α_r should be put zero for the following neighbors;

from the 1st to the 3rd neighbors around the (*b*) type sites,
from the 1st to the 4th neighbors around the (*d*) type sites,
from the 1st to the 5th neighbors around the (*h*) type sites,

From the relation $\alpha_r=0$ for these neighbors and the eqation (12), we have

$$(\alpha-\beta)_r=-\beta_r=-W/(1-W)=-1/20,$$

where $W=2/42$.

The functions of $(\alpha-\beta)_r$ for the other neighbors are difficult to estimate unless some approximations are introduced. For large r, both α_r and β_r may be equal to W and consequently $(\alpha-\beta)_r=0$. Thus, we assume $(\alpha-\beta)_r=0$ for the neighbors farther than the 5th neighbor for the (*b*) type positions, the 6th one for the (*d*) type positions and the 7th one for the (*h*) type positions. Finally, the functions for the 4th neighbor for (*b*), the 5th one for (*d*) and the 6th one for (*h*) can be given by the condition that the total of the probability functions, $\sum_s(\alpha-\beta)_{r_{s,s'}}$, is -1. Thus, they are determined as $-1/20$, $-3/80$ and $-3/40$, respectively.

We can now calculate the diffuse scattering I_D by using the above values of the probability functions. I_D is expessed as

$$I_D=I_0kN_0n(1-W)f_{Ag}{}^2\exp[-2B_{Ag}(\sin\theta/\lambda)^2]$$
$$\times\left[1-\left(\frac{6}{35}S_{u\sqrt{2}}+\frac{4}{35}S_{u\sqrt{4}}+\frac{4}{35}S_{u\sqrt{6}}+\frac{3}{35}S_{u\sqrt{8}}\right.\right.$$
$$\left.\left.+\frac{8}{35}S_{u\sqrt{10}}+\frac{9}{35}S_{u\sqrt{14}}+\frac{1}{35}S_{u\sqrt{16}}\right)\right] \tag{13}$$

where $n=2$ and

$$k=(e^2/mc^2)^2\frac{bl}{2\mu R^2}\frac{1+\cos^2 2\theta\cos^2 2\varepsilon}{2}$$

It is known that the diffuse background I_S from the powder sample is approximately expressed as

$$I_S=I_0kN_0\sum_i f_i{}^2(1-\exp[-2B_i(\sin\theta/\lambda)^2]).$$

In this equation, the correlations among the displacements of different atoms are neglected. In the case of α-AgI, I_S is given by

$$I_S=I_0kN_0n[f_I{}^2(1-\exp[-2B_I(\sin\theta/\lambda)^2])$$
$$+f_{Ag}{}^2(1-\exp[-2B_{Ag}(\sin\theta/\lambda)^2]) \tag{14}$$

The intensity of the diffuse background I_B from α-AgI is given by the sum of I_D ((13)), I_S ((14)) and the incoherent scattering $I_{incoh.}$

When the influence of the anomalous disperson is taken into account, the atomic scattering factor f is expressed as

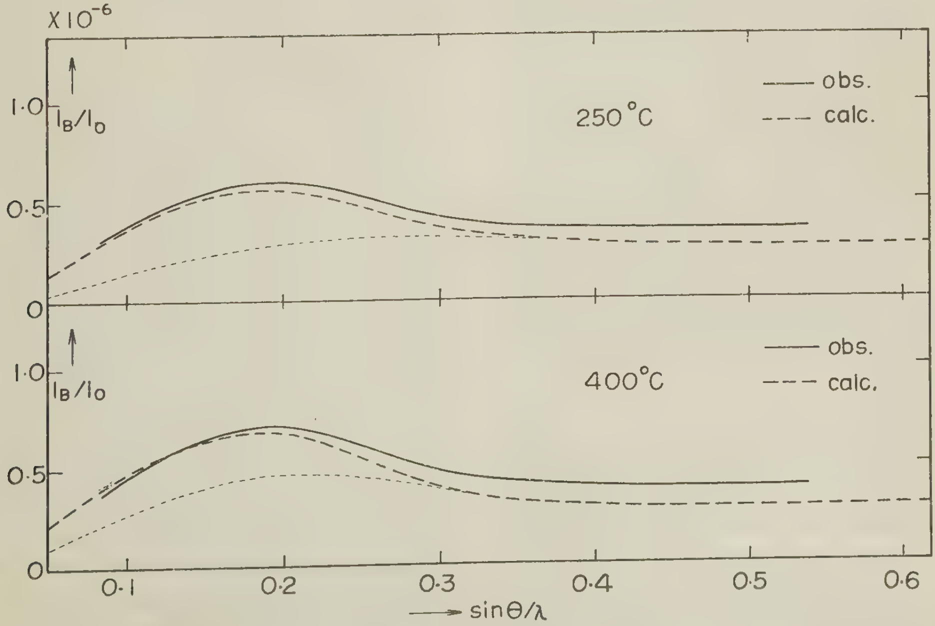

Fig. 11. Observed and calculaed intensities of the diffuse background of α-AgI.

$$f=f_0+\Delta f'+i\Delta f''.$$

In the present study in which the CuKα radiation is used, the imaginary term $\Delta f''$ for both the iodine and the silver atoms has an appreciable influence on the diffuse background, especially on the term I_S. The amounts of $\Delta f''$ are 7.2 for iodine and 4.7 for silver at $\theta=0$, while the values of f_0 are 53 and 47 respectively.[10] The square of $\Delta f''$ is not so large compared with that of f_0 at $\theta=0$, but at high diffraction angles its contribution to f^2 becomes important, because the value of $\Delta f''$ does not decrease appreciably with increasing angle. The real term $\Delta f'$ is negligibly small. Thus, I_S was calculated by using the corrected scattering factor $f=f_0+i\Delta f''$.

In Fig. 11 the calculated and the observed I_B/I_0 curves (drawn by the thick broken and solid curves respectively) are compared for 250° and 400°C. The thin broken curve indicates $I_S+I_{incoh.}$ Consequently, the difference between the thick broken curve and the thin broken one corresponds to the theoretical values of I_D. In the calculation, the Debye factors $\overline{B}$ are taken as 8 and 15 for 250° and 400°C respectively. In Fig. 11 we can see that, for both temperatures 250° and 400°C, the curves of the calculation and the observation are in a fair agreement in the smaller range of the diffraction angle, although the deviation of these curves increases gradually with increasing diffraction angle. The deviation seems to result from the rough approximation in the calculation of I_S neglecting the correlations among the displacements of atoms. In addition, as mentioned before (§ 3), there is some doubt about the use of the mean Debye factor $\overline{B}$ above 350°C. However, it seems to be difficult to give more refined expression for I_S in the present step of study.

§ 5. Discussion

As described in the foregoing sections, the result of the intensity comparison of the diffuse background as well as of the Debye lines in the absolute scale seems to favor Model A (or Strock's model) for the structure of α-AgI. This structure has the two remarkable features as follows:

(a) Statistical distribution of silver atoms over many sites.

(b) Large statistical displacements of silver and iodine atoms from their mean positions.

In model A, the probabilities of finding the atom in the sites (*b*), (*d*) and (*h*) are assumed to be equal. However, it is not appropriate to accept this assumption strictly, since we can obtain a good agreement of the intensity of diffuse background even when the assumption is properly modified. For instance, let us suppose that the two silver atoms in unit cell take only 12 (*d*) sites, but the probabilities of finding the atoms in (*b*) and (*h*) type sites are zero (Model C). The calculated intensity of diffuse scattering I_D due to this structure is shown in Fig. 12 by the dotted curve, in comparison with the curve for Model A. We can see by this figure that the assumption of different probabilities of finding atoms in the different kinds of site influences the intensity of diffuse scattering only little. Although Model C can not explain well the intensities of Debye lines, it is probable that we can find an intermediate structure between Model A and Model C which is capable of explaining the intensities of Debye lines as well as the intensities of diffuse background.

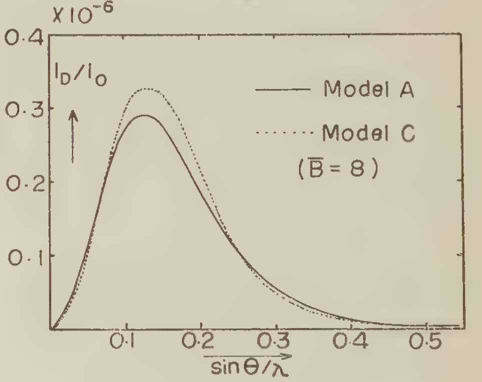

Fig. 12. Comparison of I_D curves for Model A and Model C.

In the case of the intermediate structure as above, it may be expected that the degree of disorder of the distribution of silver atoms over possible sites becomes larger with increasing temperature. If this is the case the specific heat in the α-phase will increase with rising temperature. However, since no such tendency can be found in the specific heat vs.

temperature curve shown in Fig. 1, the temperature change of the degree of disorder, if any, is supposed to be very small.

There is the following well known relation between the Debye factor B_i and the atomic displacement from the equilibrium position, ξ_i;

$$B_i = 8\pi^2 \langle \xi_i^2 \rangle .$$

If the atomic displacement in α-AgI is assumed as isotropic on the average, the temperature change of the *mean* atomic displacement ξ for iodine and silver atoms is obtained experimentally by using the $\overline{B}$ values for various temperatures. Fig. 13 shows $\sqrt{\langle \xi^2 \rangle}$ thus obtained. We can see that the atomic displacement from the equilibrium position at high temperature is very large, being comparable with the nearest neighboring distance between the sites of silver, about 0.9 Å.

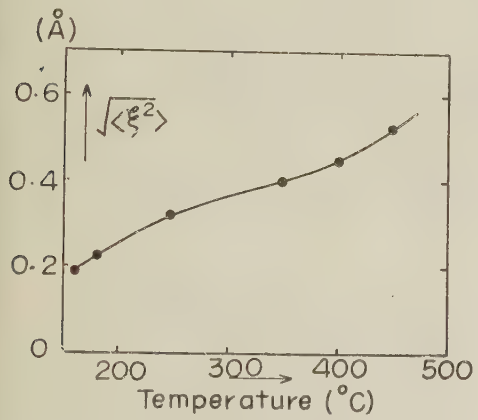

Fig. 13. Temperature change of $\sqrt{\langle \xi^2 \rangle}$.

We have studied previously the structures and the phase transitions of CuI⁽⁶⁾, CuBr⁽⁷⁾, CuCl, Ag_2HgI_4⁽⁸⁾ and Cu_2HgI_4.* In these crystals, only α-CuBr (which is stable in the temperature range from 470°C to the melting point 488°C) seems to possess the same structure as that of α-AgI, and the others have cubic ZnS type or hexagonal ZnO type structures. However, all of these crystals show a common nature that very large Debye factors for the metallic atoms must be introduced in order to explain the intensities of Debye lines at high temperatures so that the large amount of displacements of the metallic atoms is expected to occur. The origin of such common characteristic seems to be due to the thermal vibration mainly. On the other hand, in the α-AgI crystal the large value of B should be applied also to the iodine atom. This suggests that the large atomic displacements in α-AgI may be caused not only by the thermal vibration but also by the disordered structure. In fact, large local displacements of atoms are conceivable for the structure like α-AgI in which atoms are situated randomly and many sites in the lattice are left as vacant sites. Thus, we can consider that the liquid-like state of silver atoms as suggested by Strock may be an allowable picture of the structure of α-AgI in view of high randomness of the silver atoms due to the statistical distribution over many sites and the large statistical displacements from the mean positions of atoms.

In Fig. 3 showing the thermal expansion of AgI, the disagreement between the results from the ordinary dilatometry and the X-ray method is noted at high temperatures. From this fact, we may expect a possibility that a large number of vacancies of the negative ions are formed at high temperatures. However, this can not be concluded to be sure at present because the dilatometry might contain appreciable error due to the plastic deformation of the sample at these temperatures.

To study further details of the anomalous structure of α-AgI, the use of a single crystal seems to be necessary. The single crystal of α-AgI has not been obtained so far, while the single crystal of β-AgI can be prepared at room temperature in a solution of AgI with hydroiodic acid, by diluting gradually the solution with alcohl. When the single crystal of β-AgI was heated very slowly up to the temperature range of the α-phase in the furnace of the high temperature X-ray camera, it was found by Laue and rotation photographs that the crystal changed to an assembly of comparatively large grains of α-AgI orientating in nearly the same direction. This observation suggested that more perfect single crystals of α-AgI may be obtained by the similar method by refining the technique of thermal controle.

In conclusion the author wishes to express his best thanks to Prof. S. Miyake for his kind guidance and also to Dr. M. Takagi for her helpful discussions. Thanks are also due

---

* In these substances only CuCl has a single solid phase⁽⁹⁾.

Radial Distribution Function of Fluids I

By Kazuo HIROIKE

Department of Physics, Tokyo Institute of Technology

(Received December 8, 1956)

The consistency of several approximate radial distribution functions of fluids is examined in the sense that the pressure and the internal energy derived from them satisfy the thermodynamical relation $\frac{\partial}{\partial T}\left(\frac{p}{T}\right)=\frac{\partial}{\partial V}\left(\frac{E}{T^2}\right)$, where T, p, V and E have the usual meanings. It is found that the original form of Green's linear theory is the only one which satisfies the above relation. It is also shown that Green's theory can be improved further without breaking the above relation.

§ 1. Introduction

The pressure p and the internal energy E of a classical fluid of volume V and temperature T which is composed of N molecules can be expressed in terms of the radial distribution function $g(r)$ as follows[1]:

$$\frac{p}{\rho kT}=1-\frac{\rho}{6kT}\int_0^\infty g(r)\frac{d\phi(r)}{dr}4\pi r^3dr\,, \quad (1)$$

$$\frac{E}{\frac{3}{2}NkT}=1+\frac{\rho}{3kT}\int_0^\infty g(r)\phi(r)4\pi r^2dr\,, \quad (2)$$

where ρ is the number density N/V, k the Boltzmann constant and $\phi(r)$ is the potential energy of interaction between two molecules, which is assumed to be a function of the distance r alone. The radial distribution function is normalized as

$$\lim_{r\to\infty} g(r)=1;$$

and we have the following relation[2]:

$$kT\left(\frac{\partial\rho}{\partial p}\right)_T=1+\rho\int_0^\infty [g(r)-1]4\pi r^2dr\,. \quad (3)$$

It is seen from these equations that the thermodynamical properties of a fluid can be obtained from the knowledge of the distribution function $g(r)$. However, when some approximate $g(r)$'s are made use of, it often occurs that self-consistency of the theory is broken, since certain thermodynamical relations exist among the quantities on the left sides of Eqs. (1), (2) and (3). In fact it has been pointed out by several authors[3][4] that Eqs. (1) and (3) cannot be consistent if $g(r)$ based on Kirkwood's superposition approximation is used. Rushbrooke and Scoins[3] showed that this inconsistency can be reduced by adopting the so-called "netted-chain approximation" which can be used in place of the superposition approximation. It is not the purpose of this paper to investigate this inconsistency. Rather it will be pointed out that there is another inconsistency which is supposed to be more serious.

There exists the thermodynamical relation

$$\frac{\partial}{\partial T}\left(\frac{p}{T}\right)=\frac{\partial}{\partial V}\left(\frac{E}{T^2}\right) \tag{4}$$

between p and E. It is needless to say that relation (4) is satisfied by the values of p and E, which are calculated from Eqs. (1) and (2), if the exact distribution function $g(r)$ is used. If, however, some approximate $g(r)$ is used to calculate p and E, relation (4) is not always satisfied. It is the purpose of this paper to examine whether relation (4) holds or not for the approximate $g(r)$'s hitherto derived and to improve the approximations if relation (4) is found not to be satisfied.

If p and E are known as the functions of T and V, the Helmholtz free energy A can be obtained by integrating

$$d\left(\frac{A}{T}\right)=-\frac{p}{T}\,dV-\frac{E}{T^2}dT\,.$$

Then Eq. (4) is the condition that the right side of the above equation is integrable. Therefore it can be said that our aim is to examine whether or not the free energy can be derived in a consistent way.

§ 2. Notations

It is convenient for our purpose to express the pressure p, the internal energy E and the radial distribution function $g(r)$ as power series in the number density ρ. Thus,

$$\frac{p}{\rho kT}=1+B\rho+C\rho^2+D\rho^3+\cdots\,, \tag{5}$$

$$\frac{E}{\frac{3}{2}NkT}=1+E_1\rho+E_2\rho+E_3\rho^3+\cdots\,, \tag{6}$$

$$g(r)=e^{-\phi(r)/kT}[1+g_1(r)\rho+g_2(r)\rho^2+\cdots]\,. \tag{7}$$

Equation (5) is the virial expansion of $p/\rho kT$ and B, C and D are the second virial coefficient, the third and the fourth respectively. The expressions of these coefficients are found in many text-books[5]. Equation (7) is due to Mayer and Montroll[6]. The expressions of coefficients of Eq. (6) can be derived from those of Eq. (5) by the use of Eq. (4). Only D, E_3 and $g_2(r)$ will be shown here, since these will play important roles in the following deductions. (The expressions of B, C and $g_1(r)$ will be found in Eq. (24).)

$$D=-\frac{3}{8}\square-\frac{3}{4}\boxslash-\frac{1}{8}\boxtimes\,, \tag{8}$$

$$E_3=\frac{1}{12}T\frac{d}{dT}\square+\frac{1}{6}T\frac{d}{dT}\boxslash+\frac{1}{36}T\frac{d}{dT}\boxtimes\,, \tag{9}$$

$$g_2(r)=\square+2\boxslash+\frac{1}{2}\boxslash+\frac{1}{2}\boxtimes\,. \tag{10}$$

The symbols written in the form of figures represent expressions as shown below:

$$\left.\begin{aligned}
\square&=2\pi\int_{-\infty}^{\infty}r^2a_1^2(r)dr=(2\pi)^4\int_{-\infty}^{\infty}u^2\beta^4(u)du\,,\\
\boxslash&=2\pi\int_{-\infty}^{\infty}r^2\alpha(r)a_1^2(r)dr=(2\pi)^4\int_{-\infty}^{\infty}u^2\beta^2(u)\gamma(u)du\,,\\
\boxtimes&=\iiint_{VVV}\alpha(r_{12})\alpha(r_{23})\alpha(r_{31})\alpha(r_{41})\alpha(r_{42})\alpha(r_{43})d\boldsymbol{r}_2d\boldsymbol{r}_3d\boldsymbol{r}_4\,,
\end{aligned}\right\} \tag{11}$$

$$\left.\begin{aligned}
\square&=(2\pi)^{5/2}\int_{-\infty}^{\infty}u\beta^3(u)\frac{\sin ur}{r}du\,,\\
\boxslash&=(2\pi)^{5/2}\int_{-\infty}^{\infty}u\beta(u)\gamma(u)\frac{\sin ur}{r}du\,,\\
\boxslash&=a_1^2(r)\,,\\
\boxtimes&=\iint_{VV}\alpha(r_{14})\alpha(r_{13})\alpha(r_{34})\alpha(r_{42})\alpha(r_{23})d\boldsymbol{r}_3d\boldsymbol{r}_4\,,\quad(r_{12}=r)\,,
\end{aligned}\right\} \tag{12}$$

where

$$\left.\begin{aligned} \alpha(r) &= e^{-\phi(r)/kT}-1 , \\ u\beta(u) &= \frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty} r\alpha(r)\sin ur\,dr , \\ ra_1(r) &= 2\pi\int_{-\infty}^{\infty} u\beta^2(u)\sin ur\,du , \\ u\gamma(u) &= \frac{1}{(2\pi)^2}\int_{-\infty}^{\infty} r\alpha(r)a_1(r)\sin ur\,dr . \end{aligned}\right\} \qquad (13)$$

The function $\phi(r)$ and hence $\alpha(r)$, $\beta(u)$, $a_1(r)$, $\gamma(u)$ are defined also for negative values of the arguments, being assumed to be even functions. The notations in Eq. (13) as well as in Eq. (11) are the same as those used by Rushbrooke and Scoins[3)7)].

If Eqs. (5), (6) and (7) are inserted in both sides of Eqs. (1), (2) and (4) and the coefficients of ρ^3 are compared, the following relations are deduced:

$$D=\frac{\pi}{3}\int_{-\infty}^{\infty}\frac{d\alpha(r)}{dr}g_2(r)r^3dr , \qquad (14)$$

$$E_3=\frac{2\pi}{3}\int_{-\infty}^{\infty}T\frac{\partial\alpha(r)}{\partial T}g_2(r)r^2dr , \qquad (15)$$

$$E_3=-\frac{2}{9}T\frac{dD}{dT} . \qquad (16)$$

It is necessary for the validity of relation (4) to satisfy the relation (16). In the next section it will be examined whether relation (16), instead of relation (4), holds or not when some approximate $g_2(r)$'s are used in Eqs. (14) and (15).

When D and E_3 are expressed in an approximate way in terms of $\beta(u)$, $a_1(r)$ and $\gamma(u)$, it is sometimes difficult to see whether relation (16) holds or not, since these functions are not independent of each other. In such cases the difficulty will be avoided if D and E_3 are calculated explicitly in terms of a simplified interaction potential such as:

$$\begin{aligned} \phi(r) &= \Delta \quad (0<r<a) \\ &= 0 \quad (r>a) , \end{aligned} \qquad (17)$$

that is

$$\begin{aligned} \alpha(r) &= -z \quad (0<r<a) \\ &= 0 \quad (r>a) , \end{aligned}$$

where

$$z=1-e^{-\Delta/kT} .$$

This potential leads to the following expressions for $\beta(u)$, $a_1(r)$, B, C and D:

$$\left.\begin{aligned} u\beta(u) &= z\sqrt{\frac{2}{\pi}}\frac{d}{du}\left(\frac{\sin ua}{u}\right) , \\ a_1(r) &= \frac{z^2\pi}{12}(r^3-12a^2r+16a^3) \quad (0<r<2a) \\ &= 0 \qquad\qquad (r>2a) , \\ B &= bz , \\ C &= \frac{5}{8}b^2z^3 , \\ D &= -\frac{3}{8}\square-\frac{3}{4}\boxslash-\frac{1}{8}\boxtimes \\ &\frac{3}{8}\square=\frac{34}{35}b^3z^4=0.9714b^3z^4 \\ &\frac{3}{4}\boxslash=-\frac{6347}{4480}b^3z^5=-1.4167b^3z^5 \\ &\frac{1}{8}\boxtimes=0.1584b^3z^6 , \end{aligned}\right\} \qquad (18)$$

where

$$b=\frac{2\pi}{3}a^3$$

and the value of (1/8)⊠ is calculated conversely from the value of D in the case of hard spheres where it is known that $D=0.2869b^3$ [8)]. If we put $z=1$ in the above expressions, they are reduced to the case of hard spheres.

§ 3. Discussion of Several Approximate Expressions for $g(r)$

The following fact is important in examining an approximate distribution function. It can be seen from Eqs. (8), (9) and (10) that the function $g_2(r)$ has four terms of different types which are expressed as □, ⧄, ⊠, whereas the quantity D or E_3 is composed of three terms □, ⧄, ⊠ or $d\square/dT$, $d\boxslash/dT$, $d\boxtimes/dT$. When $g_2(r)$ given by Eq. (10) is inserted in Eq. (14) or (15), the term □ in $g_2(r)$ corresponds to the term □ in D or E_3, $2\boxslash+(1/2)\boxslash$ to ⧄, and ⊠ to ⊠. These correspondences may be expressed symbolically as

$$\square\rightarrow\square,\ (\boxslash+\boxslash)\rightarrow\square,\ \boxtimes\rightarrow\boxtimes . \qquad (19)$$

Thus the function $g_2(r)$ can be expressed as a sum of three terms □, ⧄ + ⧄ and ⊠, when used in calculation of D and E_3 and each of these terms contributes separately to the establishment of relation (16). Hence, as shown in later examples, relation (16) is valid even if use is made of some approximate $g_2(r)$'s with one or two of these terms omitted.

The following four kinds of approximations to $g(r)$ will be examined.

1. *The solution of the Born-Green non-linear integral equation*[9)10)]

This integral equation is based upon Kirkwood's superposition approximation. Its solution will be denoted by $g^{(1)}(r)$. The integral equation is given by

$$\log g^{(1)}(r)+\frac{\phi(r)}{kT}=\pi\rho\int_0^\infty\int_{-s}^{s}(s^2-t^2)\frac{t+r}{r} \times[g^{(1)}(t+r)-1]\,dt\,g^{(1)}(s)\frac{1}{kT}\frac{d\phi(s)}{ds}ds\,. \tag{20}$$

2. *Rodriguez's improved form of Green's linear theory*[11)]

The distribution function obtained in this theory will be denoted by $g^{(2)}(r)$. It is given

$$\left.\begin{aligned}&g^{(2)}(r)=\exp[-\phi(r)/kT+f^{(2)}(r)]\,,\\&\text{where}\\&rf^{(2)}(r)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{\varepsilon^2u\beta^2(u)}{\lambda-\varepsilon\beta(u)}\sin ur\,du,\\&\frac{1}{\lambda}=(2\pi)^{3/2}\rho,\\&\varepsilon-1=\int_{-\infty}^{\infty}r^2f^{(2)}(r)\alpha(r)\,dr\bigg/\int_{-\infty}^{\infty}r^2\alpha(r)dr.\end{aligned}\right\} \tag{21}$$

3. *The netted-chain approximation*[3)]

The radial distribution function in this approximation is obtained by selecting particular terms from the right side of Eq. (7) and by smming them up. This will be denoted by $g^{(3)}(r)$. It is given by

$$\left.\begin{aligned}&g^{(3)}(r)=e^{-\phi(r)/kT}[1+f^{(3)}(r)]\,,\\&\text{where}\\&rf^{(3)}(r)=\frac{1}{\sqrt{2\pi}}\frac{1}{\lambda}\int_{-\infty}^{\infty}\frac{\left[\beta(u)+\dfrac{\gamma(u)}{\lambda}\right]^2}{1-\dfrac{\beta(u)}{\lambda}-\dfrac{\gamma(u)}{\lambda^2}}\\&\qquad\times u\sin ur\,du.\end{aligned}\right\} \tag{22}$$

4. *The original form of Green's linear theory*[10)]

The distribution function obtained in this theory will be denoted by $g^{(4)}(r)$. It is given by

$$\left.\begin{aligned}&g^{(4)}(r)=e^{-\phi(r)/kT}[1+f^{(4)}(r)]\,,\\&\text{where}\\&rf^{(4)}(r)=\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\infty}\frac{\varepsilon^2u\beta^2(u)}{\lambda-\varepsilon\beta(u)}\sin ur\,du\,,\\&\varepsilon=\text{constant}.\end{aligned}\right\} \tag{23}$$

Expansion of the above four approximate $g(r)$'s into power series in ρ in the form of Eq. (7) leads to the four approximate expressions for $g_2(r)$, which can be used in calculation of D and E_3 by Eqs. (14) and (15). Each way of approximations will be shown by superscript figures. For example $D^{(3)}, E_3{}^{(3)}$ and $g_2{}^{(3)}(r)$ express D, E_3 and $g_2(r)$ based on the netted-chain approximation, respectively.

The expressions for B, C and $g_1(r)$ in these approximations are expressed as follows:

$$\left.\begin{aligned}&B^{(1)}=B^{(2)}=B^{(3)}=B^{(4)}=B=-\frac{(2\pi)^{3/2}}{2}\beta(0)\,,\\&C^{(1)}=C^{(2)}=C^{(3)}=C=-\frac{(2\pi)^{5/2}}{3}\int_{-\infty}^{\infty}u^2\beta^3(u)du\,,\\&\qquad C^{(4)}=\varepsilon^2C\,,\\&g_1{}^{(1)}(r)=g_1{}^{(2)}(r)=g_1{}^{(3)}(r)=g_1(r)=a_1(r)\,,\\&\qquad g_1{}^{(4)}(r)=\varepsilon^2g_1(r)\,.\end{aligned}\right\} \tag{24}$$

It is seen that, except for Green's linear theory, $g_1(r)$'s and hence C and E_2 are correct.

The functions $g_2(r)$'s for these approximations can be expressed as:

$$g_2{}^{(1)}(r)=\square+2\boxslash+\tfrac{1}{2}\boxslash+(2\pi)^{1/2}\int_{-\infty}^{\infty}ds\,\alpha(s)\frac{da_1(s)}{ds} \times\int_0^s dt\cdot t\int_{-\infty}^{\infty}du\,\beta(u)\sin ut\frac{\sin ur}{r}\,, \tag{25–1}$$

$$g_2{}^{(2)}(r)=\square+\tfrac{1}{2}\boxslash+\frac{3C}{B}a_1(r)\,, \tag{25–2}$$

$$g_2{}^{(3)}(r)=\square+2\boxslash\,, \tag{25–3}$$

$$g_2{}^{(4)}(r)=\varepsilon^3\square\,. \tag{25–4}$$

Comparison of Eq. (10) with Eqs. (25–2), (25–3) and (25–4) shows clearly that they are not correct and hence cannot give the correct expressions for D and E_3. The last term of Eq. (25–1) corresponds to $\frac{1}{2}\boxtimes$ of Eq. (10). It differs, however, essentially from $\frac{1}{2}\boxtimes$, since the former has only four pairs of molecules in its integrand while the latter has five pairs. (Note that $\alpha(r)$ and $\beta(u)$ correspond to one pair of molecules and $a_1(r)$ to two pairs.) Therefore $g_2{}^{(1)}(r)$ can give no correct expressions for D and E_3. This conclusion for D has been already pointed out[7)]. Relation (16) between $D^{(1)}$ and $E_3{}^{(1)}$ fails to be valid due to the presence of the last term of $g_2{}^{(1)}(r)$. (See Eq. (26).) It fails to be valid also for $D^{(2)}$ and $E_3{}^{(2)}$ and for $D^{(3)}$ and $E_3{}^{(3)}$. It is due to the fact that, in $g_2^{(2)}(r)$ and $g_2^{(3)}(r)$, one of $\boxslash$ and $\boxslash$ is either missing or substituted by another term, since, as explained at the beginning of this section, it is necessary that both $\boxslash$ and $\boxslash$ are contained as one group. In $g_2^{(4)}(r)$ these terms are missing completely and this makes relation (16) between $D^{(4)}$ and $E_3^{(4)}$ hold again. Actually, it is not necessary to examine relation (16) as shown above so far as Green's linear theory is concerned, because, in this case, Green[10] has already confirmed relation (4) and calculated the free energy.

After all, it is found that, among the four approximations examined above, the original form of Green's linear theory is the only one which satisfies relation (4). It seems that the above conclusion remains valid, even if the solution of the integral equation proposed by Kirkwood[12] is added to these four cases, though this is not examined here.

Finally, the expressions for D and E_3 based on the above-mentioned approximations are shown in the following, first giving the expressions for the general form and then for the simplified form, Eq. (17), of the interaction potentials:

$$\left.\begin{aligned}
D^{(1)}&=\left(-\frac{3}{8}\square-\frac{3}{4}\boxslash\right)+\left(\frac{\pi}{6}\int_{-\infty}^{\infty}drr^3\alpha(r)\frac{da_1(r)}{dr}a_1(r)-\pi\int_{-\infty}^{\infty}dr\alpha(r)\frac{da_1(r)}{dr}\int_0^r ds\,s^2a_1(s)\right)\\
&=\left(-\frac{34}{35}b^3z^4+\frac{6347}{4480}b^3z^5\right)-\frac{493}{2240}b^3z^5\,,\\
E_3^{(1)}&=\left(\frac{1}{12}T\frac{d}{dT}\square+\frac{1}{6}T\frac{d}{dT}\boxslash\right)+\frac{\pi}{3}\int_{-\infty}^{\infty}dr\alpha(r)\frac{da_1(r)}{dr}T\frac{\partial}{\partial T}\int_0^r ds\,s^2a_1(s)\\
&=\left(\frac{272}{315}b^3z^3-\frac{6347}{4032}b^3z^4\right)T\frac{dz}{dT}+\frac{4819}{20160}b^3z^4T\frac{dz}{dT}\,,\\
E_3^{(1)}&+\frac{2}{9}T\frac{dD^{(1)}}{dT}=\frac{111}{20160}b^3z^4T\frac{dz}{dT}\,,
\end{aligned}\right\}\tag{26}$$

$$\left.\begin{aligned}
D^{(2)}&=-\frac{3}{8}\square+\frac{\pi}{6}\int_{-\infty}^{\infty}dr\,r^3\frac{d\alpha(r)}{dr}a_1^2(r)+\frac{3C^2}{B}\\
&=-\frac{34}{35}b^3z^4+\frac{25}{128}b^3z^5+\frac{75}{64}b^3z^5\,,\\
E_3^{(2)}&=\frac{1}{12}T\frac{d}{dT}\square+\frac{\pi}{3}\int_{-\infty}^{\infty}dr\,r^2\,a_1^2(r)\,T\frac{\partial\alpha(r)}{\partial T}-\frac{1}{2}\frac{T}{B}\frac{dC^2}{dT}\\
&=\frac{272}{315}b^3z^3T\frac{dz}{dT}-\frac{6347}{20160}b^3z^4T\frac{dz}{dT}-\frac{75}{64}b^3z^4T\frac{dz}{dT}\,,\\
E_3^{(2)}&+\frac{2}{9}T\frac{dD^{(2)}}{dT}=\frac{653}{20160}b^3z^4T\frac{dz}{dT}\,,
\end{aligned}\right\}\tag{27}$$

$$\left.\begin{aligned}
D^{(3)}&=\left(-\frac{3}{8}\square-\frac{3}{4}\boxslash\right)-\frac{\pi}{6}\int_{-\infty}^{\infty}dr\,r^3\frac{d\alpha(r)}{dr}a_1^2(r)\\
&=\left(-\frac{34}{35}b^3z^4+\frac{6347}{4480}b^3z^5\right)-\frac{25}{128}b^3z^5\,,\\
E_3^{(3)}&=\left(\frac{1}{12}T\frac{d}{dT}\square+\frac{1}{6}T\frac{d}{dT}\boxslash\right)-\frac{\pi}{3}\int_{-\infty}^{\infty}dr\,r^2a_1^2(r)\,T\frac{\partial\alpha(r)}{\partial T}\\
&=\left(\frac{272}{315}b^3z^3-\frac{6347}{4032}b^3z^4\right)T\frac{dz}{dT}+\frac{6347}{20160}b^3z^4T\frac{dz}{dT}\,,\\
E_3^{(3)}&+\frac{2}{9}T\frac{dD^{(3)}}{dT}=\frac{493}{5040}b^3z^4T\frac{dz}{dT}\,,
\end{aligned}\right\}\tag{28}$$

$$\left.\begin{aligned} D^{(4)} &= -\frac{3}{8}\varepsilon^3\square = -\frac{34}{35}\varepsilon^3 b^3 z^4 ,\\ E_3{}^{(4)} &= \frac{1}{12}\varepsilon^3 T\frac{d}{dT}\square = \frac{272}{315}\varepsilon^3 b^3 z^3 T\frac{dz}{dT} ,\\ E_3{}^{(4)} &+ \frac{2}{9}T\frac{dD^{(4)}}{dT} = 0 . \end{aligned}\right\} \tag{29}$$

Each of third equations of Eqs. (26), (27), (28) and (29) gives the values of $E_3+(2/9)T\times(dD/dT)$ for the simplified form of the interaction potential. As stated above, they should be zero if the theory is self-consistent.

§ 4. Attempt to Improve the Approximation I

As shown in the preceding section, only Green's linear theory satisfies relation (4). However this theory is not satisfactory from the quantitative point of view. It will be desirable that some approximate procedure will be found, which, while satisfying relation (4), gives better quantitative results than Green's theory.

In the following discussion, the free energy will be expressed in terms of $g(r)$, and $g(r)$ will be determined so as to minimize the free energy. Then the internal energy E and the pressure p will be derived from the free energy so that relation (4) will be automatically satisfied.

The configurational part S_τ of entropy is defined by

$$S_\tau = -\frac{k}{V^N}\int_V\cdots\int_V \times P_N(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_N)\log P_N(\boldsymbol{r}_1,\boldsymbol{r}_2,\cdots,\boldsymbol{r}_N) \times d\boldsymbol{r}_1\, d\boldsymbol{r}_2\cdots d\boldsymbol{r}_N , \tag{30}$$

where $P_N(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_N)$ denotes the distribution function at the point $(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_N)$ in the configuration space of N molecules and is normalized as

$$\frac{1}{V^N}\int_V\cdots\int_V P_N(\boldsymbol{r}_1, \boldsymbol{r}_2, \cdots, \boldsymbol{r}_N)d\boldsymbol{r}_1 d\boldsymbol{r}_2\cdots d\boldsymbol{r}_N = 1 .$$

The reduced distribution functions $P_n(\boldsymbol{r}_1, \boldsymbol{r}_2, \cdots, \boldsymbol{r}_n)$ for n molecules are defined by

$$P_n(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_n) = \frac{1}{V^{N-n}}\int_V\cdots\int_V \times P_N(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_n,\boldsymbol{r}_{n+1},\cdots,\boldsymbol{r}_N)d\boldsymbol{r}_{n+1}\cdots d\boldsymbol{r}_N ,\quad n=1, 2, 3,\cdots . \tag{31}$$

Then the function $P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)$ is the same as $g(|\boldsymbol{r}_1-\boldsymbol{r}_2|)$. The functions $z_n(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_n)$ are defined in terms of P_n as follows:

$$\left.\begin{aligned} \log P_1(\boldsymbol{r}_1) &= z_1(\boldsymbol{r}_1) ,\\ \log P_2(\boldsymbol{r}_1, \boldsymbol{r}_2) &= z_2(\boldsymbol{r}_1, \boldsymbol{r}_2)+z_1(\boldsymbol{r}_1)+z_1(\boldsymbol{r}_2)\\ \log P_3(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3) &= z_3(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3)+z_2(\boldsymbol{r}_1, \boldsymbol{r}_2)+z_2(\boldsymbol{r}_2, \boldsymbol{r}_3)\\ &\quad +z_2(\boldsymbol{r}_3, \boldsymbol{r}_1)+z_1(\boldsymbol{r}_1)+z_1(\boldsymbol{r}_2)+z_1(\boldsymbol{r}_3) ,\\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots\\ \text{or conversely}\qquad &\\ z_1(\boldsymbol{r}_1) &= \log P_1(\boldsymbol{r}_1) ,\\ z_2(\boldsymbol{r}_1, \boldsymbol{r}_2) &= \log P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)/P_1(\boldsymbol{r}_1)P_1(\boldsymbol{r}_2),\\ z_3(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3) &= \log\frac{P_3(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3)P_1(\boldsymbol{r}_1)P_1(\boldsymbol{r}_2)P_1(\boldsymbol{r}_3)}{P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)P_2(\boldsymbol{r}_2, \boldsymbol{r}_3)P_2(\boldsymbol{r}_3, \boldsymbol{r}_1)}\\ &\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \end{aligned}\right\} \tag{32}$$

From Eqs. (30), (31) and (32) S_τ is written in terms of P_n's and z_n's as

$$S_\tau = -k\sum_{n=1}^{N}\frac{1}{V^n}\frac{N!}{n!(N-n)!}\int_V\cdots\int_V \times P_n(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots \boldsymbol{r}_n)z_n(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_n)d\boldsymbol{r}_1 d\boldsymbol{r}_2 \cdots d\boldsymbol{r}_n . \tag{33}$$

If use is made of the "generalized superposition approximation", which was adopted by Mayer[13], that is

$$z_n(\boldsymbol{r}_1, \boldsymbol{r}_2,\cdots,\boldsymbol{r}_n)=0 \quad \text{for } n\geqq 3 , \tag{34}$$

Eq. (33) becomes

$$S_\tau = -k\frac{N}{V}\int_V P_1(\boldsymbol{r})z_1(\boldsymbol{r})d\boldsymbol{r} - \frac{k}{2}\frac{N(N-1)}{V^2}$$
$$\times\iint_{VV} P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)z_2(\boldsymbol{r}_1, \boldsymbol{r}_2)d\boldsymbol{r}_1 d\boldsymbol{r}_2$$

or

$$S_\tau = -k\frac{N(N-2)}{V}\int_V P_1(\boldsymbol{r})\log P_1(\boldsymbol{r})d\boldsymbol{r}$$
$$-\frac{k}{2}\frac{N(N-1)}{V^2}\iint_{VV} \tag{35}$$
$$\times P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)\log P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)d\boldsymbol{r}_1 d\boldsymbol{r}_2 .$$

Now the configurational part E_τ of the internal energy is expressed as

$$E_\tau = \frac{1}{2}\frac{N(N-1)}{V^2}\iint_{VV}\phi(\boldsymbol{r}_1, \boldsymbol{r}_2)P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)d\boldsymbol{r}_1 d\boldsymbol{r}_2 \tag{36}$$

without any approximation. The configurational part A_τ of the free energy is obtained from Eqs. (35) and (36) as

$$A_\tau = E_\tau - TS_\tau$$
$$= kT\frac{N(N-2)}{V}\int P_1(\boldsymbol{r})\log P_1(\boldsymbol{r})d\boldsymbol{r}$$
$$+\frac{1}{2}\frac{N(N-1)}{V^2}\iint_{VV}$$
$$\times[\phi(\boldsymbol{r}_1, \boldsymbol{r}_2)+kT\log P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)] \tag{37}$$
$$\times P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)d\boldsymbol{r}_1 d\boldsymbol{r}_2 .$$

It is clear that the form of the function $P_2(\boldsymbol{r}_1, \boldsymbol{r}_2)$, which minimizes A_τ under the condition $P_1=\text{const.}=1$, is given by

$$P_2(\boldsymbol{r}_1, \boldsymbol{r}_2) = g(|\boldsymbol{r}_1-\boldsymbol{r}_2|)\propto e^{-\phi(\boldsymbol{r}_1, \boldsymbol{r}_2)/kT} . \tag{38}$$

This is the simplest form of the approximate expression for $g(r)$. Thus in our case the approximation has been found to be very poor, and it means that our attempt on the above line has not been successful. This is an example which shows that, if Mayer's superposition approximation (34) is adopted, it must be done with much care.

Recently Richardson[14] obtained the integral equation for $g(r)$ by a similar procedure as above. In place of the approximation (34) he used the approximation

$$z_3=\text{const.}=-\gamma , \quad z_n=0 \quad \text{for } n\geqq 4 . \tag{39}$$

Although the order of magnitude of γ is $O(1/N^2)$, yet the term containing z_3 on the right side of Eq. (33) cannot be neglected, since this term is multiplied by the quantity of the order of $O(N^3)$. Retaining this term, Richardson obtained the integral equation for $g(r)$ similar to the Born-Green non-linear integral equation. It is not clear at present how far his approximation is successful, but it seems to be necessary, if his idea should be carried out thoroughly, to apply similar procedures not only to z_3 but also to z_4, z_5 and so on.

§ 5. Attempt to Improve the Approximation II

In Green's linear theory the parameter ε appears, as shown in Eq. (23), where ε is supposed to be independent of T and V. In order to improve Green's theory, Rodriguez[11] determined ε by the equation

$$\varepsilon-1=\int_0^\infty r^2 f(r)\alpha(r)dr \Big/ \int_0^\infty r^2\alpha(r)dr , \tag{40}$$

considering that in Green's theory $\varepsilon-1$ is an average of the function $f(r)$ near $r=0$. Since $f(r)$ itself depends on ε, the parameter ε is given implicitly as a function of T and V. As shown in § 3, however, Rodriguez's procedure violates relation (4). To avoid this difficulty, it will be attempted to determine ε as a function of T and V in such a way that relation (4) remains valid.

The expressions of the pressure and the internal energy, when approximate expression (23) for $g(r)$ is inserted in Eqs. (1) and (2), become respectively

$$\left.\begin{aligned}
\frac{p}{\rho kT} &= 1-\frac{\beta(0)}{2\lambda}-\frac{1}{2\sqrt{2\pi}}\frac{1}{\lambda}\int_{-\infty}^{\infty}\left[-\frac{1}{2}\varepsilon\beta^2(u)+\frac{\lambda^2\beta(u)}{\lambda-\varepsilon\beta(u)}+\frac{\lambda^2}{\varepsilon}\log\left(1-\frac{\varepsilon}{\lambda}\beta(u)\right)\right]u^2du ,\\
\frac{E}{\frac{3}{2}NkT} &= 1+\frac{T}{3\lambda}\frac{\partial\beta(0)}{\partial T}+\frac{1}{3\sqrt{2\pi}}\frac{1}{\lambda}\int_{-\infty}^{\infty}\frac{\varepsilon^2\beta^2(u)T\dfrac{\partial\beta(u)}{\partial T}}{\lambda-\varepsilon\beta(u)}u^2du ,
\end{aligned}\right\} \tag{41}$$

where the superscript figures are dropped and the thermodynamical variables T and $\lambda=\{(2\pi)^{3/2}\rho\}^{-1}$ are used instead of T and V. Relation (4) is satisfied by these expressions when ε is assumed to be independent of T and λ. If ε is supposed to be a function of T and λ, it is found from Eqs. (4) and (41) that ε must satisfy the differential equation

$$\frac{\partial\varepsilon(T,\lambda)}{\partial T}\frac{\partial F(T,\lambda,\varepsilon)}{\partial\lambda}=\frac{\partial\varepsilon(T,\lambda)}{\partial\lambda}\frac{\partial F(T,\lambda,\varepsilon)}{\partial T}\,, \tag{42}$$

where

$$F(T,\lambda,\varepsilon)=\int_{-\infty}^{\infty}\left[-\frac{\beta^2(u)}{2\lambda}+\frac{\lambda}{\varepsilon^2}\log\left(1-\frac{\varepsilon}{\lambda}\beta(u)\right)+\frac{\lambda}{\varepsilon}\frac{\beta(u)}{\lambda-\varepsilon\beta(u)}\right]u^2du \tag{43}$$

and $\partial F/\partial T$ (or $\partial F/\partial\lambda$) is the derivative of F with respect to T (or λ) under the condition $\varepsilon=\text{const}$. The general solution of Eq. (42) is

$$\varepsilon=U(F)\,, \tag{44}$$

where $U(x)$ is any arbitrary function of x. Equation (44) determines ε implicitly as a function of T and λ, F itself depending on ε as seen from Eq. (43).

If the function $\overline{F}(T,\lambda,\varepsilon)$ is defined by

$$\begin{aligned}\overline{F}(T,\lambda,\varepsilon)&=F-\int_{-\infty}^{\infty}\left[\frac{\lambda}{\varepsilon}\frac{\beta(u)}{\lambda-\varepsilon\beta(u)}-\frac{\beta(u)}{\varepsilon}-\frac{\beta^2(u)}{\lambda}\right]u^2du\\&=\int_{-\infty}^{\infty}\left[\frac{\beta^2(n)}{2\lambda}+\frac{\beta(u)}{\varepsilon}+\frac{\lambda}{\varepsilon^2}\log\left(1-\frac{\varepsilon}{\lambda}\beta(u)\right)\right]u^2du\,,\end{aligned} \tag{45}$$

the expressions (41) become respectively

$$\left.\begin{aligned}\frac{p}{\rho kT}&=1-\frac{\beta(0)}{2\lambda}-\frac{1}{2\sqrt{2\pi}}\varepsilon\lambda\frac{\partial\overline{F}(T,\lambda,\varepsilon)}{\partial\lambda}\,,\\ \frac{E}{\frac{3}{2}NkT}&=1+\frac{T}{3\lambda}\frac{\partial\beta(0)}{\partial T}-\frac{1}{3\sqrt{2\pi}}\varepsilon T\frac{\partial F(T,\lambda,\varepsilon)}{\partial T}\,,\end{aligned}\right\} \tag{41'}$$

where $\partial\overline{F}/\partial T$ and $\partial\overline{F}/\partial\lambda$ have similar meanings as $\partial F/\partial T$ and $\partial F/\partial\lambda$ in Eq. (42). By the relation

$$d\left(\frac{A}{NkT}\right)=-\frac{3}{2}\frac{1}{T}\left(\frac{E}{\frac{3}{2}NkT}\right)dT-\frac{1}{\lambda}\left(\frac{p}{\rho kT}\right)d\lambda\,,$$

where A denotes the Helmholtz free energy, we finally obtain

$$\frac{A}{NkT}=-\log\lambda-\frac{3}{2}\log T-\frac{1}{2\lambda}\beta(0)+\frac{1}{2\sqrt{2\pi}}\left[\varepsilon\overline{F}(T,\lambda,\varepsilon)+\int_0^{F(T,\lambda,\varepsilon)}x\frac{dU(x)}{dx}dx\right]+C_0\,. \tag{46}$$

In this equation C_0 denotes a constant independent of T and λ and hence of T and V. Expression (46) for the free energy coincides in form with the one derived by Green[10] apart from the term with the integral $\int_0^F x\frac{dU}{dx}dx$.

Since $f(r)$ should tend to zero as ρ tends to zero or λ to a very large value, it is required that ε should have the property

$$\lim_{\lambda\to\infty}\varepsilon(T,\lambda)=1\,.$$

It is found from Eq. (43) that $\lim\limits_{\lambda\to\infty}F(T,\lambda,\varepsilon)=0$. Therefore, the function $U(x)$ of Eq. (44) must have the property that $U(0)=1$. The equation which determines ε becomes finally

$$\varepsilon=U(F)\,,\quad U(0)=1\,. \tag{47}$$

However, ε still cannot be determined uniquely since the form of $U(x)$ is arbitrary except for its initial value. It turns out that it is impossible to determine the function $U(x)$ so as to minimize the free energy. We have not yet found a method appropriate to the determination of $U(x)$. A similar situation occurs in Rodriguez's procedure as well, because there could be other expressions than Eq. (40) which have the meaning of the average of $f(r)$ near $r=0$; for example,

$$\varepsilon-1=\int_0^\infty f(r)\alpha(r)\,dr \Big/ \int_0^\infty \alpha(r)dr\,,$$

If it is assumed that $U(x)$ can be expanded in a power series in x, Eq. (47) gives, when ρ is small,

$$\varepsilon=1+0(\rho^2)$$

Thus ε does not vary so long as the first power of ρ is concerned, and the expression for $g_2(r)$ becomes equal to Eq. (25–4) with $\varepsilon=1$. If other forms of $U(x)$, for example, $U(x)=1+\sqrt{x}$, are used, the term of the first power of ρ can appear in the expression of ε and hence the expression for $g_2(r)$ can be made more accurate.

§ 6. Conclusion

Many attempts have been made thus far to obtain theoretically the radial distribution function of fluids. It may be said that one of their objects is to obtain the distribution function itself and hence to obtain the knowledge about the structure of fluids, especially of liquids, which can be compared with the structure determined experimentally by the method of X-ray scattering. The other object is to calculate the thermodynamical functions of fluids with the use of the distribution function obtained theoretically.

In either case the solution of the Born-Green non-linear integral equation has been supposed to be most preferable among different approximations and many authors have attempted to solve the integral equation analytically or numerically. However, it has been found in § 3 that this solution does not lead to relation (4) and hence is not suitable for use in the calculation of the thermodynamical quantities. We could say strictly that, for example, even if this solution is obtained exactly and used in Eq. (1) in the calculation of the pressure, it is doubtful whether the calculated one can be called the "pressure". This fact does not necessarily mean that the above solution is not a good approximation for the radial distribution function. On the contrary, it seems to be the most preferable approximation in the present stage of the theory.

Rushbrooke and Scoins showed that the inconsistency between Eqs. (1) and (3) can be reduced for the case of hard spheres by adopting the netted-chain approximation. As shown in § 3, this approximation violates relation (4). Moreover, it is not certain that this approximation will reduce the inconsistency between Eqs. (1) and (3) for more general forms of interaction potential.

The procedure proposed in § 5 may be said to offer an improvement of Green's linear theory, because the dependence of ε on temperature and volume is taken into account. At the same time our theory can be said to be an improved form of Rodriguez's theory, since relation (4) holds in the former while it does not in the latter. It is, however, desirable that more appropriate approximation will be found, in which relation (4) is satisfied, giving, at the same time, better quantitative results.

The author wishes to express his appreciation to Professor A. Harasima for his continual encouragement in the course of this work.

Note on Some Properties of Gamma Brass*

By Takao SATO and Seiichiro NOGUCHI

Department of Physics, Tokyo Metropolitan University, Tokyo

(Received November 20, 1956)

Electrical resistance and magneto-resistance of gamma brass were measured at liquid helium, liquid nitrogen and room temperature. Moreover, Hall coefficient and thermoelectric power of gamma brass were measured at room temperature. Data of the electrical resistance are presented for several samples having various concentrations. In the relation between specific resistivity and concentration, a minimum occurs at about 34 wt.% copper in the curve of resistivity *vs*. concentration. The value of the Hall coefficient and of the thermoelectric power are comparable to the values of pure metals. The magneto-resistance is small at room temperature but becomes large at liquid helium temperature. Differences of the physical properties between gamma brass and bismuth are discussed.

§ 1. Introduction

It is known as a Hume-Rothery rule that the crystal structures of the intermetallic compound are specified by their electron concentration. Especially, the intermetallic compound whose electron concentration is 21/13 possesses a crystal structure of gamma brass type. On this gamma brass type structure Westgren and Phragmen[1] carried out the structure analysis by means of X-ray diffraction and found its structure to be very similar to the body centered cubic structure except that 52 atoms are included in its unit cell.

Jones[2] discussed about the stability of gamma structure on the basis of the facts that alloys of gamma structure are usually brittle and have a large diamagnetic susceptibility and a large Hall coefficient. In his theory, alloys of gamma structure were regarded as analogous to bismuth which has nearly filled band. In this paper we shall demonstrate the dissimilarity between gamma brass and bismuth, on the basis of the specific resistivity versus concentration curve of gamma brass and other properties.

§ 2. Experiment

a) *Specimens and Procedure*

Purity of zinc used in the present investigation was of 99.95% and that of copper was of 99.98%. These alloys were melted under flux, mixture of sodium chloride and potassium chloride and were sucked up into quartz tubes of 1~2 mm diameter. Although a gamma brass is exceedingly brittle and improper to the machining, we have easily prepared a good shaped specimen by this sucking method. These specimens were sealed into quartz tubes with argon gas, and annealed for 50 hours at 550~600°C. The tubes were then cooled slowly down to room temperature. After this treatment one part of them was used for measurement and others for chemical analysis. It was confirmed by X-ray photography that each specimen consists of a homogeneous gamma phase.

Electrical resistance was measured by ordinary D-C method with potentiometer. Specimens for the measurement of Hall coefficient were about $10 \times 20 \times 0.5$ mm in size. Since the Hall coefficient was unexpectedly small, an apparatus with sensitivity of 7×10^{-9} volt was used, the details of which are the same as already reported.[3]

b) *Experimental results*

(1) Relation between specific resistivity and concentration

Specific resistivity of the specimens of 31.5, 33.3, 35.3, 38.0 and 41.6 wt.% copper were measured. The results of these experiments are given in the Fig. 1, which shows an occurrence of a minimum in resistance at gamma phase. Moreover, the specific resistivity is of the same magnitude as those of ordinary metals.

---

* This work performed by the equipments of very low temperature in the Research Laboratory of Iron, Steel and other metals of Tohoku University.

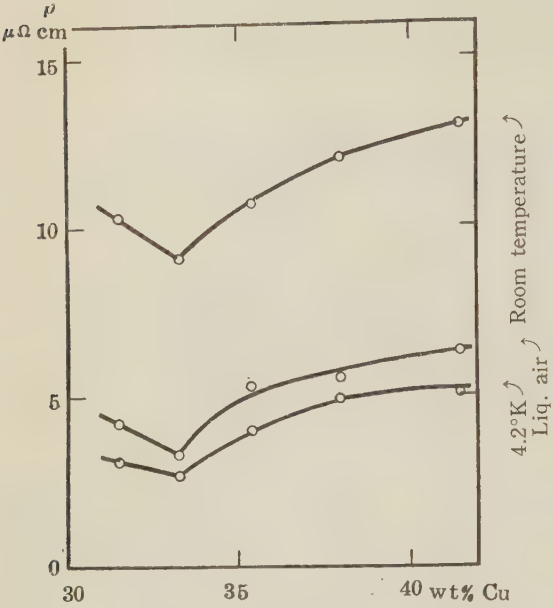

Fig. 1. Electrical resistivity *vs.* concentration curve of gamma brass.

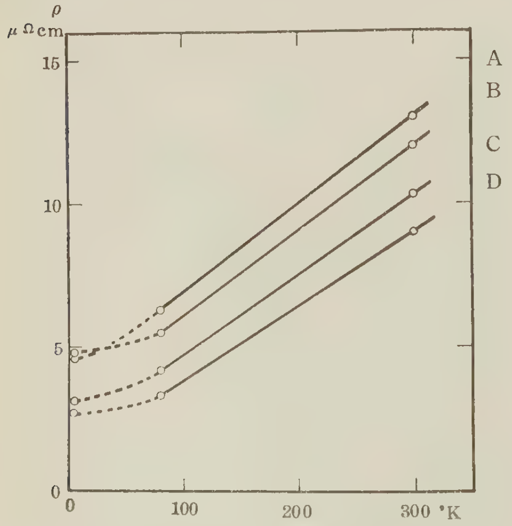
(2) Relation between specific resistivity and temperature

Temperature dependence of the resistivity is shown in the Fig. 2. In the range from 4.2° K to 1.5° K the resistance of each specimen become almost constant. In the higher temperature range, the temperature coefficient was positive.



A: 41.6% Cu B: 38.0% Cu
C: 31.5% Cu D: 33.3% Cu

Fig. 2. Electrical resistivity *vs.* temperature curve of gamma brass.

(3) Hall coefficient

The Hall coefficient of gamma brass was very small. The Hall potential of the specimen (69 wt.% zinc) of 10×20×0.5 mm in size was about 2.3×10^{-8} volt for the magnetic field of 5000 gauss at room temperature. From this result $+2.9\times10^{-4}$ cgs. emu. of Hall coefficient was obtained. This value is the same order of magnitude as those of ordinary metals.

(4) Thermoelectric power

Thermoelectromotive force of gamma brass was also very small. For instance, absolute thermoelectric power of 69 wt.% zinc at room temperature was $+1.7\times10^{-6}$ volt/deg which was comparable to the values of pure metals.

(5) Magneto-resistance

The magneto-resistance of gamma brass was so small that it was hardly possible to measure it at room temperature. It was recognized, however, that the sign of the effect is negative at very low temperatures.[4)]

§ 3. Discussion

In order to discuss about the electronic structure of gamma brass and that of bismuth, we must be concerned with following physical properties: Diamagnetic susceptibility, de Hass-van Alphen effect, Hall coefficient, thermoelectric power and magneto-resistivity. It is well known that these properties of bismuth are extremely peculiar. Diamagnetic susceptibility of gamma brass has been measured by several investigators,[5),6)] and turned out to be about the same value as that of bismuth. De Haas-van Alphen effect and the Hall effect have not yet been observed for the gamma brass. Hall coefficient of the gamma phase of copper cadmium system was measured by Richard and Evans,[7)] and was found to be of the same order of magnitude as those of normal metals. In observation for gamma brass, the Hall coefficient was about $+2.9\times10^{-4}$ cgs. emu., although the large value is errorneously cited in some text books of metals. Absolute thermoelectric power is also very small and has the value $+1.7\times10^{-6}$ volt/deg.

Since Hall coefficient and thermoelectric power are proportional to electronic charge, holes and electrons have the opposite contributions to both effects and cancel out with each other. The small magnitude of the values would be caused from such reasons.

Basing upon the fact that the magneto-resistance effect was very small at room temperature, it may be concluded that the anisotropy of the energy surface of this substance may be negligibly small, since this effect is an important measure of the anisotropy of energy surface in this phase. An anomalous magneto-resistance effect observed at low temperature are similar to that observed in other substances, for instance, p-type indium antimonide⁸⁾ and the alloys of gold or copper containing a small amount of manganese or chromium.⁹⁾ However, it is difficult to interprete it on the present theoretical ground.

Thus the gamma brass does not resemble to the bismuth with respect to the various properties except diamagnetic susceptibility. Both of gamma brass and bismuth would have nearly filled band, but the behaviour of conduction electrons at Fermi surface would differ very much from each other.

These circumstances may be recognized when one compare the shapes of the Brillouin zone of bismuth and gamma brass. The Brillouin zone of gamma brass (Fig. 3) is 36-hedron and a sphere-like shape but the Brillouin zone of bismuth (Fig. 4) is not the same. According to this difference, the behaviour of positive holes in the first zone and the behaviour of electrons in the next zone would be nearly equal in the case of gamma brass, so that physical quantity which is proportional to electronic charge $\pm e$, may cancell out with each other. However, in the case of bismuth the contribution of the holes and the electrons to the conduction mechanism would be different very much.

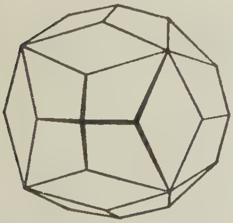


Fig. 3. The prominent zone boundary for the gamma structure.

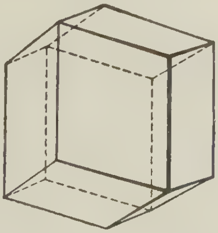

Fig. 4. The prominent zone boundary for bismuth.

It is usual that a minimum occurs in the curve of resistivity *vs.* concentration in cases of superlattice, whereas a maximum occurs in the case of intermetallic compound. The measurement of the resistivity of gamma brass has been performed by Puschen and Rjaschsky¹⁰⁾ who have found a maximum of resistivity at gamma phase on the contrary to our results. From our result it may be overhasty to conclude that gamma brass is superlattice-like. The reason of the occurrence of a minimum in resistivity might not be attributed to the ordered arrangement of atoms but to the special electronic structure of the material. Therefore, the measurement of Hall coefficient in various composition of gamma brass may be desirable, but it is not so easy to prepare a specimen for Hall coefficient.

The fact that the gamma brass, though it is a typical intermetallic compound in a certain sense, shows interesting anomalies as mentioned above, may play a significant role in future progress of our knowledge.

§ 4. Conclusions

1. It has been considered that gamma brass is similar to bismuth in electronic structure. Main experimental confirmation for this opinion is due to the fact that gamma brass has a large diamagnetic susceptibility and is very brittle. However, in other point, i.e. with respect to Hall coefficient, thermoelectric power and magneto-resistance, it is not similar to bismuth.

2. A minimum in the resistivity *vs.* composition curve of gamma brass was found. This result is opposite to the ordinary opinion for intermetallic compounds but rather similar to the superlattice alloys. However, it could not be attributed to the ordered arrangement of atoms but to the situation of its electronic structure.

With respect to the problem of the minimum in resistivity-composition curves, we have been studying other intermetallic compounds and also investigating the relation between intermetallic compound and superlattice alloy.

Moreover, we have observed the negative magneto-resistance effect in several gamma structures other than gamma brass, and so we want to investigate it in details in future.

Acknowledgement

We are indebted to Professor T. Hukuroi, Professor T. Hirone and Professor S. Ogawa for use of facilities in the Research Institute of Steel, Iron and other Metals of the Tohoku University and to the staff of their laboratory for continual help and encouragement. We wish to thank Professor Y. Takagi for valuable advice, and Mr. S. Nagasaki and Mr. M. Hirabayashi for their aid and helpful discussion.

On the Melting of Ionic Crystals

By Tatsumi KUROSAWA

Institute of Science and Technology, University of Tokyo

(Received December 1, 1956)

Comparing the data of AgCl and NaCl crystals, it is suggested that the contribution of lattice defects is more important than that of lattice vibrations, for the melting of ionic crystals. The coulombic interaction between defects can cause a sort of phase transition, and the transition temperature is near the melting point. Several experimental evidences: melting point, latent heat, viscosity and ionic conductivity of liquids, are also discussed on this ground.

§ 1. Introduction

The structure of liquids has been studied by many authors, but the knowledge about it is not so much and accurate as about solids and gases, owing to the complicated nature of liquids. Usually we regard liquids as the limiting case of the imperfect crystal or that of the imperfect gas, because of the difficulties accompanied to deal with the liquids as they are. The former picture seems to be appropriate to the liquid near the melting point, and the latter near the critical point. If the picture of the imperfect solid is a good approximation, we may expect that our knowledge about the imperfections in solids is useful for the study of liquid structures, especially of the mechanism of melting. The melting of the solid is to be explained by the abrupt increase of some kinds of imperfections. These imperfections may be, for instance, lattice vibrations, lattice defects, dislocations, grain boundaries or more complicated disorders which are often found in polymeric substances. Although such a classification of the imperfections in solids has not clear meaning in the case of liquids, it is an important problem to find which of them performs the main role in the melting process.

Above all, the pictures of lattice vibration mechanism have been investigated by many authors, e.g. Lindemann¹⁾, Braunbek,²⁾ Born and Thompson³⁾. On the other hand, Lennard-Jones⁴⁾ and others have developed the so-called "hole theory of liquids," which is somewhat similar to the picture of lattice defect mechanism. Mackenzie and Mott⁵⁾ regarded liquids as the limiting case of polycrystalline solids, and derived a relation on the basis of this picture. It is rather a dificult problem to decide which of these nechanisms is the most important one in a eal liquid, because each kind of liquids has ts own characteristics and the truth should not be a simple one, but a mixture of these nechanisms. This question can be answered nly by detailed comparisons between the heory and experiments in each case. And nversely such considerations will give some nformations about the imperfections in solids. Thus, we see that the study of the melting nechanism is important for those who have much interest in the liquid structure and also in the imperfections in solids. In this paper, we shall consider ionic crystals and shall suggest that the lattice defect mechanism may be most reasonable in ionic crystals.

§ 2. Lattice Vibrations and Lattice Defects

The melting of ionic crystals has been attributed to lattice vibrations. As its evidence it has been quoted that the Lindemann relation is satisfied in ionic crystals. If we consider alkali halides only, the Lindemann relation is really satisfied. However, if we consider alkali halides and silver halides at the same time, we find that this relation is no longer satisfied. As an example, let us take NaCl and AgCl crystals, which are known as nearly ideal ionic crystals and are the typical example of alkali halides and that of silver halides. Some data concerning these crystals are shown in Table I, where ω_t and ω_l are the angular frequencies of long transversal and longitudinal waves of the optical mode respectively, μ is the reduced mass, Θ_D is the Debye temperature determined from the specific heat at low temperatures, ρ is the density, ω_0 is the frequency of the sphere which vibrates homogeneously⁶⁾, e^2C is the coefficient of the repulsive force when both ions displace relative to each other⁷⁾, and K is the compressibility. Thus, $1/2\,\mu\omega^2$ means the hardness for the optical waves and $\rho\Theta_D^2$ means the hardness for the comparatively long acoustical waves.

These data suggest that AgCl is harder than NaCl, that is, AgCl has smaller amplitudes of lattice vibrations at the same temperature for most of the vibrational modes. The additional amplitude due to the quantum effect must be larger in NaCl, because of the smaller mass. Neverthless, NaCl has higher melting point. This fact seems to be contradictory to the view that melting occurs when the amplitude of thermal vibration reaches a certain fraction of the inter-atomic distance.

Table I. Comparisons of NaCl and AgCl.

	NaCl	AgCl
a	2.81	2.77×10^{-8} cm
Lattice	NaCl	NaCl
κ	5.62	12.30
κ_0	2.25	4.01
$\frac{\mu}{2}\omega_t^2$	1.10	1.05×10^4 erg/cm²
$\frac{\mu}{2}\omega_l^2$	2.76	3.23 〃
$\rho\Theta_D^2$	1.00	1.10*
$\frac{\mu}{2}\omega_0^2$	1.98	2.46×10^4 erg/cm²
e^2C	2.22	2.56 〃
K(0°K)	~3.3	
(20°C)	4.16	2.40×10^{-12} cm³/erg
α(20°C)	12.0	9.2×10^{-5} deg⁻¹
T_m	1073	728°K
E	1.8~2.0	0.8~1.0 ev
W_0	2.02	1.08 1.2 } ev

a: Lattice constant.
*: in arbitrary unit.
α: Volume expansion coefficient.
T_m: Melting point.

On the other hand, if higher derivatives of the interionic potential of AgCl were much greater than that of NaCl, it would be possible that thermal vibration and thermal expansion make AgCl unstable at lower temperature Such mechanisms of melting have been suggested by Born and Thompson³⁾. However, the comparison of the thermal expansion coefficients α does not support this assumption. The fact that α of AgCl is small comes from the smallness of the higher (the third) derivative of the potential energy compared with the second one, and decreases the effect of making the lattice unstable due to the thermal expansion. For a rough estimation, we use the Grüneisen relation

$$\gamma=-\frac{\partial\ln\omega}{\partial\ln V}\simeq\frac{\alpha V}{C_vK}, \qquad (2.1)$$

where V is the molar volume and C_v is the specific heat. In this relation we substitute the values of α, V, K at 20°C, and for C_v $6R$. Then we obtain

$$\gamma = 1.6\ (\text{NaCl}),\quad 1.9\ (\text{AgCl})\ . \tag{2.2}$$

And

$$-\frac{\partial \ln \omega}{\partial T} = \alpha\gamma \sim \begin{cases} 1.9\times 10^{-4}\ \text{deg}^{-1}\ (\text{NaCl}) \\ 1.8\times 10^{-4}\ \text{deg}^{-1}\ (\text{AgCl}) \end{cases} \tag{2.3}$$

In fact, the problem is so complicated that such a simple estimation gives no definite conclusion. However, it is evident that the explanation of melting on the basis of the conventional lattice vibration mechanism is not convenient to interpret such differences between NaCl and AgCl crystals.

In the next place, we consider the lattice defect mechanism. For this purpose, we compare the data in Table I again. In Table I E is the activation energy for ionic conduction, and W_0 is the formation energy of a pair of the Schottky or Frenkel defects, they are connected by a relation;

$$E = \frac{W_0}{2} + U\ , \tag{2.4}$$

where U is the activation energy of migration. Although the values of W_0 and U are not well known separately, the experiment of Etzel and Maurer[8] for NaCl gives the value of W_0 as 2.02 ev. On the other hand, any conclusive experiment is absent for AgCl, though Koch and Wagner[9] reported that the value of W_0 was about 1.08 ev and Breckenridge[10] 1.2 ev, which are appreciably smaller than that of NaCl. In NaCl the Schottky defects may predominate, and in AgCl the Frenkel defects may do so. The reason for the smallness of the formation energy of the Frenkel defects in AgCl may be as follows: (1) Strong van der Waals force between Ag^+ ions diminishes the formation energy about 1 ev, that is, when the Ag^+ ions are at the normal sites, the distance between neighbouring Ag^+ ions is $\sqrt{2}\,a$ and the van der Waals force is not so effective, but if one of the Ag^+ ions enters into an interstitial site, the distance becomes $(\sqrt{3}/2)a$ and the energy becomes $(2\sqrt{2}/\sqrt{3})^6 \simeq 19$ times larger. (2) κ is larger in AgCl, and the polarization energy diminishes the formation energy. In other words, for small displacements of ions about the equilibrium position the larger energy is necessary in AgCl, but for larger displacements such as defects the circumstances are not the same.

Generally speaking, there is a parallel tendency between E and T_m. These facts seem to support the assumption that ionic crystals melt when the concentration of defects reaches a certain amount.

§ 3 Interaction Between Defects

The concentration of defects in the state of equilibrium is given by

$$f = c\exp(-W_0/2kT), \tag{3.1}$$

where f is the fractional density of defects, W_0 is the formation energy of a pair of defects at 0°K, and c is a factor of the order of 10∼100. If we give the values 2.1 ev and 1.2 ev for W_0 of NaCl and AgCl respectively, and 30 for c, then we have the values of f at the melting point to be about 3×10^{-4} and 2×10^{-3} respectively. These values may be too small to cause a large change such as melting. Moreover we can not understand why the mere increase of the number of defects leads to the discontinuous change at the melting point.

The defects interact each other with the potential $\pm e^2/\kappa r$, r being the distance between defects. This interaction causes such a tendency that a defect is surrounded by a cloud with the charge of the opposite sign, as an ion in a strong electrolytic solution. It causes an apparent decrease of the formation energy, and this effect becomes appreciable at high temperatures. If we take into account this effect according to the Debye-Hückel's[11] theory, the equilibrium condition without the interaction,

$$W + 2kT\ln f = 0 \tag{3.2}$$

is replaced by

$$W + 2kT\ln f - 2\sqrt{\pi}\,\frac{e^2}{\kappa a}\left(\frac{e^2}{\kappa a k T}\right)^{1/2} f^{1/2} = 0\ , \tag{3.3}$$

where W is the formation free energy per pair of defects, and if we assume that

$$W = W_0 - \beta T\ , \tag{3.4}$$

we have

$$c = \exp(\beta/2k). \tag{3.5}$$

We can see from Eq. (3.3), that the exstence of the third term works to increase f, and causes a sort of phase transition. To see this more clearly, we transform Eq. (3.3) into

$$\frac{W_0}{2kT}-\sqrt{\pi}\left(\frac{e^2}{\kappa a\,kT}\right)^{3/2}f^{1/2}=\frac{\beta}{2k}-\ln f\,. \tag{3.6}$$

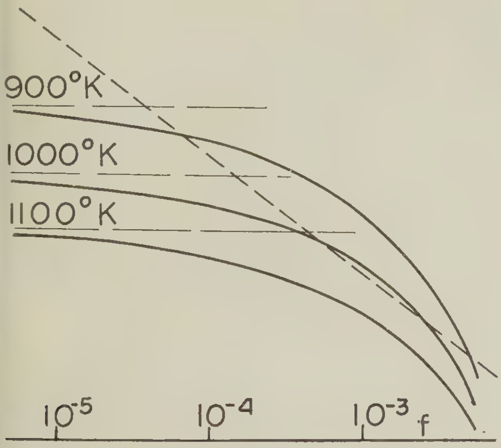

Fig. 1. The both hand sides of Eq. (3.6) for NaCl.

The results of numerical calculations for the case of NaCl are shown in Fig. 1, in which the full lines denote the left hand side of Eq. (3.6), the dotted lines are the right hand side and the broken lines are the left hand side without the second term, at several temperatures. We used the values $W_0=2.1$ ev and $c=30$. The points of intersection are the equilibrium concentrations at each temperature. From this figure, we can see that there is no solution above a certain critical temperature T_c, and this temperature is about 1000°K for NaCl, nearly equal to the melting point 1073°K. The values of W_0 and c have some ambiguities, but the change of T_c is not so large with the change of W_0 or c over a reasonable range. For instance, if the values $W_0=2.02$ ev and $c=5.4$ are used according to Etzel and Maurer,(8) T_c becomes 1170°K.

We must notice here that the true transition temperature should not be T_c, but be somewhat lower temperature, where the free energies of two phases are equal. Since we do not know about the other phase, it is impossible to calculate this temperature. We expect, however, that this true transition temperature may be nearly equal to T_c. Although it is not certain if such a transition exist really and corresponds to the melting, several experimental evidences, which are discussed in the next section, lead us to such a conclusion.

§ 4. Comparisons with Experiments

(1) The melting point and the formation energy of defects

If we denote the left hand side of Eq. (3.3) by $F(f, T)$, then T_c is given by the equations

$$F(f, T_c)=0 \tag{4.1}$$

and

$$\left[\frac{\partial F(f, T)}{\partial f}\right]_{T=T_c}=0\,, \tag{4.2}$$

that is

$$W(T_c)=2kT\left\{\ln\frac{\pi}{4}\left(\frac{e^2}{\kappa akT_c}\right)^3+2\right\} \tag{4.3}$$

and

$$f_c=c\exp\left(-\frac{W_0}{2kT_c}\right)=\exp(-2)\,\frac{4}{\pi}\left(\frac{\kappa akT_c}{e^2}\right)^3$$
$$=\exp(-2)f(T_c)\,, \tag{4.4}$$

where f_c is the fractional density of defects which is extrapolated to T_c from the values at lower temperatures. We calculate f_c or W_0 from Eqs. (4.3) and (4.4) under the expectation that $T_c \doteqdot T_m$, instead of solving T_c from Eq. (4.3). This procedure is rather convenient, because the values of W_0 are not

Table II. The values of f_c and W_0.

known in most substances. The calculated and observed values of W_0 and f_c are listed in Table II for several substances, where we put in general $\beta=6k$, or $c=20$ arbitrarily except for silver halides. We used the values of κ and a at room temperature. These calculated values have only approximate meaning, because the Debye-Hückel's theory may not be valid at high concentrations near T_c. Neverthless the agreement is satisfactory when the experimental values are available. The calculated values are also reasonable even when the experimental value is not available. It is to be noted that the values of f_c are always of the order of 10^{-4} in alkali halides and of 10^{-3} in silver halides.

The KCl-KBr system has the lowest melting point for the composition containing about 75 mole per cent KBr, where the ionic conductivity of the mixed crystals has the highest value[16]. The explanation for this fact is very easy from our view point.

According to Eq. (4.4) the real concentration at T_c is about seven times larger than the value extrapolated from the low temperatures. As mentioned in § 3, however, the real transition temperature is somewhat lower than T_c. Therefore we may expect that the difference is not so large as predicted by Eq. (4.4).

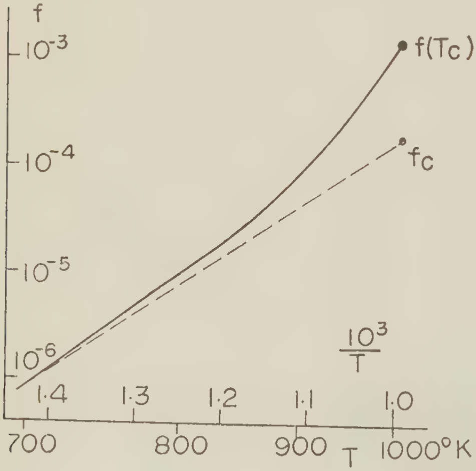

Fig. 2. ln f vs. T for NaCl.

In Fig. 2, f is plotted as a function of T for NaCl. Due to the interaction between defects, the relation of ln f vs. $1/T$ is no longer linear. Such a behaviour has not been observed in most experiments on the ionic conductivity except for a few cases. Although the reason of this discrepancy is not clear, this may be explained partley by the fact that the melting point is lower than T_c and the curvature of ln f vs. $1/T$ curve is rather small.

(2) Latent heat and volume change at melting

According to our theory, the melting of ionic crystals is to be explained by the abrupt increase of defects, and this abrupt increase may be the main structural change at melting. If this is true, the latent heat is to be close to the energy necessary to increase the defects.

When the concentration of defects is large, we estimate the interaction energy between defects by $-(\alpha_M e^2/\kappa a)f^{1/3}$, which is the interaction energy between defects in cubic array, where α_M is the Madelung constant. Thus the energy necessary to increase the concentration from f_s to f_l (the concentration of defects in solid and liquid respectively) is

$$\int_{f_s}^{f_l}\left[W_0-\frac{\alpha_M e^2}{\kappa a}f^{1/3}\right]df$$
$$=W_0(f_l-f_s)-\frac{3}{4}\frac{\alpha_M e^2}{\kappa a}(f_l^{4/3}-f_s^{4/3})\,. \tag{4.5}$$

Because $f_l \gg f_s$, we neglect f_s, and in virtue of the above discussion, we put

$$L_m \simeq W_0 f_l-\frac{3}{4}\frac{\alpha_M e^2}{\kappa a}f_l^{4/3}\,, \tag{4.6}$$

where L_m is the latent heat of melting.

On the other hand, if the volume change at melting is mainly due to defects, and the defects are predominantly Schottky defects, f_l may be nearly equal to the fraction of the volume change $\Delta V/V$. Hence we have

$$L_m \simeq W_0\left(\frac{\Delta V}{V}\right)-\frac{3}{4}\frac{\alpha_M e^2}{\kappa a}\left(\frac{\Delta V}{V}\right)^{4/3}\,. \tag{4.7}$$

In Table III the values of $\Delta V/V$ and L_m are listed, the data of the density and the latent heat are taken from "International Critical Tables". Since the density of solids at melting point is not known, we are obliged to use the extrapolated values from the room temperature. NaCl is the exception, for which the thermal expansion coefficient up to the melting point has been measured.[17] Although the values of $\Delta V/V$ and W_0 are not accurate and the formula (4.7) is only approximate, the agreement between theoretical and experimental values of the latent heat is comparatively good, especially for alkali halides. And the difference may be still more reduced, if we consider that the true interaction energy is less (algebraically) than the estimated value in Eq. (4.5). The agreement is less satisfactory for silver halides, where the calculated values are smaller than the experimental values. This may be explained as follows; in alkali halides the Schottky defects predominate, and it is a good approximation to take $f_l \cong \Delta V/V$, but in silver halides the Frenkel defects may be dominant, so that $f_l > \Delta V/V$ and the calculated latent heats become too small. As we see in Table III, the values of $\Delta V/V$ are about 20% in alkali halides but less than 10% in silver halides, this fact is consistent with the view that the former melts by the defects of Schottky type and the latter by the Frenkel type.

Table III. The latent heats.

Crystal	$V_l/V_{s'}$	$V_{s'}/V_s$	$\Delta V/V$	W_0 (ev)	L_m(ev)

V_l: the molar volume of liquids at melting point.

V_s: the molar volume of solids at melting point.

$V_{s'}$: the molar volume of solids at room temperature.

W_0: experimental values if available, otherwise calculated values in Table II. In the latter case, we show them enclosing.

It is interesting to see that, generally the value of $\Delta V/V$ in alkali halides is very large compared with that in the other types of solids, for instance, in alkali metals 2∼3%, in noble metals 4∼5% and in molecular crystals 5∼10%. This seems to suggest that the mechanism of melting appreciably differs in the ionic crystals from the other crystals. Especially in alkali metals the defects will play no role because of the lack of such a strong interaction between defects as in ionic crystals.

(3) Viscosity and electrical conductivity in ionic liquids

Since ionic liquids contain a great amount of defects, very frequent migrations of ions are expected through or by these defects, and these will cause the fluidity and the high electrical conductivity of ionic liquids. First, we consider the viscosity on this line.

In most ionic crystals, positive ions are more mobile than negative ions, so that the fluidity of ionic liquids will be limited by the mobility of negative ions. In ionic liquids, the concentration of defects f, is near to 0.2, and an ion or a defect is surrounded by $6f\,(\geq 1)$ vacancies in average. Therefore, the migration of the negative ions in liquids will be similar to that of the pair vacancies in solids, rather than that of single vacancies, because the activation energy of migration is far smaller in the former.

Then the jump frequency of a negative ion to any one of the like neighbours will be

$$2f^2\nu z\cdot\exp(-Q_-/kT)\,, \tag{4.8}$$

where z is the number of like nearest sites, 12 for NaCl type crystals, fz of them are vacant, $2f$ is the probability that the jump to a like nearest vacant site is of the pair vacancy type and Q_- is the activation energy of migration, which will be more or less smaller than that of pair vacancy in solids. Here we neglected the complicated correlations between vacancies. Hence the diffusion constant of a negative ion is

$$D=8\nu f^2a^2\exp(-Q_-/kT)\,, \tag{4.9}$$

and the mobility μ is

$$\mu=\frac{D}{kT}=\frac{8\nu f^2a^2}{kT}\exp(-Q_-/kT). \tag{4.10}$$

The simplest but somewhat doubtful way to connect this μ with the viscosity η is as follows. We regard the motion of a negative ion under an external force F as the motion of a macroscopic ball of radius R in a viscous fluid, and use the Stokes' law

$$F=6\pi R\eta v=\frac{v}{\mu}\,. \tag{4.11}$$

Thus we have

$$\eta = \frac{kT}{48\pi f^2 \nu R a^2} \exp\left(\frac{Q_-}{kT}\right) . \tag{4.12}$$

If we take the values, $T \simeq 1000°\mathrm{K}$, $\nu \simeq 3 \times 10^{12}\,\mathrm{sec}^{-1}$, $a \simeq 3 \times 10^{-8}\,\mathrm{cm}$, $R \simeq 2 \times 10^{-8}\,\mathrm{cm}$ and $f \simeq 0.2$, we obtain

$$\eta \simeq 4.3 \times 10^{-4} \exp\left(\frac{Q_-}{kT}\right) \text{(poises)} . \tag{4.13}$$

On the other hand, the experimental values of η are fitted by a formula

$$\eta = \eta_0 \exp\left(\frac{Q_\eta}{kT}\right) , \tag{4.14}$$

and the values of η_0 and Q_η are tabulated in Table IV[18]. The values of η_0 are in rather good agreement with the calculated values in the order of magnitude. We expect that Q_η is nearly equal to the activation energy of the pair vacancy and somewhat smaller than that in solids. For KCl, this energy is calculated by Dienes,[19] and his result gives 0.375 ev, which is in good accord with Q_η. The values of Q_η for other liquids are also reasonable on this view. Although our estimation is very crude, the qualitative feature may be correct.

Table IV. The values of η_0 and Q_η.

Liquid	η_0(10^{-4} poises.)	Q_η(ev)
NaCl	2.11	0.40
NaBr	2.85	0.35
KCl	4.29	0.33
KBr	2.92	0.35

In the above discussion, we neglected the temperature dependence of the former factor of Eq. (4.12), especially of f, but we can expect that this factor may have little temperature dependence, i.e.

$$\frac{d \ln \eta}{d \ln T} = -\frac{Q_-}{kT} + 1 - \frac{d \ln \nu}{d \ln T} - 2\frac{d \ln f}{d \ln T} . \tag{4.15}$$

The last two terms may be estimated as follows. The thermal expansion coefficient of liquids is about $3 \times 10^{-4}\,\mathrm{deg.}^{-1}$, this may be divided approximately into two parts, that is, the part due to the increase of the vacancies α_v, and that due to the increase of the lattice constant α_l, which is the origin of the thermal expansion in solids. The value of α_l in solids is about $1 \times 10^{-4}\,\mathrm{deg}^{-1}$ at room temperature and $2 \times 10^{-4}\,\mathrm{deg}^{-1}$ near the melting point. As we expect that α_l is larger in liquids, α_v may be at most $1 \times 10^{-4}\,\mathrm{deg}^{-1}$ and $d \ln f / dT \simeq 5 \times 10^{-4}\,\mathrm{deg}^{-1}$. On the other hand,

$$-\frac{d \ln \nu}{d \ln T} \simeq \alpha_l \gamma T \simeq +0.5 , \tag{4.16}$$

so that the sum of the last three terms is about +0.5, which is much smaller than Q_-/kT (about 4~5).

In the next place, let us consider the ionic conductivity of liquids. It is mainly determined by the mobility of positive ions in most ionic liquids. In the same manner as above, we can derive

$$\sigma = \frac{4e^2 \nu f^2}{akT} \exp\left(-\frac{Q_+}{kT}\right) . \tag{4.17}$$

Inserting the same numerical values as (4.13),

$$\sigma \simeq 30 \exp\left(-\frac{Q_+}{kT}\right)\left(\frac{1}{\mathrm{ohm \cdot cm}}\right) . \tag{4.18}$$

The experimental values are fitted by a formula

$$\sigma = \sigma_0 \exp\left(-\frac{Q_\sigma}{kT}\right) , \tag{4.19}$$

and the data are tabulated in Table V. In this case Q_σ is small, so that the temperature dependence of the former factor can not be neglected and the meaning of Q_σ becomes somewhat obscure. However, as the general tendency of Q_σ, it is reasonable that in the case of larger negative ion or smaller positive ion Q_σ is smaller. The values of σ_0 are also acceptable.

Table V. The values of σ_0 and Q_σ.

Liquid	σ_0($\Omega^{-1}\,\mathrm{cm}^{-1}$)	Q_σ(ev)
NaCl	13.8	0.10
NaBr	10.0	0.08
NaI	(230)	(0.27)
KF	201	0.32
KCl	28.4	0.18
KBr	11.9	0.13
KI	10.1	0.13
RbCl	11.6	0.14

The experimental values are taken from "International Critical Tables".

§ 5. Discussions and Conclusions

At the beginning of the above discussions, we have assumed that the melting of ionic rystals is due to defects, and the interaction etween them is essential. We took the nteraction into account by the Debye-Hückel's heory. At the high concentrations near T_c, owever, the Debye-Hückel's theory is no onger correct.

According to the second approximation of the Debye-Hückel's theory[11], the third term of Eq. (3.3) is reduced by a factor $\left\{1+\sqrt{\frac{4\pi e^2}{\kappa k T a^3}f\cdot d}\right\}^{-1}$, where d is the closest distance of approach between defects theoretically, that is, in our case a for NaCl type crystals. If we consider d as an adjustable parametre, the theory agrees well with experiments in the case of electrolytic solutions, but d becomes generally very small and even negative. Then we should not expect that the inclusion of d with the real value a would give a better approximation than the calculation by means of Eq. (3.3). For the case of the high concentrations near T_c, all the theory can not be reliable quantitatively.

Neverthless, it has some meanings to calculate the equilibrium conditions according to the second approximation of the Debye-Hückel's theory for several values of d. The results for NaCl at 1000°K and 1100°K are in Fig. 3 and Fig. 4. The meanings of the figures are same as in Fig. 1. Roughly speaking, for $d<0.5\,a$ the transition can occur.

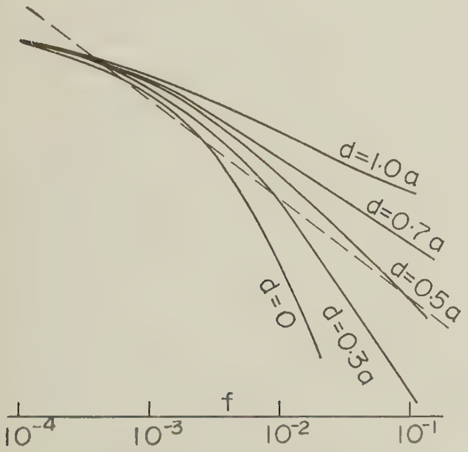

Fig. 3. NaCl 1000°K.

An electrolytic solution with $\kappa=5.6$, $T=1073$°K and $Z=1$ corresponds to a solution with the same concentration and $\kappa=80$, $T=300$°K, $Z=2$. On the other hand, the aqueous solution of bivalence ions obeys the Debye-Hückel's theory up to considerable concentrations (above 0.1 mol./lit., which corresponds to $f\sim 3\times 10^{-3}$ in our case, and κ of water at 300°K is 78), so long as we consider d as an adjustable parametre, and the values of d are very much smaller than the real values generally. Then we may expect a similar trend for the defects in ionic crystals.

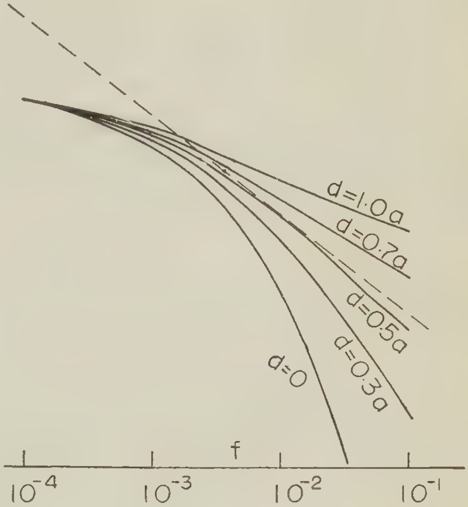

Fig. 4. NaCl 1100°K.

Although the theory contains several difficulties, it may be true that the apparent formation energy of defects decreases appreciably owing to the interaction between them, when f becomes of the order of 10^{-4}, and that f approaches this value near the melting point. Then the defects may play an important role in melting, though we may not deny the role of the lattice vibrations. And on this assumption, we can explain many facts, which can not be explained by the lattice vibration mechanism, at least qualitatively.

The author wishes to express his sincere thanks to Professor J. Yamashita for his helpful discussions.

Rotational Lrttice Vibration in Complex Crystals[*]

Part I. Vicrational Modes and Specific Heat

Sumitada ASANO and Yasuo TOMISHIMA

Department of Physics, Faculty of Science, Okayama University

(Received January 12, 1957)

In complex crystals which contain groups of atoms bonded strongly with each other such as anionic radicals, complex ions and hydrated cations, low-frequency rotational vibrations of these groups of atoms may be expected to exist in addition to low-frequency translational vibrations, as in the case of ideal molecular crystals. By using an one-dimensional lattice, the modes of these vibrations are analysed. According to the results obtained, we may conclude that new additional modes appear, which is related to the rotational vibrations of the groups of atoms, and they may be classified, in general, into the optical and acoustical branches just as in the case of the translational vibrations. In addition, the effects of the introduction of these new modes upon the specific heat at low temperatures are investigated, by using the results of the analysis for the one-dimensional lattice.

§ 1. Introduction

In molecular crystals, in which the intra-molecular forces are much stronger than the intermolecular forces, there may be a set of $3N$ modes (N: total number of molecules) of low-frequency tortional vibrations as well as $3N$ modes of low-frequency translational vibrations[1]. On the other hand, in complex crystals[**], such as sulphates and phosphates etc., the ions constituting the radicals $[SO_4]^{2-}$ and $[PO_4]^{3-}$ may be considered as strongly bonded with each other, compared with the forces binding the radical groups with each other and that binding the radical group and the partner cation[2]. This is evidenced, to some extent, by several experimental facts: For example, the peak wave-length in vibration spectra of most of the isolated radicals are of the order of several microns[3], whereas the Reststrahlen wave-lengths of usual crystals are of the order of several tens microns. The absorption maxima characteristic to the internal vibrations of a particular radical in various types of complex crystals are nearly constant and are hardly affected by the binding with cations in the lattice. They often persist even in solution[4]. These complex crystals are dissociated into radicals and cations when they are dissolved in suitable solvents. The size of one particular radical is nearly constant regardless of the kind of the partner cation[5]. Therefore, the radical in such a complex crystal may suffer a rotational vibration around the equilibrium orientation except at a high temperature, besides a translational motion as a whole. (cf. Fig. 1) At a high temperature the radical may wander from one equilibrium orientation to another one passing through a potential barrier, when the coordination of the ions in the radical has a central symmetry.

---

[*] The results given in this paper were presented in part at the Tokyo Sectional Meeting of the Physical Society of Japan in November 1956.

[**] A complex crystal means here broadly a crystal containing groups of atoms (or ions) which are bonded with each other more tightly than with the lattice, such as anionic radicals, complex ions and hydrated cations (aquo-cations), whereas a simple crystal means an ordinary one consisting of single atoms (or ions).

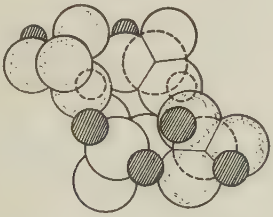

Fig. 1. A packing drawing of the atoms in a monoclinic unit cell of Li_2SO_4 crystal. The small hatched spheres are the lithium ions, the large spheres the oxygen ions; sulphur ions are hidden at the centers of the tetrahedra of their surrounding oxygen ions. Further, among the ions belonging to this unit cell two lithium ions and two oxygen ions are not seen also behind the oxygen ions. They are shown by the spheres with dotted outlines. The sizes of the spheres are proportional to the ionic radii[6].

In this part the vibrational modes in one-dimensional complex lattice are analysed and furthermore the deviation of its specific heat at low temperatures from that of the Debye model is discussed by making use of the results of the analysis.

§ 2. Rigid Rotor Model

For the sake of simplicity the following assumptions are made:

(1) The radical is regarded as a rigid rotor. Hence the additional high-frequency vibrational modes, i. e. the modes of internal vibrations which may be excited within the radical are ignored. The translational vibration of the radical as a whole may be separated from the rotational vibration and regarded as concerning with ordinary translational phonons, as stated later.

(2) Each ion constituting a radical is regarded as a point charge with the atomic mass, and furthermore the coordination of the ions in a radical has a central symmetry around the central ion such as tetrahedral or octahedral one.

(3) The motion of a radical consists of the translational motion and the rotational one around its center of mass. The radical at the equilibrium orientation may be brought into an arbitrary one by a single rotation, and if the angle θ of this rotation is small (to the extent that the square of θ is negligible for unity), we can define a vector $\boldsymbol{\theta}$ called angular displacement, which has the magnitude equal to θ and the direction pararell to the axis of rotation, satisfying the right-winding screw relation. The $\boldsymbol{\theta}$ determines the orientation of the radical uniquely and $\dot{\boldsymbol{\theta}}$ is identical with the angular velocity of the radical.

The effective potential energy Φ of the constituents i. e. the radicals and the cations of the crystal is given by

$$\Phi=\Phi(u_\alpha(k),\, \theta_p(k))\,, \tag{2.1}$$

where $u_\alpha(k)(\alpha=1, 2, 3)$ is the component of the Cartesian displacement of the center of mass of the kth constituent $(k=1, 2, \cdots, n)$ referring to its equilibrium position and $\theta_p(k)$ $(p=1, 2, 3)$ is the component of the angular displacement of the kth constituent. When the kth constituent is a cation, $\theta_p(k)$ should be omitted in (2.1), since the cation is regarded as a point charge. Let us introduce the notation

$$\begin{aligned} &\Phi_\alpha(k)\equiv(\partial\Phi/\partial u_\alpha(k))_0, \quad \Phi_p(k)\equiv(\partial\Phi/\partial\theta_p(k))_0 \\ &\Phi_{\alpha\beta}(kk')\equiv(\partial^2\Phi/\partial u_\alpha(k)\partial u_\beta(k'))_0\,, \\ &\Phi_{\alpha p}(kk')\equiv(\partial^2\Phi/\partial u_\alpha(k)\partial\theta_p(k'))_0\,, \end{aligned} \tag{2.2}$$

and

$$\Phi_{pq}(kk')\equiv(\partial^2\Phi/\partial\theta_p(k)\partial\theta_q(k'))_0\,,$$

where the index 0 signifies the configuration $u_\alpha(k)'\text{s}=0,\ \theta_p(k)'\text{s}=0$.

Then

$$\Phi_\alpha(k)=\Phi_p(k)=0\,. \tag{2.3}$$

So we may write

$$\Phi=\frac{1}{2}\sum_{k,k'}\Big[\sum_{\alpha,\beta}\Phi_{\alpha\beta}(kk')u_\alpha(k)u_\beta(k')$$

$$+\sum_{\alpha,p}\Phi_{\alpha p}(kk')u_\alpha(k)\theta_p(k')$$

$$+\sum_{p,q}\Phi_{pq}(kk')\theta_p(k)\theta_q(k')\Big]. \qquad (2.4)$$

We introduce the notations

$$D_{\alpha\beta}(kk')\equiv\frac{1}{(m_k m_{k'})^{1/2}}\Phi_{\alpha\beta}(kk),$$

$$D_{\alpha p}(kk')\equiv\frac{1}{(m_k I_{k'})^{1/2}}\Phi_{\alpha p}(kk'),$$

$$D_{pq}(kk')\equiv\frac{1}{(I_k I_{k'})^{1/2}}\Phi_{pq}(kk'), \qquad (2.5)$$

and

$$\omega_\alpha(k)\equiv m_k^{1/2}u_\alpha(k),$$

$$\omega_p(k)\equiv I_k^{1/2}\theta_p(k),$$

where m_k and I_k are the mass and the moment of inertia of the kth constituent respectively.

From the assumption (3) it may be deduced that the variable defined by

$$L(k)\equiv I_k\dot{\theta}(k) \qquad (2.6)$$

is canonically conjugate to $\theta(k)$, and then $L_p(k)$, and $\theta_p(k)$ satisfy the commutation relations quite similar to those which are satisfied by the components of the linear momentum and coordinate conjugate to one another. Therefore, $L(k)$ may be replaced with the differential operator

$$L_p(k)=-i\hbar\partial/\partial\theta_p(k). \qquad (2.7)$$

Furthermore, the rotational kinetic energy of the kth radical may be written in the form

$$(L(k))^2/2I_k. \qquad (2.8)$$

If $\omega_\alpha(k)$'s and $\omega_p(k)$'s are rewritten by the notations $\omega_{\alpha'}(k)$'s with the newly labeled indices α''s which are $1, 2, 3$ or $1, 2, \cdots, 6$ according as the kth constituent being a cation or a radical, and similarly $D_{\alpha\beta}(k,k')$, $D_{\alpha p}(k,k')$ and $D_{pq}(k,k')$ by $D_{\alpha'\beta'}(k,k)$, then the kinetic and potential energies T and Φ for the motion of the constituents can be written as follows:

$$T=\frac{1}{2}\sum_k\sum_{\alpha'}P_{\alpha'}{}^2(k),$$

$$\Phi=\frac{1}{2}\sum_{k,k'}\sum_{\alpha',\beta'}D_{\alpha'\beta'}(kk')\omega_{\alpha'}(k)\omega_{\beta'}(k), \qquad (2.9)$$

where

$$P_{\alpha'}(k)\equiv-i\hbar\,\partial/\partial\omega_{\alpha'}(k).$$

By introducing the normal coordinates q_j which are given by the appropriate linear combinations of $\omega_{\alpha'}(k)$'s, we obtain the usual expressions[7)]

$$T=\frac{1}{2}\sum_j P_j{}^2,$$

$$\Phi=\frac{1}{2}\sum_j\omega_j{}^2q_j{}^2, \qquad (2.10)$$

where

$$P_j\equiv-i\hbar\,\partial/\partial q_j,$$

and the Hamiltonian of the system is given by

$$H=T+\Phi=\frac{1}{2}\sum_j(P_j{}^2+\omega_j{}^2q_j{}^2). \qquad (2.11)$$

Thus the energy of the lattice vibrations (including the rotational energy) may be quantized as so-called phonons.

§ 3. One-dimensional Complex Lattice

In order to clarify the aspects of the rotational vibration of the radicals, we investigate the simplest model i. e. a chain of two different types of constituents occupying alternate sites, one is a sphere with finite radius d', mass M and moment of inertia I, and the other a point particle with mass m. The former corresponds to the radical and the latter to the partner cation. (cf. Fig. 2) If we consider only the transverse vibration of the chain, the displacement of each constituent may be refered to one transverse direction and the axis of rotation of each sphere may be taken as perpendicular to its displacement and the chain.

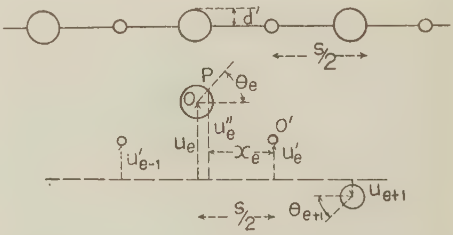

Fig. 2. One-dimensional complex lattice.

We assume two kinds of potential functions between nearest-neighbours in the lth unit cell

$$\phi_1(\overline{OO'})=\phi_1(\sqrt{(u_l-u_l')^2+(s/2)^2}),$$

$$\phi_2(\overline{PO'})=\phi_2(\sqrt{(u_l''-u_l')^2+x_l{}^2}). \qquad (3.1)$$

The meanings of the notations in (3.1) are illustrated in Fig. 2. Then the forces acting on the sphere from the adjacent particle are given by $-\partial\phi_1/\partial u_l$ and $-\partial\phi_2/\partial u_l''$; the former represents a central force acting on the radical and the latter a non-central one. When u_l, u_l'' and $u_l' \ll s/2$ and $s/2-d'$, and θ_l is small,

$$-\partial\phi_1/\partial u_l=-c_1(u_l-u_l')\ ,$$

and

$$-\partial\phi_2/\partial u_l''=-c_2(u_l+d'\theta_l-u_l')\ , \qquad (3.2)$$

where c_1 and c_2 are the force constants for the central and noncentral forces given by

$c_1=\phi_1'(s/2)/(s/2)\ ,\quad c_2=\phi_2'((s/2)-d')/((s/2)-d')\ .$

Then the equations of motion of the constituents in the lth cell are written as

$$\begin{aligned} M\ddot{u}_l&=(c_1+c_2)[(u_l'-u_l)-(u_l-u_{l-1}')]\ ,\\ m\ddot{u}_l'&=(c_1+c_2)[(u_{l+1}-u_l')-(u_l'-u_l)]\\ &\quad -c_2d'(\theta_{l+1}-\theta_l)\ ,\\ I\ddot{\theta}_l&=c_2d'(u_l'-u_{l-1}')-2d'^2c_2\theta_l\ . \end{aligned} \qquad (3.3)$$

By the following special substitutions

$$\left.\begin{aligned} u_l&\equiv u\\ u_l'&\equiv u'\\ \theta_l&\equiv\theta \end{aligned}\right\}\times\exp(2\pi iyl-i\omega t)\ , \qquad (3.4)$$

(3.3) is reduced to

$$\begin{aligned} &[M\omega^2-2(c_1+c_2)]u+(c_1+c_2)(1+e^{-2\pi iy})u'=0\ ,\\ &(c_1+c_2)(1+e^{2\pi iy})u+[M\omega^2-2(c_1+c_2)]u'\\ &\qquad\qquad +c_2d'(1-e^{2\pi iy})\theta=0\ ,\\ &c_2d'(1-e^{-2\pi iy})u'+[I\omega^2-2c_2d'^2]\theta=0\ . \end{aligned} \qquad (3.5)$$

From (3.5) we obtain the secular equation to determine ω

$$\{x^2-2(1+\sigma)x+4\sigma\sin^2\pi y\}\left(x-\frac{2B\sigma}{\alpha}\right)$$
$$-4(x-2\sigma)\frac{B^2\sigma}{\alpha}\sin^2\pi y=0\ , \qquad (3.6)$$

where

$$x\equiv(\omega/\Omega)^2\ ,\quad \Omega^2\equiv(c_1+c_2)/m$$
$$B\equiv c_2/(c_1+c_2)\ ,\quad \sigma\equiv m/M\ ,\quad \alpha\equiv I/Md'^2 \qquad (3.6a)$$

At long wave-length limit: $y\approx0$

$$[x]_{y\simeq0}=2\pi^2\frac{(1-B)\sigma}{1+\sigma}y^2$$
$$\times\left[1+\pi^2\frac{\Gamma}{(1+\sigma)^2}y^2+O(y^4)\right], \qquad (3.7a)$$

$$[x]_{y\simeq0}=2(1+\sigma)$$
$$\times\left[1-\pi^2\frac{\sigma\{(1+\sigma)\alpha-B(B+\sigma)\}}{(1+\sigma)^2\{(1+\sigma)\alpha-B\sigma\}}y^2\right]+O(y^4)\ , \qquad (3.7b)$$

$$[x]_{y\simeq0}=2\frac{B\sigma}{\alpha}$$
$$\times\left[1+\pi^2\frac{\alpha(\alpha-B)}{(1+\sigma)\alpha-B\sigma}y^2\right]+O(y^4)\ , \qquad (3.7c)$$

where

$$\Gamma\equiv\sigma(1-B)+(B-\alpha)(1+\sigma)-(1/3)(1+\sigma)^2\ . \qquad (3.7d)$$

The first two branches, (3.7 a and b), correspond to the usual acoustical and optical branches in translational mode which contains no rotational energy at $y=0$ (abbreviated as TA- and TO-branches respectively), whereas in the last one (3.7c) the rotational energy occupies, in general, the large portion of the total mechanical energy and the frequency depends less strongly upon wave-number, as stated later, therefore we will call this the optical branch in the rotational mode (abbreviated as RO-branch). When $c_1=0$, the TA-branch disappears and when $c_2=0$, the RO-branch does not exist.

At short wave-length limit: $y=1/2$ (3.6) can be solved simply as

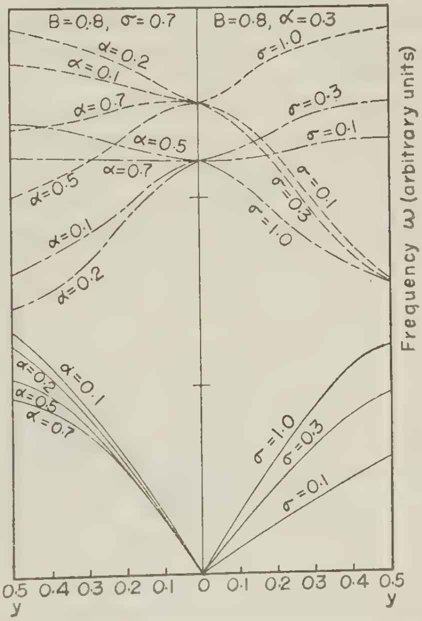

Fig. 3. Variation of frequency with wave-number.
Dotted curves: rotational optical mode.
Chain curves: translational optical mode.
Real curves: translational acoustical mode.

$$[x]_{y=1/2}=2\sigma\ , \qquad (3.8a)$$

and

$$[x]_{y=1/2}=1/\alpha\,[(\alpha+\sigma B)\pm\sqrt{(\alpha-\sigma B)^2+4B^2\alpha\sigma}]\ , \qquad (3.8b)$$

which correspond to these three branches.

We can solve (3.6) for given values of B, σ, α and y. Fig. 3 shows the actual dependence of ω upon y(wave-number$=|y/s|$,$-1/2\leq y\leq 1/2$) for various sets of B, σ and α. The values of ω at $y=0$ in the TO- and RO-branches are adjusted in such a way that they coincide with those in the case $\sigma=1$, $\alpha=0.3$, by multiplying an appropriate factor proper to each case. In general, the constancy of the frequency of the TO-branch ω_t, is realized for small values of σ, as in the case of the one-dimensional simple lattice (consisting of point particles), and that of the frequency of the RO-branch, ω_γ, also for small values of α and $\alpha\simeq B$.

In the model stated above, the rotational vibration of a radical is mainly due to the forces exerted by the adjacent cations. Therefore, in the RO-branch where the rotational vibrations of the radicals have the main contribution in the lattice vibrations, their frequencies are less dependent on whether the radicals in adjacent unit cells vibrate with the same or with the different phases, in other words on the wave-number y.

From (3.5) we obtain

$$\frac{u}{u'}=-(1+e^{-2\pi iy})\Big/\left(\frac{x}{\sigma}-2\right),$$

$$\frac{d'\theta}{u'}=-B(1-e^{-2\pi iy})\Big/\left(\alpha\frac{x}{\sigma}-2B\right). \qquad (3.9)$$

The real parts of (3.9) give the amplitude ratios of the actual displacements in the lattice vibration. Therefore, the ratio ρ of the rotational energy to the total mechanical energy is given, for each branch, by

$$\rho=\frac{4\alpha B^2\sin^4\pi y\Big/\left(\alpha\dfrac{x}{\sigma}-2B\right)^2}{4\cos^4\pi y\Big/\left(\dfrac{x}{\sigma}-2\right)^2+\sigma+4\alpha B^2\sin^4\pi y\Big/\left(\alpha\dfrac{x}{\sigma}-2B\right)^2}\ . \qquad (3.10)$$

Fig. 4 shows the dependence of ρ upon y. We can conclude that the contribution of the rotational energy in the TA- and TO-branches are considerably smaller than that of the translational one, in particular, for a long wave-length range, whereas in the RO-branch the large portion of the mechanical energy is contributed by the rotational motion of the radicals except for the intermediate values of α and σ. Moreover ρ tends to increase with increasing wave-number in all branches.

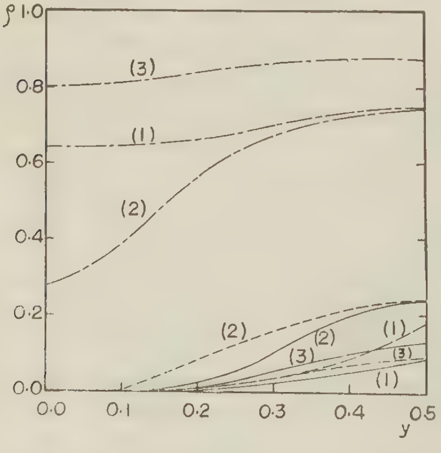

Fig. 4. Dependence of ρ upon y.
Chain curves: rotational optical mode.
Dotted curves: translational optical mode.
Real curves: translational acoustical mode.
(1) $B=0.8$, $\alpha=0.3$, $\sigma=0.1$.
(2) 〃 , 〃 , $\sigma=1.0$.
(3) 〃 , $\alpha=0.1$, $\sigma=0.7$.

From (3.7b and c) we obtain

$$[(\omega_r/\omega_t)^2]_{y=0}=\frac{B}{\alpha}\,\frac{\sigma}{1+\sigma}\ . \qquad (3.11)$$

Since $B\simeq\alpha$ and $\sigma\simeq 1$ in order of magnitude, $\omega_r\simeq\omega_t$ at $y=0$. According to the assumption (2) in § 2, the moment of inertia I of the radical around the axis passing through its center of mass i. e. the central ion is independent of the orientation of the axis relative to the radical and given by

$$I=M_c k_c d^2\ , \qquad (3.12)$$

where M_c is the mass of a coordinated ion, d the distance between a coordinated ion and the central ion of the radical, k_c a numerical constant peculiar to the symmetry of the coordination in the radical, i. e. 8/3 or 4 respectively according as it being tetrahedral or octahedral.

In identifying the sphere in our linear chain model with a real radical, we may put

$$M=M_0+n_cM_c$$

and

$$d'=d\,, \tag{3.13}$$

where M_0 is the mass of the central ion of the radical and n_c the coordination number. Putting (3.12) into last equation of (3.6a) and taking into account of (3.13), we obtain

$$\alpha=k_0(n_c+M_0/M_c)^{-1}. \tag{3.14}$$

Its values are listed in Table I for some anionic radicals with tetrahedral and octahedral structures.

Table I.

Radical	Molecular weight	α
$[BF_4]^{2-}$	86.82	0.58
$[SO_4]^{2-}$	96.00	0.44
$[ClO_4]^{-}$	99.46	0.43
$[MnO_4]^{-}$	118.94	0.36
$[PO_4]^{3-}$	94.98	0.31
$[MoO_4]^{2-}$	159.95	0.27
$[WO_4]^{2-}$	247.92	0.17
$[SiF_6]^{2-}$	407.97	0.53
$[PtCl_6]^{2-}$	247.92	0.35

Since σ may be expected to be considerably small, unless the partner cation is an extremely heavy metal, it would be reasonable, in general, to assume a small value of σ and α for a real complex crystal. Hence the assumptions on the constancy of the frequency and on the concentration of the rotational energy in the RO-branch would be allowable.

§ 4. Specific Heat at Low Temperatures

In this section, we will treat again only the isotropic complex crystals consisting of point-like cations and rigid anionic radicals. Then we have no need to take into account of the RA-branch (accoustical branch in rotational mode), as stated in App. II.

Blackman has used the linear chain model to discuss schematically the behaviors of the specific heat of simple crystals and shown its deviation from the Debye's continuum approximation[8]. Let us investigate now how affects the additional introduction of the rotational lattice-vibration the behavior of the specific heat at low temperatures, by using the results of the linear chain model calculated in § 3. Although there are $3(n-2)$ additional high-frequency modes of internal vibrations of each radical (n: the number of atoms in a radical), their contribution to the specific heat, which may be given by the sum of the Einstein functions, would be negligible at low temperatures. Therefore we may ignore these internal vibrations.

For a finte chain of L cells, there are

$$2L\Delta y=2L\left(\frac{dy}{d\nu}\right)\Delta\nu \tag{4.1}$$

vibrations in the frequency range $(\nu, \nu+\Delta\nu)$ with respect to each one of the three branches, i. e. TA-, TO- and RO-branches; the factor 2 in (4.1) takes account of the dual ranges for the y-value.

Accordingly the heat capacity C_V at T°K is given by

$$C_V=2Lk\int\frac{e^{h\nu/kT}}{(e^{h\nu/kT}-1)^2}\left(\frac{h\nu}{kT}\right)^2 \times\left[\left(\frac{dy}{d\nu}\right)_1+\left(\frac{dy}{d\nu}\right)_2+\left(\frac{dy}{d\nu}\right)_3\right]d\nu\,, \tag{4.2}$$

where $2\pi\nu=\omega$ and the suffixes appended to $(dy/d\nu)$ correspond to the three branches.

If we will apply Debye's approximation to this case, the relation between the frequency and y is given by, (cf. (3.7a))

$$\nu_{app}=\Omega\left[\frac{(1-B)}{2}\frac{\sigma}{1+\sigma}\right]^{1/2}y\,. \tag{4.3}$$

In the case of ideal molecular crystals, whose one-dimensional analogue was treated in App. I, $6N$ continuum modes will appear (N: the number of molecules), if we take into account the $3N$ translational modes and $3N$ torsional modes. Load et al[9] have calculated the specific heat of crystalline benzene taking into account these $6N$ modes and found that the observed molar heats are fitted by the single Debye function with $\Theta_D=150$°K even in fairly low temperatures. Since the RA-branch disappear in our case in which the cations are assumed to have infinitesimal size, the RO-branch have no corresponding continuum branch to be related with Debye's approximation. (cf. App. I and II) Accordingly we will determine the maximum frequency ν_D by the following normalization condition.

$$\int_0^{\nu_D}2L\left[\frac{\Omega^2(1-B)}{2}\frac{\sigma}{1+\sigma}\right]^{-1/2}d\nu=3L$$

or

$$\nu_D=\Omega\left[\frac{\sigma(1-B)}{2(1+\sigma)}\right]^{1/2}\frac{3}{2}\,. \tag{4.4}$$

Then the heat capacity in the continuum approximation is given by

$$(c_V)_{app}=3Lk\left(\frac{T}{\Theta_D}\right)\int_0^{\Theta_D/T}\frac{\xi^2e^\xi}{(e^\xi-1)^2}d\xi\,, \tag{4.5}$$

where

$$\Theta_D=h\nu_D/k\,. \tag{4.6}$$

C_V given in terms of (4.2) may be numerically computed using the results in §3. (cf. Fig. 3) Therefore, if we simply equate the accurate expression (4.2) to the approximate one (4.5), we can calculate a value for Θ_D for any particular T and then obtain the Θ_D-T curves for various sets of values of B, σ and α, which are analogous to those in the Blackman's computation[8]. We expect that the values of Θ_D calculated in this way will agree exactly with (4.6) only for very small T, and that for only this limiting case the Debye formula (4.5) is exact. These curves are actually shown in Fig. 5, in which the maximum frequency $\nu_m\left(=\frac{\Omega}{2\pi}\sqrt{x_m}\right)$ corresponding to the largest one, x_m, of the six roots of (3.6) at $y=0$ and 1/2, which are given by (3.7) and (3.8), is chosen in each case so that $h\nu_m/k=200°\text{K}$ by adjusting the constant Ω.

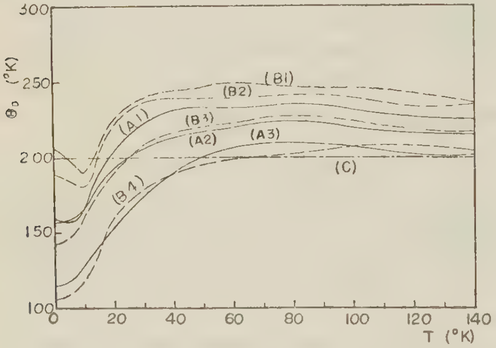

Fig. 5. Temperature dependence of Θ_D.
(A1) $B=0.8,\ \alpha=0.3,\ \sigma=1$
(A2) 〃 , 〃 , $\sigma=0.3$
(A3) 〃 , 〃 , $\sigma=0.1$
(B1) $B=0.8,\ \alpha=0.7,\ \sigma-0.7$
(B2) 〃 , $\alpha=0.5$, 〃
(B3) 〃 , $\alpha=0.2$, 〃
(B4) 〃 , $\alpha=0.1$, 〃
(C) Continuum approximation

In A-group B and α are constant and σ variable, whereas in B-group B and σ are constant and α variable. The curves (A1), (B1) and (B2) have minima, whereas the curves (A2), (A3), (B3) and (B4) have not.

Referring to Fig. 5, we note in particular the following points:

(1) θ_D is far from being independent of temperature and shows marked variations at low temperatures.

(2) At high temperatures, Θ_D tends to a fairly constant value proper to each case but it is considerably different from the low-temperature limit at $T=0$. That is, the specific heat at high temperatures can be fairly represented by means of the Debye formula with a suitably chosen value for the parameter Θ_D.

(3) The region for the linear law $C_V\propto T$, which is the analogue of the T^3-law in actual three-dimensional crystals, is extrememely narrow and only recognized as a horizontal tangent at $T=0$.

(4) Curves (A1), (B1) and (B2) have minima, where Θ_D is stationary. Since the corresponding temperatures are sufficiently low compared with Θ_D, we have in the neighbourhood of the minimum spurious T^3-variation quite unrelated to the real T^3-region at $T=0$, as observed always in real simple crystals.

(5) The remaining curves have no minima, although the curves rapidly increase above the low-temperature limit of Θ_D at $T=0$ with increase of T.

All the above features would be retained in the real three-dimensional cases in somewhat less exaggerated way.

§5. Conclusions

According to the above results we may assume that the frequency in the RO-branch is nearly independent on the wave-number and of order of magnitude comparable to the frequency of the Reststrahlen and that the mechanical energy of lattice vibration in this branch is considered as the rotational energy of the radicals approximately. A vibrational mode in RO-branch is characterized by the motion such that the rotational vibration of the radicals is much more conspicuous compared with the translational motions of the radicals and cations.

In the three-dimensional case, where a unit cell contains n radicals and n partner cations, $3\times3n=9n$ branches i. e. three TA- and $3(2n-1)$ TO-branches and $3n$ RO-branches will appear. ω_j's in §2 may be classified into these $9n$ branches. Therefore, the quantized energies of the lattice vibration in complex crystals may be classified as the TA-, TO- and RO-phonons. If the crystal structure of a complex crystal were an ideal one, the RO-phonons would be classified into transverse and longitudinal ones, as in the case of the TA- and TO-phonons.

When the binding forces between ions constituting a radical is not so strong that it is hardly regarded as a rigid rotor, then our model is not available. On the contrary, if the forces between radicals and cations and between different radicals are considerably weak and ω_r has a value small enough to be treated as a free rotor, it would be irrelevant to take into account the rotational vibration, since such a low-frequency vibration will give only a constant contribution to the specific heat even in a relatively low temperature range owing to the validity of the equipartion law. However, ω_r would be expected to have a fairly large value, since the binding forces between radicals and cations and between different radicals would be considered as too large in actual complex crystals to allow a nearly free rotation of the radicals, although they are much weaker than the intraradical forces.

In the complex salt crystals, which contain tetrahedral or octahedral complex ions such as $[MCl_4]^{n-}$ or $[M(CN)_6]^{n-}$ (M: metallic ion), the binding forces within these complex ions may be expected to be stronger than those with the lattice. Some crystals preferably take water of crystallization by forming the solid salts hydrates. The tendency of the hydration is comspicuous, in particular, for the metallic cation of small ionic radius and high ionic charge i.e. large polarizing power$^{10)}$. In the case such as $BeSO_4\cdot4H_2O$, $NiSO_4\cdot7H_2O$ and $CrCl_3\cdot6H_2O$ the water may be coordinated to the cation of the salt, not only in crystallographical sense, but to form a coordinated complex ion in the sense of Werner's theory, and we have actually the salts of hydrated cations (aquo-cations) $[Be(H_2O)_4]SO_4$, $[Ni(H_2O)_6]SO_4H_2O$ and $[Cr(H_2O)_6]Cl_3$. In aquo-cations $[Be(H_2O)_4]^{2+}$, $[Ni(H_2O)_6]^{2+}$ and $[Cr(H_2O)_6]^{3+}$ the coordinated water molecules would be strongly polarized by the central metallic ion. Accordingly the present theory would be applicable not only to the complex crystal containing anionic radicals but also to those containing complex ions or aquo-cations, if the binding forces within these complex ions and aquo-cations are considerably tight as in the case of anionic radicals. Only in the ideal complex crystals, whose unit cell consists of n rigid anionic radicals and n rigid aquo-cations, the three RA-branch of the lattice vibrations will appear. (cf. App. II)

The features on the Θ_D-T relation (except the item (5)), stated in § 4, are quite analogous to those in the case of simple ionic crystals, where the rotational mode is not necessary to be taken into account. As the striking difference caused by introducing the rotational modes we may mention that the Θ_D-T curve has no minimum occasionally at an intermediate temperature, even when the curve rises towards higher temperatures beyond the Θ_D value at $T=0$. (cf. curves (A2), (A3), (B3) and (B4) in Fig. 5) The Θ_D-T curve of a simple ionic crystals, in such a case, always has a minimum, although the minimum lies very close to $T=0$ and its existence may be not marked in some cases$^{11)}$.

This is due to the fact that the factor Γ in the coefficient of the second terms in (3.7a) may take a positive value for appropriate values of the three parameters B, σ and α, whereas the corresponding coefficient in the case of a one-dimensional simple lattice is always negative$^{11)}$. Referring to Fig. 5 and (3.7a), a positive coefficient occurs for small values of σ and α. Accordingly we could infer that in some actual complex crystals the Θ_D-T curve has no minimum and that they do not have the spurious T^3-region in the temperature dependence of the specific heat.

Unfortunately we cannot find suitable experimental data on the specific heats of complex crystals at low temperatures which are to be compared with the present theoretical conclusion. If the measurement is made accurately for complex crystals in the future, a clew for the problem mentioned above may be given.

In conclusion, the authors express their sincere thanks to Professor K. Umeda who read the manuscript and gave them valuable advices.

Appendix I.

Vibrational Modes in One-dimensional Lattice Consisting of Spheres of One Kind.

For the lattice consisting of spheres of one kind with finite radius d, mass M and moment of inertia I, the secular equation to determine the frequency as a function of the wave-number is given by

$$\alpha x^2-4(B\cos^2\pi y+\alpha\sin^2\pi y)x$$
$$+16\,B(1-B)\cos^2\pi y\sin^2\pi y=0\ , \qquad \text{(A-1)}$$

where

$$x\equiv(\omega/\Omega)^2,\quad \Omega^2\equiv(c_1+c_2)/M\ ,$$
$$\alpha\equiv I/Md^2\ ,\quad B\equiv c_2/(c_1+c_2)\ .$$

Then two branches appear, namely TA-branch and RA-branch (that is, accoustical branch in rotational mode), whose frequencies depend upon y as shown in Fig. 6a.

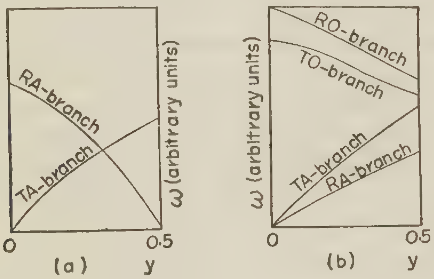

Fig. 6a and b. Schematic diagrams of the $\omega-y$ relation. $(-1/2\leq y\leq 1/2)$

If we expand $(\omega/\Omega)^2$ at $\omega\simeq 0$, we have in the TA-branch

$$(\omega/\Omega)^2_{TA}=4(1-B)\pi^2y^2+O(y^4) \qquad \text{(A-2a)}$$
$$\text{near}\quad y=0\ ,$$

and in the RA-branch

$$(\omega/\Omega)^2_{RA}=4(1-B)(B/\alpha)\pi^2\left(\frac{1}{2}-y\right)^2$$
$$+O\left(\left(\frac{1}{2}-y\right)^4\right)\qquad \text{near } y=1/2\ . \quad \text{(A-2b)}$$

Appendix II.

Vibrational Modes in One-dimensional Lattice Consisting of Spheres of Two Kinds.

In the case of the lattice consisting of spheres of two kinds occupying alternate sites, whose radii, masses and moments of inertia are d, d'; M, M'; and I, I' respectively, the secular equation is given by

$$[x^2-2(1+\sigma)x+4\sigma\sin^2\pi y]$$
$$\times[\alpha\alpha' x^2-2B(\alpha+\sigma\alpha')x+4B^2\sigma\sin^2\pi y]$$
$$-[(x-2\sigma)(\alpha' x-2B)+(x-2)(\alpha x-2B\sigma)]$$
$$\times 4B^2\sigma\sin^2\pi y$$
$$+16\,B^4\sigma^2\sin^2\pi y(\sin^2\pi y+2\cos^2\pi y)=0\ , \qquad \text{(A-3)}$$

where

$$x\equiv(\omega/\Omega)^2\ ,\qquad \Omega^2\equiv(c_1+c_2)/M'\ ,$$
$$\alpha\equiv I/Md^2\ ,\qquad \alpha'\equiv I'/M'd'^2\ ,$$
$$B\equiv c_2/(c_1+c_2)\ ,\quad \sigma\equiv M'/M\ .$$

In this case four branches appear as shown in Fig. 6b. In the TA- and RA-branches near $y=0$, ω^2 can be expressed such as

$$(\omega/\Omega)_{TA}{}^2=\frac{2(1-B)\sigma}{1+\sigma}\pi^2y^2+O(y^4) \qquad \text{(A-4a)}$$

and

$$(\omega/\Omega)_{RA}{}^2=\frac{2(1-B)B\sigma}{\alpha+\alpha'\sigma}\pi^2y^2+O(y^4)\ , \qquad \text{(A-4b)}$$

respectively. When $\alpha'\to\infty$, (A-3) coincides with (3.6) and RA-branch disappears. (cf. (A-4b)) This is the case treated in § 3.

The Structure of Evaporated Barium Films

By Yoshihiko MIZUSHIMA, Zenjiro ODA and Osamu OCHI

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Tokyo

(Received November 9, 1956)

The electrical resistance and nitrogen sorption at liquid oxygen temperature were measured for barium films evaporated and heat-treated under various conditions. The conditions which provided the properties of the film were:

1. Temperature of substrate during deposition, T_d,
2. Temperature of substrate at annealing, T_a, and
3. Pressure of residual gas during deposition, P_d.

Comparing the temperature variation of electrical resistance with sorption property for nitrogen, the authors reached the following conclusions:

1. Granular structure plays an important role in resistance as well as in nitrogen sorption,
2. The contribution of the imperfections included in each crystalline lattice is also remarkable at low temperature, but decays easily at higher temperature.

Discussions are also given on the mechanism of nitrogen sorption on barium film.

§ 1. Introduction

The complexity of the physical properties of an evaporated metal film can be more or less attributed to its structure-sensitivity, which is easily affected by treatment conditions. From this point of view, relations between factors during evaporation and the resulting film structure must be studied accurately, and the effects of the treatment conditions should be connected with the unified atomic model of the film construction. Recently, information on lattice imperfections has been markedly accumulated, so that the detailed results given here are able to be investigated systematically by the model of lattice imperfections.

Among the properties of evaporated barium film, the reaction with various gases[1] is most extensively investigated because of its practical application, and few is reported on the structure and the resulting adsorption properties of the barium film. Reimann[2] was the first investigator who pointed out the large capacity of the gas-evaporated film for various gases. He attributed this excess capacity to the large surface area of "black" deposit. The same phenomenon was found by Ehrke and Slack[3] and later by Haase[4].

On the other hand, investigations of evaporated metal films by the measurement of electrical resistance have been often reported[5-8]. The resistance is known to be sensitive to the condition of evaporation and the subsequent treatment. To interpret this, ideas[9],[10] have been proposed that in an evaporated film disordered parts contribute to the resistivity and the heat treatment diminishes such disorders.

Furthermore, a number of studies by electron diffraction[11] and electron microscope[12]-[15] show that evaporated metal films have a granular structure with a variety of crystallines.

The present series of studies were undertaken to illustrate the micro-structure of evaporated barium films produced and treated under various conditions.

§ 2. Electrical Resistance of Evaporated Barium Film

2.1. *Experimental*

Test tubes used in this measurement are shown in Fig. 1, in which two platinum electrodes are enamelled on glass wall for resistance measurement. As a barium source commercial barium tube getter was used and directly heated by passing electric current. To secure the uniform thickness and size of the film, a nickel cylinder with a slot was mounted around the source. After thorough glass baking and outgassing of metal parts by the ordinary vacuum techniques, the system was evacuated to 10^{-7} mmHg and the evaporation was carried out under a prepared condition and then evacuating to high vacuum again the bulb was sealed off. When necessary, another getter was evaporated previously in order to maintain the high vacuum during measurement. The weight of the evaporated amount or the thickness of the film was kept almost the same from sample to sample. The electrical resistance was measured by a Wheatstone bridge, where the power consumed in the film was below 10^{-8} watts on the average. When the fast change must be followed, an electronic automatic recorder was also used.

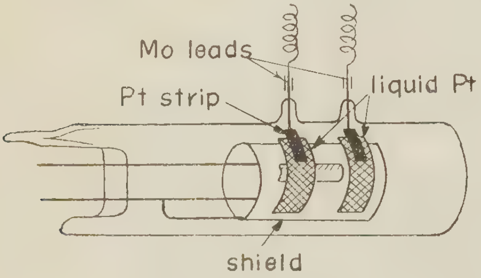

Fig. 1. Test tube for electrical resistance measurement.

Temperature was varied by using the following baths; liquid oxygen for −183°C, dry ice-propyl alchohol mixture connected to vacuum pump for about −110°C, dry ice-toluene mixture from −78°C to room temperature, transformer oil up to 100°C and small electric furnace for higher temperatures. When the temperature must be changed continuously, the rate of temperature change was controlled manually in the range 0.5∼2 degrees/min.

2.2. *Results on Resistance-Temperature Coefficient*

As will be introduced later, the resistance characteristics of an evaporated film are completely reversible so long as the temperature is varied below the highest one ever experienced by the film. Moreover, so far as the films maintain metallic character (positive temperature coefficient), the resistance vs temperature curves show themselves almost parallel with each other. In Fig. 2 are shown curves for films of various histories, to say, with reduced resistance by stabilization or by recrystallization, or with increased resistance by slight aggregation.

One can see that for this case a rule similar to the Mathiesen's holds good irrespective of the histories, and that the properties of the film may be infered from the residual resistance. Moreover, from these curves we can obtain the temperature coefficient of resistance for barium; $\alpha = 0.0035$ is almost the same as the usual temperature coefficient of bulky barium metal.

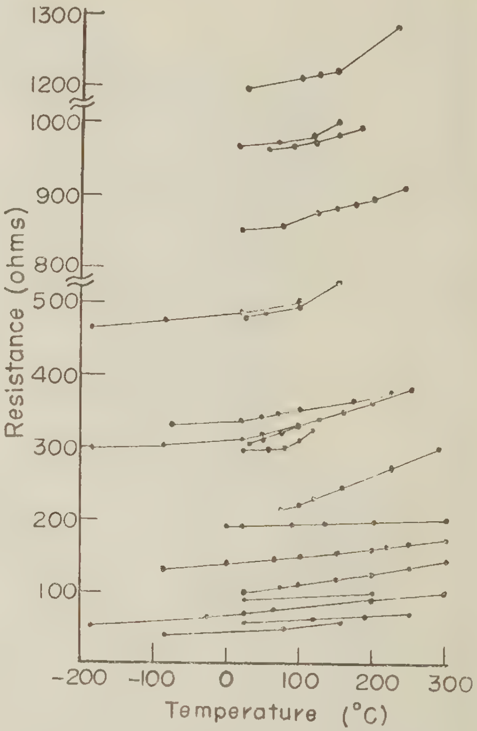

Fig. 2. Electrical resistance vs. temperature relations for various films.

2.3. *Recovery of Electrical Resistivity at Low Temperatures*

Barium films produced at low substrate temperature have large residual resistivity. However, when the film is brought to higher temperature, the excess resistivity decreases irreversibly. The rate of decrease increases at high temperature, and after long annealing near room temperature, the resistivity attains the lowest equilibrium value. We name this process as "stabilization" following Harris and his co-workars⁶⁾. As will be proved later, this process is attributed to the disappearance of lattice imperfections, existing in the evaporated film. An example of this stabilization process is shown in Fig. 3, where the temperature is raised stepwisely. Up to above room temperature these treatment is continued and the resistance attains to its lowest value so far as the recrystallization does not occur. To analyse this process, both rates before and after the sudden change of temperature are obtained. The analysis will be given in 3.2.

Furthermore, the degree of such stabilization is affected by the residual pressure during evaporation P_d. The result is shown in Fig. 4, where we take the ratio of the resistance value immediately after the evaporation to that after the annealing at 20°C for an hour. The result is underestimating, since the temperature coefficient is not taken into account. However, it is clear that the increase in P_d makes the unstable imperfections in the film richer.

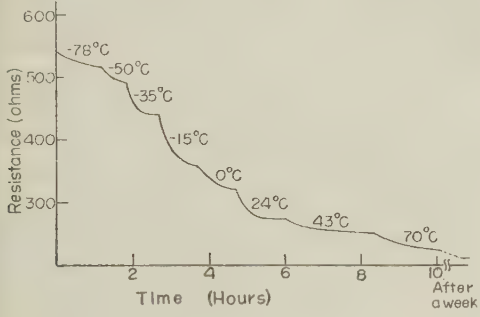

Fig. 3. Stabilization of a low-temperature evaporated film.

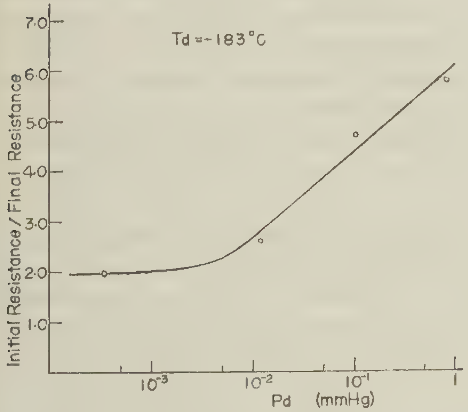

Fig. 4. Effect of residual gas pressure during evaporation on the stabilization of low-temperature evaporated film.

2.4. *Process of Recrystallization and Aggregation*

For the films already suffered the stabilization at or below room temperature, the resistance-temperature characteristics are completely reversible. However, when this film is heated to higher temperatures a new irreversible decrease of resistance regarded as recrystallization is observed above certain temperature. However, if the heat treatment is continued further, an irreversible increase regarded as oxidation or aggregation takes place. In Fig. 5 these tendencies are shown.

The recrystallization occurs in a narrow temperature range and has a different feature from the stabilization process. However, such a phenomenon is observed only in a few cases in total several tens of the experiments and at temperatures ranging from 100° to 300°C.

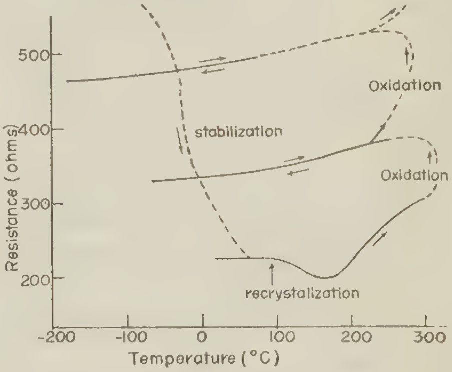

Fig. 5. Change of electrical resistance with aggregation (or oxidation) at high temperature.

The oxidation or the aggregation is observed between 100°C and the softening point of glass (~500°C), and we will call them as aggregation for convenience sake. The film, subjected to slight aggregation, keeps a metallic character in the plot of resistance vs temperature

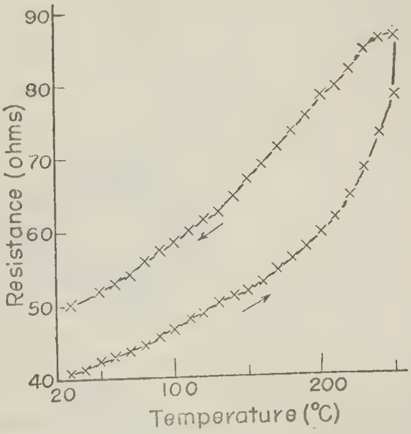

Fig. 6. Change of resistance with temperature.

as shown in Fig. 6 and the Mathiesens' rule still holds.

2.5. *State of Semi-Conducting Character*

As shown in Fig. 7, the aggregation (or oxidation) proceeds further until the film resistance becomes infinity, under the constant temperature. In such a case when the aggregation proceeds extensively and over some limits, the temperature dependency deviates from the metallic character to a stable semi-conducting one. When the film is further subjected to the aggregation at higher temperatures, another different semi-conducting character appears. The activation energies are shown in Fig. 8 and usually lie between 0.08 and 0.003 eV. The point of inflextion lies, if exists, around 150°C.

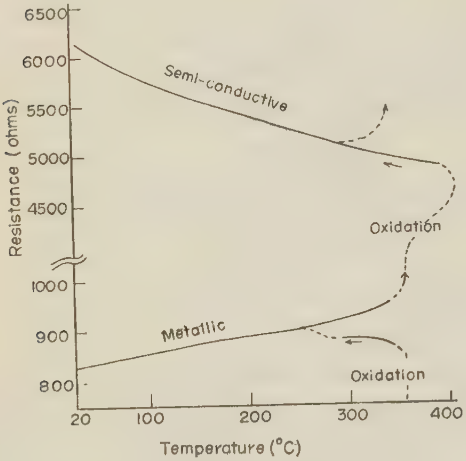

Fig. 7. Semi-conducting character of the film after extensive aggregation.

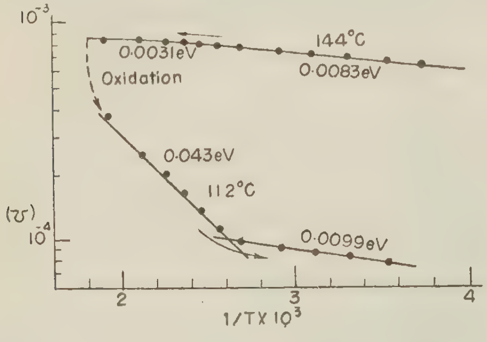

Fig. 8. Activation energy of semi-conducting film.

When the film is very thin, to say below 50 Å, the temperature dependency of resistance shows the similar semi-conducting properties, even evaporated at lower temperatures and without any heat treatment. This should be attributed not to the oxidation of film by residual oxygen but to the characteristics of the thin films, because the outgassing has been carried out extensively.

§ 3. Discussions

3.1. *Irreversible Decrease of the Low Temperature Evaporated Film*

In general, the factors contributing to the electrical resistance of the metal can be divided into;

1. temperature-independent component (residual resistivity), and
2. temperature-proportional component.

As mentioned above, the resistance of the evaporated barium film changes irreversibly by the heat-treatment at temperatures to which the film is not yet subjected. The nature of such a decrease in resistance is found to relate to the residual resistivity alone.

Furthermore, the temperature-independent component is, in our case, divided as follows;

1. electron scattering at grain boundaries and surfaces,
2. electron scattering at imperfect points in crystal lattice.

By the measurement of Hall coefficient it is roughly proved that the number of conduction electrons does not change so much as to explain such a large change of resistance.

In the evaporated metal films the irreversible decrease of resistance consists of two distinctly different processes. The first is the stabilization, which for barium with intermediate melting point according to the classification of Levinstein[13], occurs below room temperature. The second is the recrystallization, which is very similar to the sintering process of metallic powder. These two processes are not joined continuously, but are different in the temperature range and reaction rate. According to Wilkinson and Birks[8], in the temperature range of stabilization on gold film, there is a little change in X-ray diffraction pattern, but in the region of recrystallization at higher temperatures significant sharpening of the lines is observed. We may define here that the slow decrement process at lower temperatures is a recovering process in which imperfect lattice region tends to disappear and that the fast decreasing process at higher temperatures corresponds to the growth of the crystalline particles in the film. Since the latter process will require a higher activation energy, it is reasonable to appear at higher temperatures.

3.2. *Stabilization*

The kinetics of the stabilization for evaporated metal films have been already studied by Harris et al[6] with gold. They assumed that in all recovery region only one mechanism is prevailing, and that the imperfections can diffuse out to grain boundaries, where they disappear. However, refering to the recent data on the recovery of imperfections in metals, these assumptions is found to be incorrect. As the method of Vand[10] is also doubtful, another method of analysis following Overhauser[16] is employed. Let f be the density of imperfections in question, and Q an activation energy of recovery, then by the usual notations we can set

$$-\left(\frac{df}{dt}\right)_T = \text{const}\, e^{-Q/kT} \tag{1}$$

Let r_0 be the residual resistivity at the final equilibrium, then $r-r_0$ denotes the excess resistance due to the imperfection at any instant t. When T_1 and T_2 does not differ so much,

$$\log\left\{\frac{d(r-r_0)}{dt}\right\}_{T_1} \Big/ \left\{\frac{d(r-r_0)}{dt}\right\}_{T_2} = \frac{Q}{k}\left(\frac{1}{T_2}-\frac{1}{T_1}\right) \tag{2}$$

For convenience we take R as a resistance at any time and at any temperature,

$$\log\frac{\left(\frac{dR}{dt}\right)_{T_1}}{\left(\frac{dR}{dt}\right)_{T_2}} = \frac{Q}{k}\left(\frac{1}{T_2}-\frac{1}{T_1}\right) \tag{3}$$

Thus we can calculate the activation energies of recovery as a function of heat-treatment temperature irrespective of the recovery mechanism. In this case, it is assumed that in small temperature range from T_1 to T_2 the energy is nearly constant. The results are shown in Fig. 9, where, curves 1 with peak near 0°C correspond to the sample produced with high evaporating speed, and curves 2 without peak to the sample with low speed.

In the case of noble metals many reports are found on the recovery of residual resistivity induced by radiation damage or cold work[17],[18]. Comparing these results with the stabilization of evaporated metals[19],[20], it is supposed that nearly the same recovery mechanism is prevailing in both cases. If this is accepted, the energy corresponding to the flat portion of the curves in Fig. 9 can be attributed to the migration of interstitial atoms or lattice vacancies.

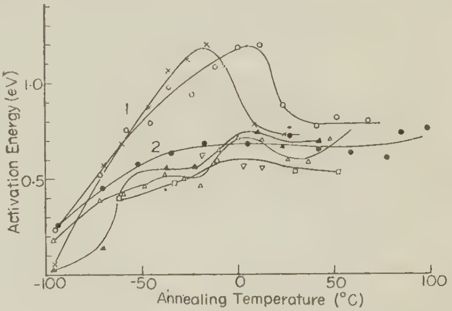

Fig. 9. Change of activation energy with heat treatment temperature. Curve 1; fastly evaporated films, curve 2; slowly evaporated films.

Following Overhauser[16] one can get theoretically

$$\frac{df}{dt} = -kf^m e^{\beta f} \tag{4}$$

where m is the true reaction order, and the last exponent a stress-induced extra term. This extra term makes the apparent reaction order larger. Plotting $\log\left\{\frac{d(r-r_0)}{dt}\right\}$ at any temperature against $\log(r-r_0)$ one can estimate the value of m. The values of m thus obtained are abnormally high, for instance 38.9 at −78°C, 17.9 at 20°C and 10.8 at 50°C, whereas with copper films[20] the values are 9.6 at −78°C, 4.0 at −8.5°C and 1.26 at 31.5°C. In the latter case, reaction order approaching unity indicates that this recovery is due to one agent, at least below room temperature. For barium, however, the reaction order is very high, indicating that this reaction is not an unique process, but readily affected by stresses induced by the deformation of lattice, probably because barium is softer than copper.

Furthermore, the fact that the activation energy is not constant shows that the diffusion process in barium is very complicated and different from noble metals. In f.c.c. metals vacancies are more readily created and more stable to diffusing out than interstitial atoms. In b.c.c. metals as barium, however, there are no large differences in mobilities between vacancies and interstitial atoms and hence combined processes may take place easily in a complicated manner. These facts afford facilities for discussing the recovery mechanism.

The possibility that imperfections other than point defects, to say dislocations or grain boundaries, play some roles in the stabilization, is almost negligible. In general, recovery of dislocations seems to occur at such high temperatures as recrystallization occurs. In addition, dislocations contribute very little to the resistivity than point defects[21] and are hardly possible to cause a large change of resistance ranging some hunderds per cents of the final equilibrium value.

3.3. *Recrystallization*

As shown in 2.4 the decrease of resistance due to the recrystalization takes place in the temperature range 100° to 300°C. On the other hand, non-transition metal of similar melting point, to say silver, has a recrystallization temperature of about 200°C, after cold-working. Empirical formula of Tamman[23], semi-empirical formula of Kramer[24], and theoretical formulas[25] give recrystallization temperature of metal as roughly 40 per cents of its melting point (absolute). The value estimated for barium is about 150°C and lies in the range of observed one. Electron-micrographs for other metal films show that the recrystallization makes the grain large.

However, such a recrystalization is not usually observed because of chemical reactivity of barium, that is, the minute oxidation products on the surface prevent the sintering of grain boundaries. Such influences of impurities or occluded gases on the recrystallization temperature after cold working is widely accepted. In other evaporated metals, for instance nickel films[26], the chemical reactivity is much lower, so recrystallization temperature has been easily observed. Furthermore, in a very thin film the aggregation of particles may also mask the contribution of recrystallization to the film resistance.

3.4. *Aggregation, Oxdation, and Semi-Conducting Property*

The resistivity-increasing tendency is defined here as the process of aggregation, or oxidation of the film. In this temperature range either the migration of metal atoms or a chemical reaction with the gas evolved from glass wall will take place. By any means, these processes increase the film resistance and when exceeding some limits, give semi-conducting character. In barium films, it is difficult to decide which mechanism is prevailing. However, in view of the experimental condition, it seems probable that the aggregation process is predominant, and only near the softening point of glass (~500°C) the oxidation by the gas evolved from glass wall becomes significant.

The activation energy of such a semi-conducting property is too small to be interpreted in terms of an energy-band model of normal oxide. Even in case of both a very thin barium film without suffering any oxidation and a film of noble metal[27),28], which have suffered appropriate heat treatment at and above room temperature, such a low activation energy also appears. By continual processing of aggregation the film resistance can reach any large value up to infinity without changing other properties appreciably, to say activation energy and visual appearance. All these facts indicate that the thin barium film has a granular structure composed of fine crystalline particles, and the contact between them becomes poorer with either aggregation or oxidation. The evidences for such a granular structure are also given by electron diffraction[29], electron micrograph[30] and by the gas sorption property described below. This semi-conducting property of metal film has been discussed theoretically by Mostovetch[31].

§ 4. Nitrogen Sorption at Low Temperature

4.1. *Experimental*

The vacuum apparatus comprised (i) a conventional pumping system, using Hickman pump and mechanical fore pump by means of which pressures below 10^{-6} mmHg were obtained, (ii) gas dosing systems and (iii) a sorption system containing a evaporation bulb and a Pirani gauge which was protected by a liquid oxygen trap and could be isolated by mercury cut-offs. Barium was evaporated from a commercial tube getter heated electrically. By changing the temperature of the glass wall during evaporation (T_d), and the residual gas pressure during evaporation (P_d) the structure of evaporated film was varied. T_d was provided with liquid oxygen, water bath and an electric furnace and P_d with the admission of argon previously purified by another barium getter. After extensive evacuation and glass baking, the trap was cooled with liquid oxygen and the evaporation source was outgassed carefully and then evaporation was carried out under prepared conditions. After immersing the bulb in liquid oxygen, under extensive evacuation, the sorption system was closed and pure nitrogen, prepared by thermal decomposition of BaN_6, was admitted and then the pressure change was followed. After the sorption experiment evaporated amount was determined mainly by the chemical analysis.

To examine the influence of the speed of evaporation, a new barium source appropriate for this purpose was designed. As shown in Fig. 10 metallic barium was loaded in a iron boat and covered with a protective film of nickel. The distance between evaporation source and the substrate was changed twofold, whereby the density of arriving atoms could be changed fourfold. Furthermore, the rate of evaporation was varied 100 times with the source temperature changed from 470° to 780°C.

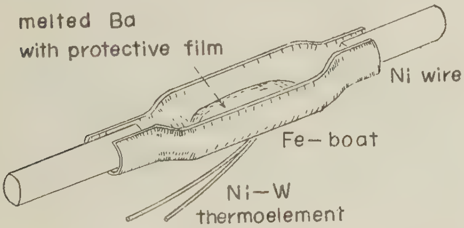

Fig. 10. Barium evaporation source convenient for controlling the rate of evaporation.

To investigate the influence of nitrogen adsorption on electrical resistance of the film, another type of bulb having two liquid platinum electrodes enamelled on the inner wall was used. Connecting this to the adsorption apparatus and after the same procedure as above, the electrical resistance of the film was recorded in the course of nitrogen adsorption. Gas pressure was measured by a McLeod gauge.

4.2. *Rate and Amount of Nitrogen Sorption at Low Temperature*

When the nitrogen is admitted to the film at liquid oxygen temperature, a very fast sorption is observed initially and then followed by a slow one, which reaches an equilibrium gradually after an hour or more. No more sorption takes place with added nitrogen. Some examples of the sorption for the films previously treated at different conditions are shown in Fig. 11.

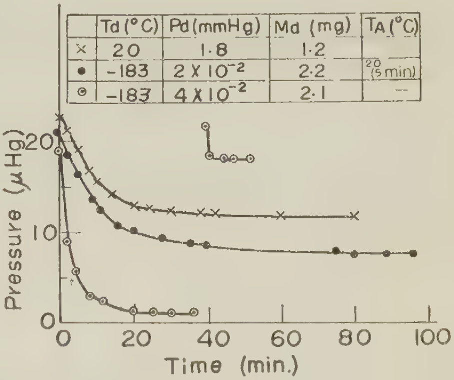

Fig. 11. Rate of nitrogen sorption at −183°C on films evaporated under various conditions.

The rate of sorption can be expressed by the following equation,

$$-\frac{dP}{dt}=kP(P-P_f) \qquad (5)$$

where P is a nitrogen pressure, P_f is a pressure after sufficiently long time. Integrating this equation, a linear relation between $\log(P-P_f)/P$ and t is obtained, thus making possible to calculate the rate constant k from the slope of the line kP_f.

The saturation amount of sorption S_1 is found to be almost independent of the equilibrium pressure and so we can take this amount

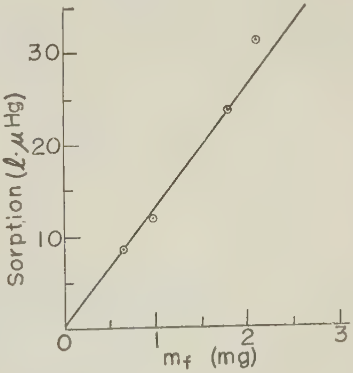

Fig. 12. Relation between deposited amount and sorption amount. Evaporation condition; $P_d=2.5\times10^{-2}$ mmHg, $T_d=-183$°C.

as a measure of the effective area of barium film. Following Beeck[32),33)], the low-temperature adsorption isotherm of nitrogen on evaporated metal films shows a long plateau in such a range of equilibrium pressure; hence the sorption amount in this range may be treated as a characteristic quantity of the film.

The relation between the amount of nitrogen sorption at low temperature and the weight of the film, which is evaporated at some fixed condition ($P_d=3.5\sim5\times10^{-2}$ mmHg, $T_d=-183$°C) is almost linear as shown in Fig. 12. In the following, therefore, we take the saturation amount of sorption divided by the film weight as a characteristic value intimately connected to the evaporation condition.

4.3. *Influence of the Residual Gas Pressure at Evaporation* (P_d)

The low temperature sorption of the film evaporated in various argon pressure is shown in Fig. 13. Vacuum-evaporated film shows rather poor sorption, whereas for the film produced in an atmosphere of inert gas S_1 increases markedly. The value for the film evaporated at $P_d=1.8$ mmHg is 9 times as large as that for the vacuum-evaporated film. The gas-evaporated film above 0.8 mmHg has a visual appearance of lamp-black.

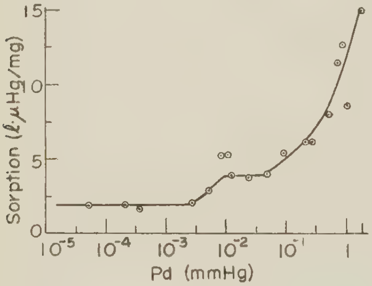

Fig. 13. Relation between the residual gas pressure at evaporation (P_d) and sorption amount. $T_d=20$°C.

4.4. *Influence of the Substrate Temperature* (T_d *and* T_a)

Setting P_d in the pressure range from 1×10^{-2} to 5×10^{-2}, nitrogen sorption is measured as a function of wall temperature during deposition. The result is shown in Fig. 14 by circle. Since the film evaporated at −183°C ($T_d=-183$°C) is very unstable, we examined the variation of sorption with stabilization. Fig. 15 shows the decrease of sorption with time when the film is kept in a bath of room temperature. Also crosses in Fig. 14 show the result when the film produced at $T_d=-183$°C was annealed at each desired temperature (T_a) for an hour in high vacuum prior to adsorption. The higher the temperature, the smaller becomes the distance between these two curves; this fact suggests that at high temperatures the stabilization becomes faster and almost accomplishes in an hour.

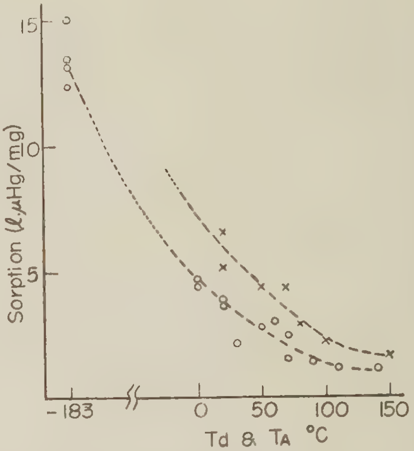

Fig. 14. Relation between the wall temperature at evaporation T_d and sorption amount (circles) and its change with annealing temperature T_A (crosses) at $P_d=1\sim5\times10^{-2}$ mmHg.

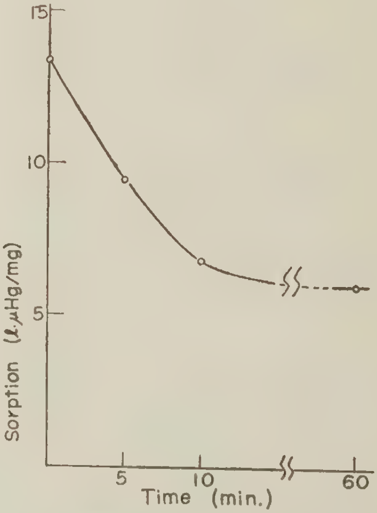

Fig. 15. Change of sorption amount for low-temperature evaporated film with stabilization at room temperature.

4.5. *Reversibility of Nitrogen Sorption*

Nitrogen sorption on barium film is not reversible. When the newly prepared film is saturated with nitrogen at −183°C (S_1) and then evacuated for an hour at that temperature, some fraction of sorbed gas can be desorbed only in the early stage. Admitting the gas again at the same temperature, the film takes up only a smaller amount (S_2) than that in the first. Although the first sorption cannot be repeated twice, the second sorption S_2 is completely reversible and can be tried many times. On the other hand, when the evacuation is carried out at room temperature (for an hour), larger desorption occurs and the capacity of low temperature sorption recovers partly. This third sorption S_3 can be also repeated. Always the relation $S_1 > S_3 > S_2$ holds. The rates of these three sorptions are shown in Fig. 16 and 17 where Eq. (5) can be fairly applied to the first and the third type of sorption, but the second type is generally too fast to be followed.

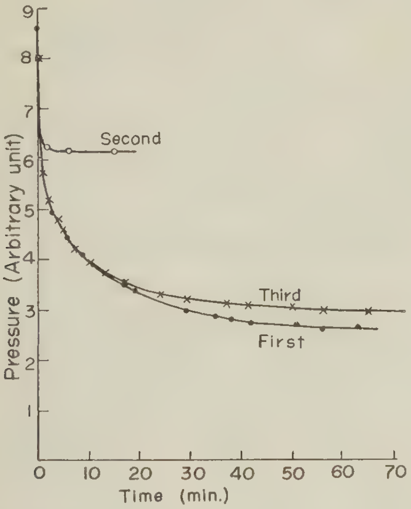

Fig. 16. Change of sorption rate after sorption-desorption cycles has been carried out.

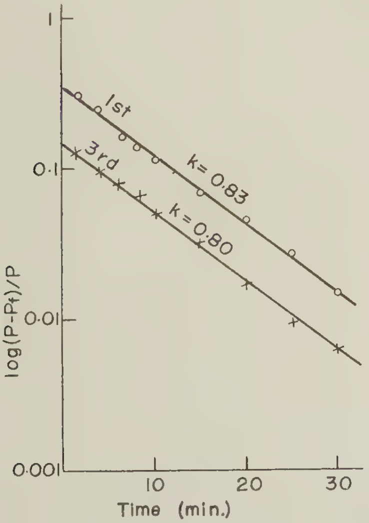

Fig. 17. Plots of Eq. (5) applied to first and third types of sorption.

Sorptions of the first and the second type measured for the film produced under various evaporation temperatures T_d are shown in Fig. 18. We see that the unstable large capacity of the low-temperature-evaporated film corresponds to the difference between the first and the second type, that is irreversible slow part of sorption.

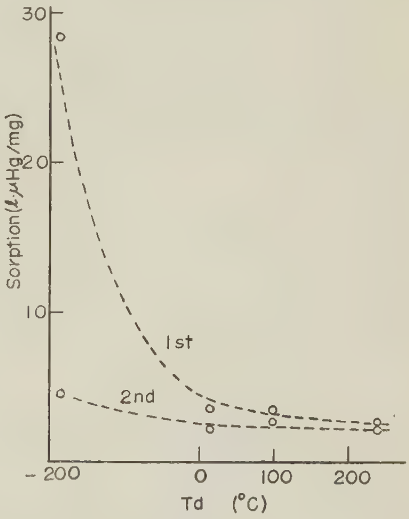

Fig. 18. Variation of first and second sorption with wall temperature T_d.

4.6. *Influence of Evaporation Rate*

The influences of evaporation rate and density of arriving atoms for the room-temperature-evaporated film are shown in Figs. 19 and 20, where solid marks correspond to the bulb with the evaporation source near to the substrate wall, blank marks to the bulb with the source further, triangles to the evaporation condition of $P_e = 0.1 \sim 0.13$ mmHg, and circles to the condition of high-vacuum evaporation. In this temperature range the evaporation changes 100-folds according to the data for vapor pressure of barium. While the temperature of evaporation source, i.e., the rate of evaporation has no effect on the sorption for the vacuum-evaporated film, there is a conceivable influence on the gas-evaporated film. In addition, these figures show that the density of depositing atoms has no influence on both films.

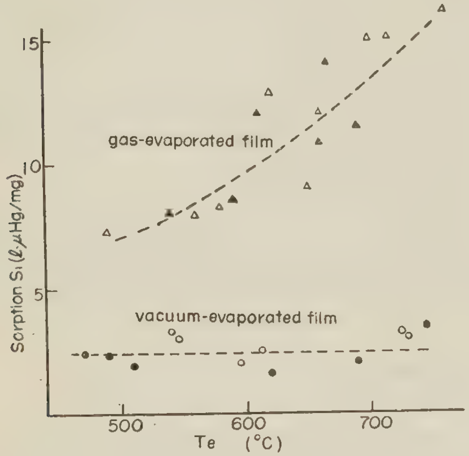

Fig. 19. Effect of evaporation rate on the first sorption amount.

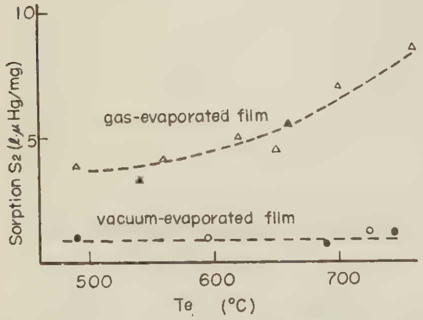

Fig. 20. Effect of evaporation rate on the second sorption amount.

4.7. *Nitrogen Sorption and Electrical Resistance of Film*

To know how nitrogen sorption affects on the electrical resistance of the film, simultaneous measurements of the two quantities were attempted. In Fig. 21 is shown the behavior of both nitrogen pressure and resistance for low-temperature high-vacuum-evaporated film, which has not been stabilized. Firstly, sorption were carried out at −183°C, and secondly stabilization applied and then the gas was admitted. Fig. 22 shows the behavior when the gas was admitted to a film previously stabilized at room temperature. From these curves one can see the following features:

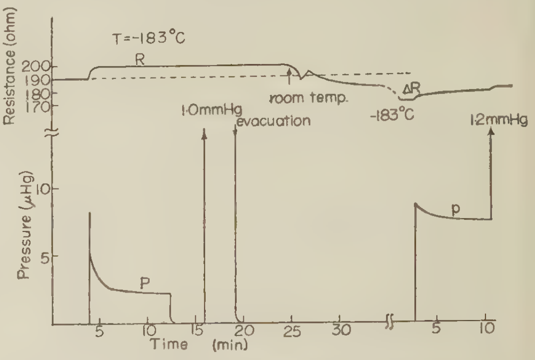

Fig. 21. Change of electrical resistance of film with nitrogen sorption at −183°C. The film has not been stabilized.

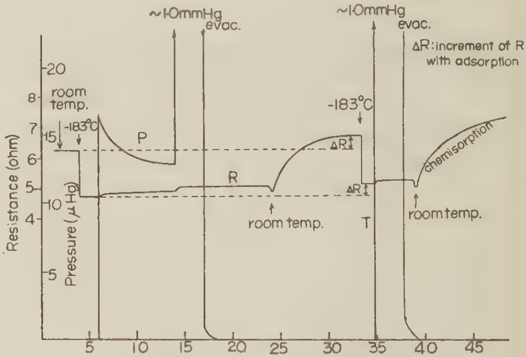

Fig. 22. Change of electrical resistance of film with nitrogen sorption. The film has been stabilized prior to sorption at room temperature.

1. Nitrogen sorption results in the increase of resistance which does not recover with desorption at low temperature.
2. The rate of sorption and the rate of resulting resistance-increase fall with the degree of stabilization and increase with nitrogen pressure.
3. Nitrogen, once sorbed at low temperature, prevents the stabilization significantly even in high vacuum. Therefore, nitrogen should be regarded as being occluded in the film.
4. Room-temperature evacuation partly recovers the sorption-induced resistivity, in quite a parallel manner with the behavior of sorption already mentioned in 4.5.
5. When the film, which has been already

saturated with nitrogen at low temperature, is brought up to room temperature, an instantaneous desorption and subsequent re-sorption take place with remarkable increase in resistivity. This fact suggests that the room-temperature sorption is of different nature from the low-temperature sorption.

5. Discussions

5.1. *Effects of Various Evaporation Conditions on the Gas Sorption Capacity*

Among many factors which may prescribe he film structure, the following is considered n this paper:

1. Rate of film growth (Density of arriving atoms),
2. Rate of evaporation (Temperature of the evaporation source),
3. Temperature of glass wall during evaporation T_d and annealing temperature T_a.
4. Residual gas pressure during evaporation P_d.

As described in 4.6 the first and second factors re almost insensitive to the low-temperature itrogen sorption in our experimental condiions, and so no comments are made hereafter.

The large sorption surface of low-temperaure-evaporated film is very unstable at high emperature and decreases with time. In the neasurement of electrical resistance the same henomenon has been already observed, and his similarity was also confirmed with nickel ilms[26], leading to the conclusion that the ame mechanism can be applied both for the ecay of adsorption capacity and stabilization f the film. Therefore, it may be possible to onsider that the unstable part of sorption is ue to crystal imperfections. If so, this is due ot to dislocations as discussed previously, ut to lattice vacancies (or their combinations), which can absorb nitrogen molecules. The ower the substrate temperature T_d, the more mperfect the deposited crystal structure beomes. The imperfections thus produced can nduce excess resistivity and absorb molecules. f the vacancies trap nitrogen molecules, the ubsequent stabilization may be hindered narkedly because of the reduced number of ree vacancies.

On the other hand, the large sorption capaty of the gas-evaporated film seems to be aused by another mechanism. Since this film is very stable even at room temperature, it is unreasonable to attribute this large capacity to lattice imperfections mentioned above and so other interpretation is made in the next.

5.2. *Structure of Gas-evaporated Film*

As reported by many investigators[2],[3],[27], evaporation in an atmosphere of inert gas makes so-called metal black. The origin of this black may be mainly due to the loss of kinetic energy of barium atoms by the collisions with gas molecules during flight. Following the calculation of Tsukagoshi[34], even in such a low pressure as 0.1 mmHg thermal energy of an evaporating atom is lowered to that of gas molecules by collisions of 100 times or more. However, the experimental results show that the black is formed only above 0.8 mmHg of inert gas, and that the film produced at 0.1 mmHg has already large capacity, whereas its appearance does not differ so markedly from that of vacuum-evaporated film. Furthermore, as shown in Fig. 19, when the kinetic energy of evaporating atoms is decreased by lowering the temperature of evaporation source, the sorption becomes rather smaller in contrast to the above implication. Therefore, the effect of the residual gas is not considered simply as to carry off the kinetic energy of barium atom.

On evaporating gold in an argon atmosphere of high pressure (~10 mmHg), one can observe a cloud of particles originating near the source and diffusing around away. Perhaps this may occur also in the case of barium. Near the evaporation source, evaporated atoms suffer sufficient collisions with argon atoms to prevent the tight binding of metal atoms and form aggregates, which diffuse onto the wall. Then the aggregates should stabilize corresponding to the temperature of the substrate or the gas. By means of electron microscope the metal black is revealed as large particles of irregular shape piled up randomly, and by electron diffraction, each particle is proved to be a fairly large crystalline and not amorphous as is easily imagined from its visual appearance. The average size of unit particle does not differ markedly both in gas- and vacuum-evaporated films. But the definite difference is found in the state of accumulation; in case of vacuum-evaporated film each particle has not always free surface and connected with each other, and in case of metal black each particle is isolated and has large free surfaces. This situation may explain the large and stable sorption capacity of the black.

5.3. *The Nature of Nitrogen Sorption at Low Temperature*

It has been generally considered that at −183°C nitrogen molecule adsorbs on a solid surface by the van der Waals forces, and this character has been used to the measurement of surface area of solid. However, nitrogen sorption on barium film cannot be regarded as simply physical adsorption due to van der Waals forces because of its slowness and irreversibility in the first sorption. However, the second sorption is instantaneous and completely reversible with rather smaller amount. The difference between the first and second sorption indicates the irreversible part at low temperature. The third sorption which occurs after evacuation at room temperature suggests that the heat of sorption for this irreversible part is not so large as for usual chemisorption. The capillary condensation is not responsible for this irreversibility, for it occurs at rather higher pressure and does not remain after evacuation in high vacuum.

Arizumi and Kotani[35] studied the sorption of carbon monoxide on barium film, and found that below −70°C the sorption was of physical nature and the gas partly diffused into crystal with slow rate. Their theoretical expression for the rate of sorption is

$$-\frac{dP}{dt}=-K_AP\left\{N_0-\frac{NV}{RT}(P_0-P)\right\}$$
$$-K_SP\left(K_AN_0t+\log\frac{P}{P_1}\right) \qquad (6)$$

where K_A, K_S, N_0, P_1 and P_0 are constants. The last term expresses absorption into interior. By a suitable abbreviation, Eq. (6) can be reduced to our empirical formula (5). This formula defines at first the fast sorption on the surface and then the succeeding slow absorption. The fact that this slow stage is not found at −183°C on many metal films other than barium[36),37)] may be due to the exceptionally large interatomic distance of barium, rather larger than the size of nitrogen molecule (∼4.0 A); owing to this special feature of barium the slow absorption into the crystallite may be very easy. According to our estimation given in the Appendix of this paper, the van der Waals heat of trapping at lattice deficiency is so large as not expected in an usual physical adsorption. This may be a reason why the irreversible sorption of nitrogen occurs on barium film at temperature. From this idea, it can be concluded that the irreversible part of sorption represents the absorption into lattice imperfections and results in the increment of electrical resistivity, but the reversible one represents the pure physical adsorption on the surface with almost no influence on electrical resistivity. However, in view of the feature of the adsorption of argon at −183°C and 10^{-2} mmHg, which takes place almost instantaneously with very small amount, it may be necessary to consider that this irreversible nitrogen sorption is, at least partly, of chemical nature, which is concluded by previous authors[36),37),38)] for other metals.

5.4. *Quantitative Study of Imperfection*

Up to date the quantitative measurement of lattice imperfection in metal is very scare. Hence we attempt here some discussions on the number of imperfections in evaporated barium film. If we assume that each nitrogen molecule occupys each barium vacancy, then for a film evaporated at −183°C there exist 2.5×10^{21} vacancies/cm^3, and for a film evaporated at room temperature, about a tenth of that. While these values for vacancy density seems too high, such a large value has been proposed in case of Kirkendahl diffusion[39)]. Especially, when evaporated at low temperature, the barium film has a large stress in it and therefore it may be rather probable to consider that nitrogen molecules enter not only into lattice vacancies but into strained interstitial positions, combined pairs of imperfections and others, so as to give apparently such a large value for lattice vacancy.

The measurement of specific resistivity due to imperfections could not be exactly consecuted, but under the assumption of the same contribution from vacancy and interstitial atom, the resistivity of the vacancy is roughly estimated as 0.3 Ωcm/per cent vacancies. This is qualitatively in agreement but slightly smaller than the one theoretically estimated for copper[40)]. If imperfections other than lattice vacancies are taken into account, the agreement will become fair. Because the presence of such a large number of imperfecions will cause a large stress in the low-temerature-evaporated film, effects of stress hould be considered in a kinetics of recovery s described in 3.2.

6. Conclusion

1. Evaporated barium film exhibits a character of granular structure in gas sorption and electrical resistivity.

2. When evaporated at low substrate temperature, the crystal structure becomes imperfect and this induces excess nitrogen sorption as well as excess resistivity.

3. At and below room temperature marked decreases of electrical resistivity and of low-temperature sorption of nitrogen take place with the recovery of imperfection.

4. Semi-conductive characteristics at high temperature is probably caused by aggregation or oxidation.

5. Gas-evaporated film has a large sorption area due to the special construction of the film.

The authors wish to express their sincere thanks to Mr. T. Ichimiya for his earnest guidance and discussions.

§ 7. Appendex

Energy of van der Waals adsorption at vacancy.

Suppose a simple situation, in which a nitrogen molecule occupies a vacant lattice point substitutionally in an infinite metallic lattice at 0°K. The centre of the nitrogen molecule is taken as an origin of polar coordinate. Smaller terms can be neglected such as zero point energy, change of distribution energy of electron after absorption, and that of thermal energy of lattice. We take into account three terms, that is, van der Waals attraction between the nitrogen molecule and the metal, repulsion between the molecule and the nearest-neighboring metal atoms, and the stress in the outside medium caused by the relaxation of metal atoms.

Van der Waals energy has been calculated by, for example, Margenau et al.[41] and Bardeen[42]. Their calculations assume the adsorption on a flat surface and therefore their integrals must be modified to spherically symmetrical way. The calculation is simple and the result shows that each term is increased 6 or 8 times larger than in their original equations. As a definition of metallic surface, one must take the relaxation of atoms into account.

For a repulsive term, we apply r^{-m} potential and its coefficient is calculated analytically by an usual method from compressibilities. For simplicity m is taken as 12, an average exponent for N_2, Ba and Ni. Following Hirschfelder[43] the coefficient can be taken as a geometrical mean of both metal and liquid nitrogen. For nitrogen molecule Kihara's potential[44] with rigid core is used. Total repulsive potential is calculated against the number of repulsion between nitrogen and nearest-neigboring atoms.

Thirdly, in the medium outside the nearest-neighboring atoms, a stress is caused by the relaxation of them. This potential is calculated with a model of continuous medium of spherical symmetry, and can be expressed simply by $\frac{12\pi r_0}{\beta}(r-r_0)^2$, where β is a compressibility, r_0 is an original interatomic distance of the nearest-neighbors. Thus the total potential is given by

$$-A(r-r_M)^{-3}+\sqrt{B_1B_2}(r-0.47)^{-12}+C(r-r_0)^2$$

The result of numerical calculations for barium is shown in Fig. 23, where energy minimum exists below zero, showing the possibility of van der Waals adsorption in a lattice vacancy. In this case the trapping energy is high because of loosely packed structure and large interatomic distance of barium, which insure less error of calculation than for other metals. With a rough approximation for the compression of electron cloud in nitrogen molecule, the same calculation is carried out for nickel,

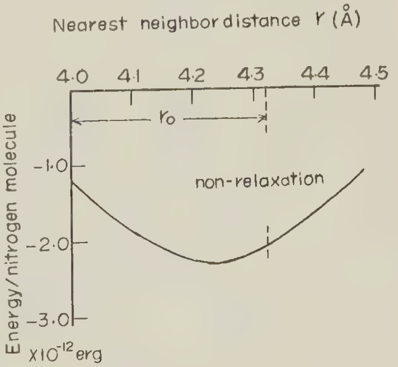

Fig. 23. Potential energy diagram for a nitrogen molecule trapped in a vacant lattice point of barium.

which gives the value of 11 Kcal/mole, which is consistent with the calorimetric heat of adsorption by Beeck[34], 10 Kcal/mole.

In general, the heat of adsorption larger than 20 Kcal/mole is said to prevent the desorption of adsorbed gas at room temperature. In the cases of nickel and barium which exhibit the complete and imcomplete desorption of nitrogen respectively, the calculations are in good accordance with the experimental situations by sorption and electrical resistance measurements.

Studies of High Polymers by Radioactive Method (II) Self-diffusion of Polystyrene in Its Dilute Solution

By Shintaro SUGAI and Jiro FURUICHI
Physics Department, Faculty of Science, Hokkaido University

(Received October 22, 1956)

Self-diffusion of high polymer in dilute solution was studied by use of C^{14}-labelled polystyrene. Especially the dependence of the self-diffusion coefficient of polystyrene upon its molecular weight was determined. Then, from the results, the molecular extension, the shielding ratio, and other molecular quantities of polystyrene molecule in the dilute solution were calculated by use of the diffusion theory of Debye and Bueche, and compared with the data obtained by other methods.

§ 1. Introduction

The molecular extension of the polymer in its dilute solution is one of the most important molecular quantities of the polymer solution. Therefore, many workers have recently attempted to study the molecular extension in the polymer solution from various measurements, mainly from viscometric and optical ones$^{1)}$. However, self-diffusion studies in dilute solutions seem to be, also, a very suitable method for the discussion of molecular extension and molecular form, because the most natural form of the polymer molecule in the solution can be investigated only by means of this method.

In the case of viscometric measurement, the molecular form is distorted by the shear stress. Similarly, in the case of optical measurement, the electronic excitation of the molecule is given by the light, and then variations of natural form and extension of the molecule seem, also, to be possible results.

On the other hand, self-diffusion of the molecule is caused only by its thermal motion, therefore self-diffusion studies are probably the most suitable method to use in making research on the molecular natures.

However, unfortunately, this appropriate method has never been employed, except in a few cases$^{2)}$. This is probably because the process of manufacturing the radioactive polymer was usually very difficult.

In the present studies, the self-diffusion of polystyrene in its dilute solution has been measured using C^{14}-labelled polystyrene made in England for the purpose of preparing the standard β-ray source, and then the natural extension and other molecular quantities of polystyrene molecule in its dilute solution have been calculated by use of the sphere model of chain polymer.

§ 2. Experimental Procedures

C^{14}-labelled polystyrene made in England was, firstly, fractionated by the ordinary method. Unfortunately, the specific radioactivity of the sample in the present case was considerably small, so carriers could not be added to it, and also sharp fractionation of itself could not be employed.

The average molecular weights of the fractionated radioactive polystyrene have been determined from the intrinsic viscosity measurements in their dilute benzene solutions$^{3)}$.

Then the fractionated radioactive polymer in its benzene solution, whose concentration is 1 gr/lit., was diffused into the same nonactive fractionated solution.

Nonactive polystyrene was fractionated by the same method as is used in the case of the fractionation of a radioactive one.

However these two samples were not of the same molecular weight distributions, and moreover the specific radioactivity of the present radioactive sample was very small as noted above, therefore it was very difficult to obtain the nonactive polystyrene fraction having the same average molecular weight and the same molecular weight distribution as the radioactive one.

In the present case, by fractionating the nonactive sample very sharp, approximately the same average molecular weight fraction as the radioactive one was obtained, although the molecular weight distributions of the two samples were probably different.

A diffusion cell of sintered glass type was employed[4]. The average diameter of the sintered glass hole was 0.05 cm. The upper limit of the molecular extensions of polystyrene used in the present case seems to be approximately 1500 A, then the polystyrene molecule is considered to diffuse freely through these holes.

The schematic diagram of cell is shown in Fig. 1.

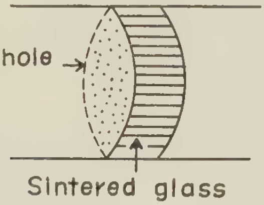

Fig. 1. Schematic diagram of the diffusion cell.

If, at the beginning of the experiments, radioactive solution is put into the left side compartment of the cell, and nonactive one is put into the right side compartment, then the self-diffusion coefficient D of the polystyrene molecule can be calculated by measuring the radioactive concentration of the two compartments after diffusion for the given duration of the time t:[5]

$$\log\{(C_l^t - C_r^t)/C_l^0\} = -KDt(1/V_l + 1/V_r) \quad (1)$$

where C_l^t and C_r^t are respectively the radioactive concentration of the left and right compartments at time t and C_l^0 is the initial radioactive concentration of the left compartment.

Furthermore, K is a cell constant and, previous to the experiments, should be determined using standard substances.

In the present case, K was determined from the diffusion of the aqueous solution of potassium chloride.

V_l and V_r are respectively the volume of the left and right compartments of the cell.

The values of diffusion coefficient D determined by such a method, however, did not exactly coincide one with another as the duration of time t of the diffusion varies, therefore the average value of D at various times had to be calculated.

The radioactivity of the solution was measured by the same method as was previously described[6].

§ 3. Experimental Results and Discussion

The experimental results of the self-diffusion of polystyrene in the dilute benzene solution at 30°C are indicated in Table I, in which the viscosity and the intrinsic viscosity of the solution are included.

Table I. Self-diffusion coefficient of polystyrene in its dilute benzene solution at 30°C.

Mol. Weight M	Concentration of Solution	Viscosity η	Intrinsic Viscosity	D
10^5	gr/lit.	10^{-3}poise		10^{-7} cm^2/sec
1.1	1.0	6.08	55	4.0
2.5	〃	6.36	100	2.4
8.0	〃	6.72	212	1.2
10.5	〃	6.82	255	1.0
	0(solvent)	5.95		

Viscosity of the solution was measured by Ostwald type viscometer, at the same temperature, under a small shear stress.

However extrapolation of the shear stress to zero was not employed.

Generally speaking, diffusion coefficient D of the molecule in the dilute solution can be expressed in the term of the frictional constant F of a polymer molecule as follows:

$$D = kT/F \quad (2)$$

where k and T have a well known meaning.

Of course, the viscosity of the solution η is related, also, to the frictional constant F. Therefore an important relation is judged to exist between the self-diffusion coefficient of the polymer molecule in the solution and the viscosity of the same solution.

R. L. Saxton and H. G. Drickamer have indicated such a relation in the case of polymeric liquid sulfer[7].

P. Debye and F. Bueche have checked similar circumstances even in the cases of some solid polymers[8], and pointed out the following empirical relation:

$$D\eta_b/\rho = \text{constant} \quad (3)$$

where η_b is the bulk viscosity of the solid polymer and ρ is its density.

If Debye's free draining model is used, diffusion coefficient D of the polymer molecule in the dilute solution is simply expressed in terms of the intrinsic viscosity of the solution and the molecular extension:

$$D[\eta]/\rho\cdot M/\langle r^2\rangle_{av}=\text{constant} \qquad (4)$$

'here $[\eta]$ is the intrinsic viscosity of the solu- on, M is the molecular weight of the poly- ıer, and $\langle r^2\rangle_{av}^{1/2}$ is the root mean square nd to end distance of the polymer molecule, ıat is, the molecular extension.

As for a solid polymer, the diffusion theory eems to be able to be developed by the same rgument as that in the case of the dilute olution.

F. Bueche has employed such procedure⁹⁾, nd obtained Eq. (3) by accepting the idea hat the relation $\langle r^2\rangle_{av}/M$ is nearly constant ı a solid polymer¹⁰⁾.

In the present case, $D[\eta]/\rho$ is not exactly onstant, as shown in Fig. 2.

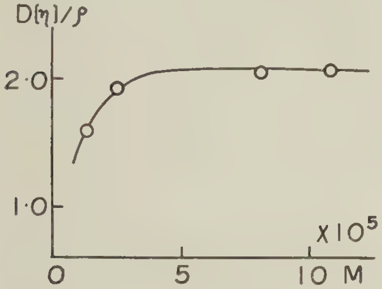

Fig. 2. Values of $D[\eta]/\rho$ at the various molecular weights. (Unit of $D[\eta]/\rho$ is arbitrary.)

Then, the polystyrene molecule cannot be considered to behave as a free draining randomly coiled chain polymer in the dilute benzene solution.

To analyse the molecular extension of polystyrene in the solution from the present results, therefore, the more generalized polymer models have to be employed.

By the way, many authors have previously attempted to develop the theory of high polymer solution¹¹⁾. In the present case, the sphere model devised by P. Debye and A. M. Bueche was used.

This was done because their theory is not essentially different from the other typical theories of polymer solution, and a more generalized application is possible.

P. Debye and A. M. Bueche have derived a theoretical relation between D and molecular weight M valid over a limited range M¹²⁾:

$$\left.\begin{array}{l} D=AM^{-\varepsilon}\\ \varepsilon=1/2+1/4\cdot\sigma/\psi\cdot d\psi/d\sigma \end{array}\right\} \qquad (5)$$

and also a relation between D and the viscosity of the solvent η_0:

$$D=kT/6\pi R_s\eta_0\psi(\sigma) \qquad (6)$$

where σ is shielding ratio, $\psi(\sigma)$ is a certain function of σ, and R_s is the radius of polymer sphere.

Applying Eq. (5), the average values of ε and σ of the present case can be determined from the dependence of $\log D$ upon $\log M$ as shown in Fig. 3.

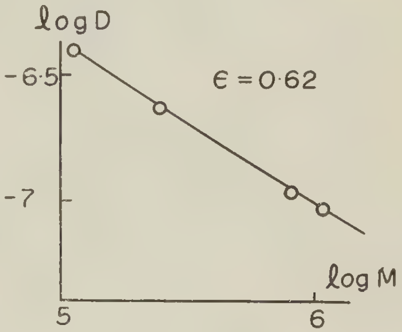

Fig. 3. Dependence of $\log D$ upon $\log M$.

Then if such a value of σ and the viscosity of the solvent are used, R_s can be calculated.

The results are presented in Table II, in which molecular extension $\langle r^2\rangle_{av}^{1/2}$ of polystyrene is determined from R_s, using the well relation of randomly coiled chain polymer as known follows:

$$R_s=(1/6\langle r^2\rangle_{av})^{1/2} \qquad (7)$$

However, it should be noted that the above value of σ is an average one, and also, generally σ must depend upon M.

Moreover, Eqs. (5) and (7) are based on the randomly coiled chain polymer, therefore in molecular extension in Table II the volume exclusion effect of chain elements of the molecule and the effect of interaction between

Table II. Molecular extension and average shielding ratio of polystyrene in benzene solution calculated from Eqs. (5) and (7).

Mol. Weight M	Shielding Ratio σ	ε	$\langle r^2\rangle_{av}^{1/2}$
10^5			A
1.1	3.2	0.62	364
2.5	〃	〃	627
8.0	〃	〃	1378
10.5	〃	〃	1647

the chain elements and the solvent molecules are not taken into consideration.

In order to investigate such circumstances, in the present case, the theory of intrinsic viscosity of Debye and Bueche has been combined with their diffusion theory.

According to Debye and Bueche's model, the intrinsic viscosity of the polymer solution is given by

$$[\eta]=CR_s{}^3\phi(\sigma)/M \qquad (8)$$

where $\phi(\sigma)$ is also a certain function of σ.

From Eqs. (6) and (8), in which the assumption of randomly coiled chain polymer is not used, one has

$$(D\eta_0)^3=C'\phi(\sigma)/\{\psi(\sigma)\}^3\cdot(kT)^3/M[\eta]^3 \qquad (9)$$

where C' is a numerical constant.

Therefore, from measurements of D, η_0 and $[\eta]$ of the solution, and from Eq. (9), the value of $\phi(\sigma)/\{\psi(\sigma)\}^3$ is calculated as a function of M.

The values of $\phi(\sigma)/\{\psi(\sigma)\}^3$ as a function of σ are listed in Table III.

Table III. Values of $\phi(\sigma)/\{\psi(\sigma)\}^3$.

σ	$\phi(\sigma)$	$\psi(\sigma)$	$\{\psi(\sigma)\}^3$	$\phi(\sigma)/\{\psi(\sigma)\}^3$
1	0.0947	0.176	0.00545	173.7
2	0.327	0.432	0.08062	4.056
3	0.600	0.600	0.2160	2.777
4	0.857	0.701	0.3447	2.487
5	1.07	0.770	0.4565	2.343
8	1.52	0.858	0.6316	2.406
10	1.70	0.890	0.7049	2.411
∞	2.50	1.000	1.000	2.500

In Table IV are shown the molecular radius R_s and the shielding ratio σ determined from Eqs. (9) and (6).

However, in this case, the molecular extension cannot easily be obtained from the value of the radius of polymer sphere by Eq. (7).

On the other hand, recently, many authors made theoretical studies on the relation between R_s and other molecular quantities considering the volume exclusion effect and so on[13].

For example, B. H. Zimm et al have proposed the following equation[14]:

$$R_s{}^2=R_0{}^2+0.0572A_2M^2/N_0R_0+\cdots \qquad (10)$$

where R_0 is the molecular extension of randomly coiled chain polymer, A_2 is the second virial coefficient, N_0 is Avogadro number and M is the molecular weight of the polymer.

However, it could be easily examined that the second and higher terms are considerably smaller than the first main term $R_0{}^2$ of the right side of Eq. (10) by using the value of A_2 for polystyrene-benzene pair[15], then the molecular extension can be considered to be connected, at the first approximation, with the polymer radius R_s by Eq. (7) even in the present case.

In Table V, the molecular extension calculated from the radius R_s in Table IV, by using Eq. (7), is shown.

Table IV. The radius of the polystyrene sphere R_s and the shielding ratio σ in the benzene solution determined from Eqs. (9) and (6).

Mol. Weight M	$\phi(\sigma)/\{\psi(\sigma)\}^3$	σ	R_s
10^5			A
1.1	2.71	3.2	146
2.5	2.65	3.5	233

* This value was calculated by the assumption $\sigma=0$.

The value of $\langle r^2\rangle_{av}^{1/2}$ in Table V is perhaps more exact than that in Table II.

Finally, the data obtained by other methods, for instance viscometric and optical ones, are shown in Table VI to be compared with the present results.

§ 4. Conclusion and Acknowledgements

Self-diffusion of polystyrene in the dilute benzene solution was measured by the radioactive method.

Self-diffusion coefficient depends approximately upon the molecular weight of the polystyrene so that the free draining randomly coiled chain approximation is not simply satisfied.

Therefore, using the general sphere model of the polymer molecule introduced by P. Debye and A. M. Bueche, the molecular extension and the shielding ratio are calculated as a function of the molecular weight of polystyrene from the present experimental results, and they are compared with other authors' data.

The present authors are exceedingly grateful for the discussion by other members belonging to the Research Institute of High Polymer Physics in Hokkaido University and also for a grant of financial aid from the Ministry of Education of the Japanese Goverment.

An Investigation of the Dynamic Mechanical Properties of Glassy Polymers by the Composite Oscillator Method

By Keiji YAMAMOTO and Yasaku WADA

Department of Applied Physics, Faculty of Engineering, Tokyo University, Tokyo

(Received December 18, 1956)

The dynamic Young's modulus and loss factor are determined by the composite oscillator method for several glassy polymers: phenol resin, polymethyl methacrylate, polystyrene, nylon 6 and polyester, in the temperature from −70° to +90°C at frequencies 50, 100 and 200 kc/s. The loss factor curve of polymethyl methacrylate shows an anomaly at ca. −20°C which is concluded to be due to the γ-transition, the activation energy being estimated as 7 kcal/mole. The moisture dependence of this transition is also shown and the molecular process involved is hypothetically proposed. For polyethylene a peak of loss factor is observed at 10°C. A procedure to eliminate the false attenuation peaks observed in applying the composite oscillator method to high polymers is described.

§ 1. Introduction

In studies of viscoelastic properties of polymeric materials, it is advisable to measure the dynamic modulus and loss factor over a wide range of temperature. At frequencies of the order of one hundred kilo-cycles the composite oscillator method[1] has a special advantage for this purpose, since the specimen used can be designed in a very small size and consequently the temperature of the specimen can easily be conditioned.

Though a few authors[2-4] have attempted to apply his method to high polymer research, no extensive results along this line have so far been available. In the present paper the data obtained by this method in our laboratory will be given for several polymers, together with possible interpretations on the molecular process of the observed viscoelastic behaviors.

§ 2. Experimental

The apparatus employed has been described previously[5]. Essentially, it consists of a device for applying voltage of variable frequency to a composite oscillator system and for observing the frequency dependence of the resultant current. A composite oscillator system is made by cementing a specimen rod of 3 mm square cross section to an X-cut quartz transducer of identical cross section by the use of Araldite cement and is set into longitudinal vibration, the nodal point of the quartz being supported. The dynamic Young's modulus and the associated loss factor of the specimen can be deduced from analysis of the current-frequency relation.

The composite oscillator technique has succefully been applied to a dynamical test of low loss materials, e.g., metals and inorganic glasses. In applying this method to high polymers, however, one has to take some additional cautions as in what follows.

In carrying out this method, the length of a specimen should be adjusted so as to make the resonant frequencies of the quartz(f_q) and the specimen (f_s) lie within about ten percent. Otherwise, the damping of the whole oscillator system would become abnormally large, thus causing an experimental error. In case of high polymers which often have a strong temperature dependence of elastic modulus, f_s for the specimen of a given length varies fairly rapidly with temperature and hence the discrepancy between f_q and f_s is apt to increase above the limit in both upper and lower sides of the experimental temperature. In the measurement over a wide temperature range, therefore, it is required to use specimens of different length, each of which being adapted for each temperature subdivision.

A further source of experimental errors takes place when f_s closely approaches to f_q. In this case a spurious increase of loss factor is generally observed, probably owing to the following reason: Since, in this case, the quartz/polymer interface nearly coincides with an antinodal plane, the appreciable difference in acoustic impedance between them will give rise to such an anomaly. This "spurious" peak of loss factor shifts along temperature axis if the specimen is slightly varied in length and thus can readily be distinguished from a "true" peak associated with material properties.

In the previous paper[5)], a peak of loss factor was reported at 30°C for phenol resin. This peak, however, was found to correspond to the above-mentioned spurious one. The corrected, new data obtained for this polymer will be given in detail in the next section.

In the composite oscillator method the length of the specimen should be large enough in comparison with its cross-sectional dimension. Since the sound velocity is of the order of 2×10^3 m/s for glassy polymers, a half wavelength is estimated as *ca.* 1 cm at 100 kc/s. In most of the present experiments, specimens in length of three half waves are used. For high loss polymers such as polyethylene, however, a specimen of one half wave length is used in order to avoid experimental difficulties, because, otherwise, the damping of the composite oscillator would be so large that the resonance might hardly be observed. In this case calculated values of both modulus and loss factor are thought to have some errors. No correction, however, is made to them, since the only effect of the correction is to change the results by a small factor, the over-all behavior remaining the same, while the temperature dependence of the properties is of particular interest in this research.

The composite bar with its holder is placed in a test tube which is immersed in a Dewer vessel containing a liquid—water above 0°C and alcohol-dry ice mixture below. The temperature in the test tube is measured by means of a mercury or pentane thermometer. Measurements are made after a steady state has been reached at each temperature.

All the specimens used are pure commercial products, including neither plasticizer nor filler and are annealed at 100°C for more than ten hours so as to remove unreacted monomers, other volatile impurities and, if any, residual thermal stress.

§ 3. Phenol Resin

In Fig. 1, a family of curves of loss factor are illustrated in case of phenol resin, being computed from the measurements without any consideration to the error sources discussed in the preceding section. Each curve corresponds to a specimen of different length respectively, f_s (kc/s) being shown beside each experimental point. As above predicted, a spurious increase of loss factor is found in the temperatures where f_s deviates too far from f_q or f_s closely approaches to f_q.

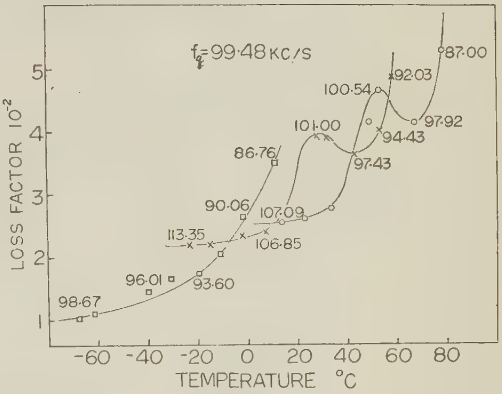

Fig. 1. Examples of erroneous measurements for phenol resin, f_s(kc/s) shown beside each experimental point.

Elliminating erroneous data from Fig. 1, the temperature dependence of the modulus and loss factor for phenol resin is presented in Fig. 2. As is seen, the loss factor increases

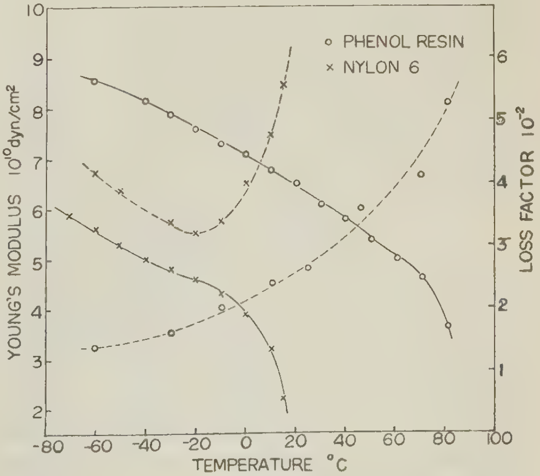

Fig. 2. Young's modulus (solid line) and loss factor (broken line) for phenol resin and nylon 6 at 100 kc/s.

monotonously with temperature and thus shows no anomalous maximum in the temperature range studied.

The results presented in the followings have all been obtained by taking care of the error sources before stated.

§4. Polymethyl Methacrylate

The data for polymethyl methacrylate (PMMA) are illustrated in Fig. 3, where the modulus is brought into a single curve since it does not vary with frequency within the experimental error.

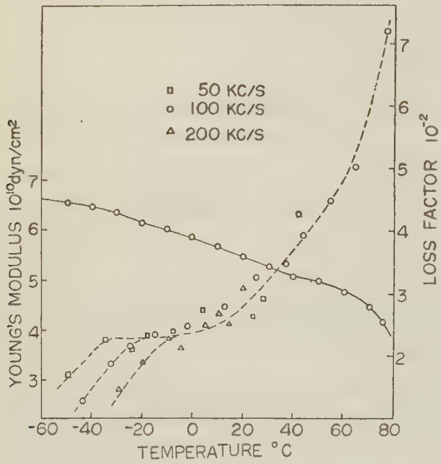

Fig. 3. Young's modulus (solid line) and loss factor (broken line) for polymethyl methacrylate.

Dynamic studies for PMMA in low frequency range[6-10] have related that, besides the glassy transition (or α-transition as is frequently called[8]), this polymer has a second (or β-) transition at lower temperature and the possible mechanism responsible for the latter is believed to be allied to the mobility of the side group ($-COOCH_3$) of this polymer[6,7]. In the ultrasonic measurement as is our case, however, the β-transition is expected to shift to a higher temperature and become undistinguishable from the α-transition, because the activation energy involved in the former, *ca.* 20 kcal/mole as generally accepted, is much smaller than that in the latter. As a consequence, the anomalous behavior of the loss factor observed at about −20°C in Fig. 3 should be regarded as not the β-transition, but a third (or γ-) transition.

While several investigators[8-10] have discussed on the γ-transition for PMMA, there exists so far no conclusive evidence whether or not this type of transition could be observed in this polymer. Among them, Hoff and others[9] have concluded a lack of this transition for PMMA on the basis of their audio-frequency dynamic data, which however have been presented only in an extremely small figure and probably may be too scattered to distinguish so small an anomaly as has been observed in our experiment. Recently Kawai[12], on the other hand, has suggested the existence of this transition in PMMA from the dielectric loss data.

Anyway, the apparent activation energy ΔH for the γ-transition can be evaluated from the present data as 7 kcal/mole, assuming the frequency of measurement is proportional to $\exp(-\Delta H/RT)$, where R is the gas constant and T the absolute temperature of the loss maximum. This estimate of ΔH, being much smaller than that of the β-transition, does not seem unreasonable to the hypothesis that the γ-transition of PMMA might be due to the rotation of a portion of the side group.

Fig. 4 illustrates the moisture dependence of the loss factor in the transition region. As can be observed, the transition shifts to a higher temperature with increase of moisture. Taking into account the above hypothesis, it might be said that the absorbed water makes hindrance to the rotation of the side group. In fact, Maeda[13] recently has reported that the absorbed water in PMMA, especially at low temperatures, occupies the free space between adjacent chains and consequently

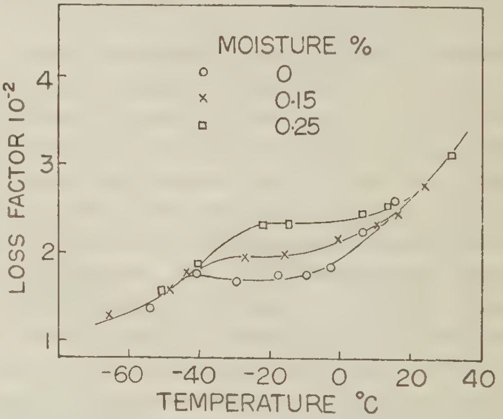

Fig. 4. Moisture dependence of loss factor for polymethyl methacrylate in the transition region (100 kc/s).

as a hindering effect on kinetic motions of he polymer chain.

Much more extensive data will be required efore the above hypothesis on the γ-transi- on can be considered anything more than ntative.

5. Polystyrene

The experimental results for polystyrene re shown in Fig. 5. It can be seen that the oss factor curve tends to rise gradually with

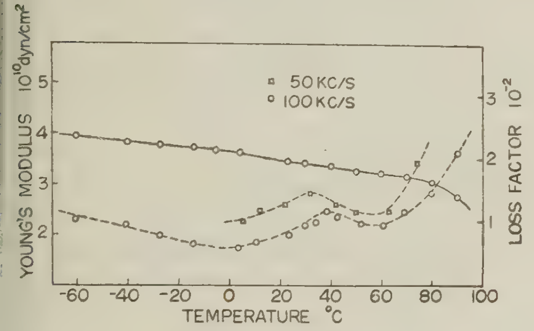

Fig. 5. Young's modulus (solid line) and loss factor (broken line) for polystyrene.

escending temperature and indicates the pos- ible existence of a peak below the test tem- erature. A similar behavior has been observ- d for this polymer by other authors[10,14].

The loss curve in Fig. 5 appears o exhibit a peak also at room tem- erature. This anomaly seem difficult o explain, since polystyrene mole- ule has no movable side group in ontradistinction to PMMA. In fact, he observed peak is so slight as to e reasonably ascribed to an ex- erimental error, but it may be vorthy to note that the curves here resented have good reproducibility. Nothing more can be said about this nomaly in the present stage.

6. Polyethylene and Other Plymers

The modulus and loss factor of olyethylene are illustrated in Fig. 6. It is vell established[5,15,16] that this polymer has a oss peak at room temperature when measured t ultrasonic frequencies. Also in the present tudy, a prominent peak is found in loss factor t 10°C. Combining this result with those in ther reports[5,16], a value of 28 kcal/mole is evaluated for the apparent activation energy. The molecular process involved in this transition is, as Mason[15] has stated, probably ascribed to the mobility of polymer chains in the amorphous region.

In the case of nylon 6 (see Fig. 2) which is also partially crystalline as polyethylene, the loss factor curve indicates the existence of a peak above room temperature.

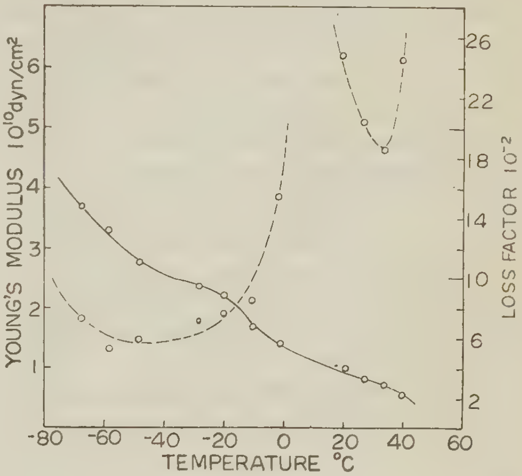

Fig. 6. Young's modulus (solid line) and loss factor (broken line) for polyethylene (100 kc/s).

Finally, the data are presented in Fig. 7 for two polyester samples of different crosslinking degree. While softening occurs at different temperatures for each sample, the modulus as well as the loss factor of both samples fall into a single curve respectively below the softening temperature. This indicates that, at the glassy state at least, the

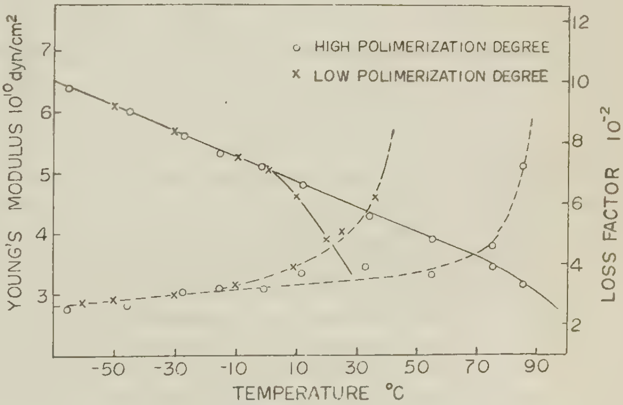

Fig. 7. Young's modulus (solid line) and loss factor (broken line) for two polyester samples. (100 kc/s).

dynamic elasticity of high polymers at ultrasonic frequencies almost energetics in nature, as has been discussed in detail in the previous paper[5].

§ 7. Acknowledgements

In conclusion, the authors express their sincere appreciation to Prof. Y. Suge for his continuous encouragement throughout this study. They also wish to thank to Dr. S. Iwayanagi and other members of the high polymer laboratory in the Scientific Research Institute for their valuable discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 4, APRIL, 1957

On the Effective Diffusion Tensor of a Segment in a Chain Molecule and its Application to the Non-Newtonian Viscosity of Polymer Solutions

By Yuichi IKEDA

*Kobayasi Institute of Physical Research, 2431 Kokubunzi, Tokyo**

(Received December 27, 1956)

The effect of hydrodynamic interaction between segments in a chain molecule plays an important role in the theory of the intrinsic viscosity of high polymer solutions. In this paper, the effect of hydrodynamic interaction is reflected into the concept of the effective diffusion tensor of a segment in a chain molecule. In performing the calculation, r_{iG}, the distance from the centre of gravity of the chain molecule to the cited segment, is considered as a parameter. In result, each segment has an anisotropic effective diffusion tensor, the radial component of which is about 10% larger than the transversal ones on the average. With this anisotropic diffusion tensor, the shear gradient dependence of the intrinsic viscosity of polymer solutions is deduced, making use of Rouse model. The agreement with experiments is satisfactory.

§ 1. Introduction

The molecular theory of the intrinsic viscosity of polymer solutions is now almost completed by Zimm[1], after many authors' efforts following Huggins[2], Kramers[3] and Debye[4]. The viscoelastic properties of dilute polymer solutions in alternating shear gradient are also well explained. However, the shear gradient dependence of the intrinsic viscosity is not satisfactorily explained, although some theories[5,6] have been given. Zimm's theory, the most exact one ever established, gives no shear gradient dependence of intrinsic viscosity, perhaps because of the complete linearity of the diffusion equation. It should be noted that in his theory the hydrodynamic effect is completely averaged using the probability distribution function in equilibrium. On the other hand, Kuhn and Kuhn[5] are the first who derived non-Newtonian intrinsic viscosity. They introduced the concept of internal viscosity into the dumb-bell model of the macromolecule, and in result, the dumb-bell model they took has an anisotropic diffusion tensor, which causes the non-Newtonian viscosity. However, the idea of "internal viscosity" is not clear. If it really exists, we might be able to derive it making use of Rouse model, considering hydrodynamic interactions.

---

* Present address: Fuji Spinning Co., Ltd., 2 Chōme 1, Honchô, Nihonbasi, Chūō-ku, Tokyo.

Having these circumstances in mind, we will attempt to estimate the effective diffusion tensor of a segment in a chain molecule, with specified position r_{iG} apart from the centre of gravity of the chain. In this case, when the effect of hydrodynamic interaction s taken into consideration, the effective diffusion tensor of a segment becomes an ansotropic one because of the anisotropic distribution of other segments around the cited segment. With this anisotropic diffusion tensor, we can get a higher approximation of the hydrodynamic interaction effect than Zimm's, in the theory based on a Rouse model. In result, we can get the non-Newtonian intrinsic viscosity of polymer solutions.

§2. The Effective Diffusion Tensor of a Segment

We will take a Rouse model with N identical segments, each of which is designated by an index i running from 1 to N. The root mean square of distance of neighbouring segments is l. The diffusion tensor D^{ij} can be defined by

$$\vec{j}^i=\sum_j \frac{D^{ij}}{kT}\vec{F}_j\,, \tag{1}$$

where $\vec{j}^i$ is the velocity of the ith segment minus the velocity of the unperturbed flow of olvent, and $\vec{F}_i$ is the force acting on the ith egment. The components of the diffusion tensor can be rewritten as

$$D^{ij}=kT\left\{\frac{1}{\zeta}\mathbf{1}^{ij}+\frac{1}{8\pi\eta_0 r_{ij}}\left[\mathbf{1}^{ij}+\frac{\vec{r}_{ij}{}^{i}\vec{r}_{ij}{}^{j}}{r_{ij}{}^{2}}\right]\right\}, \tag{2}$$

as Kirwood[7] has shown*. D^{ij} ($i \neq j$) vanishes when the hydrodynamic interaction can be neglected.

Firstly, we will consider the case where $\vec{F}_i$ has a value of $\vec{F}$ independent of i, then we have

$$\vec{j}^i=(\sum_j D^{ij})\vec{F}\,, \tag{3}$$

so we may define the effective diffusion tensor $\mathbf{D}^i{}_{\text{trans}}$ of the ith segment in the translational movement of the polymer as follows:

$$\mathbf{D}^i{}_{\text{trans}}=D^{ii}+\langle\sum_{j\neq i} D^{ij}\rangle_i\,, \tag{4}$$

where $\langle\ \ \rangle_i$ means the average taken over all other $\vec{r}_{jG}$ ($j=1, \cdots, i-1, i+1, \cdots, N$) except $\vec{r}_{iG}$, where $\vec{r}_{iG}$ is the vector running from the centre of gravity to the ith segment. Strictly speaking, Eq. (4) does not give the exact definition of $\mathbf{D}^i{}_{\text{trans}}$, because in the translational motion, the movement is represented not by $\vec{F}_i=\vec{F}$ but by $\vec{j}^i=$constant vector $\vec{j}$. However, the treatment for describing $\mathbf{D}^i{}_{\text{trans}}$ starting form $\vec{j}^i=\vec{j}$ is rather difficult. Fortunately, it is seen from some papers[1,9,10] that $\vec{F}_i$ does not so much depend on i, and it is natural to think that $\vec{F}_i$'s acting on two segments have almost same values when they are near each other, because the circumstances around each segment are nearly the same. Moreover, we can justify the definition Eq. (4) in another way. When we assume each segment has its diffusion constant $\overline{D^i{}_{\text{trans}}}$ which is given by averaging $\mathbf{D}^i{}_{\text{trans}}$ over $\vec{r}_{iG}$, we obtain the translational diffusion constant of a chain molecule D_{trans} in rigorous way as follows:

$$\vec{j}=\vec{j}^i=\frac{\overline{D^i{}_{\text{trans}}}}{kT}\vec{F}_i \text{ or } \vec{F}_i=\left(\frac{\overline{D^i{}_{\text{trans}}}}{kT}\right)^{-1}\vec{j}\,, \tag{5}$$

so consequently we have

---

* Eq. (2) is not so general as Kirkwood considered. Eq. (12) in his paper cannot be written generally, because F_α is determined not only by $\overset{\circ}{v}{}^{\beta}$'s and $\dot{q}^{\beta}$'s in the chain space but also by the components of $\mathbf{v}$ perpendicular to chain space. However if we take a Rouse model, the configuration space is identical to the whole space; so we may adopt Eq. (2) in this case[8].

$$\sum_i \vec{F} = \sum_i \left(\frac{\overline{D^i{}_{\text{trans}}}}{kT} \right)^{-1} \vec{j} = D^{-1}_{\text{trans}} \vec{j} \tag{6}$$

or

$$D_{\text{trans}} = \left[\sum_i \left(\frac{\overline{D^i{}_{\text{trans}}}}{kT} \right)^{-1} \right]^{-1} .$$

We can show that the value of D_{trans} calculated from Eq. (6) is in good agreement with the exact one[11] irrespectively of the degree of hydrodynamic interaction effect. This seems to justify the applicability of Eq. (4).

Now we will consider the effective diffusion tensor of a segment in the rotational motion of a polymer. In this case, the circumstances are analogous to the translational case; when the value of $\vec{r}_{iG}$ is near $\vec{r}_{jG}$, $\vec{F}$ does not differ so much from $\vec{F}_j$. However, as the chain rotates around the centre of gravity (strictly speaking, around the centre of resistance[1]), $\vec{F}_i$ will be nearly equal to $-\vec{F}_j$ when $\vec{r}_{iG} = -\vec{r}_{jG}$. Consequently, we may define $\mathbf{D}^i{}_{\text{rot}}$ by

$$\mathbf{D}^i{}_{\text{rot}} = D^{ii} + \alpha \langle \sum_{j \neq i} D^{ij} \rangle_i \, , \tag{7}$$

where α is a constant factor which can be determined from more detailed analysis. We will now take 1/4 for α, tentatively. Now, using the diffusion constant which is obtained by averaging Eq. (7), we can calculate the intrinsic viscosity, $[\eta]'$, employing Rouse model. The result is shown in Table I, compared with Kirkwood-Zwanzig-Plock's result[12]. The agreement is good through all degrees of hydrodynamic interaction effect, and hereafter we may use Eq. (7) as $\mathbf{D}^i{}_{\text{rot}}$, where $\alpha = 1/4$. More precise theories[1,9] give a little smaller values then Kirkwood-Zwanzig-Plock's. So, the value of α should be taken a little smaller than 1/4. However, as our theory is not so strict, it will be meaningless to decide the value of α in detail.

Table I. The values of $F(x)$ and $xF(x)$, where $F(x) = \left(\frac{N_a N^2 l^2 \zeta}{36 M \eta_0} \right) [\eta]'$ and $x = \lambda_0 N^{1/2}$; $\lambda_0 = \zeta / \{ (6\pi^3)^{1/2} \eta_0 l \}$.

x	$F(x) = \left(1 + \frac{2x}{3}\right)^{-1}$ (Eq. (15))		after Kirkwood-Zwanzig-Plock[12]	
	$F(x)$	$xF(x)$	$F(x)$	$xF(x)$
0	1.00	0.00	1.00	0.00
0.5	0.75	0.38	0.69	0.35
1.0	0.60	0.60	0.54	0.54
2.0	0.43	0.86	0.38	0.75
3.0	0.33	1.00	0.29	0.88
4.0	0.27	1.09	0.24	0.96
5.0	0.23	1.15	0.20	1.02
10.0	0.13	1.30	0.12	1.17
20.0	0.07	1.40	0.07	1.31
∞	0	1.50	0	1.48

We will now estimate Eq. (7) as a function of i. Substituting Eq. (2) into Eq. (7), with $\alpha = 1/4$, we have

$$\mathbf{D}^i{}_{\text{rot}} = \frac{kT}{\zeta} \mathbf{1} + \frac{1}{32 \pi \eta_0} \left\langle \sum_{j \neq i} \frac{1}{r_{ij}} \left\{ \mathbf{1} + \frac{1}{r_{ij}{}^2} \begin{pmatrix} x_{ij}{}^2 & x_{ij} y_{ij} & x_{ij} z_{ij} \\ y_{ij} x_{ij} & y_{ij}{}^2 & y_{ij} z_{ij} \\ z_{ij} x_{ij} & z_{ij} y_{ij} & z_{ij}{}^2 \end{pmatrix} \right\} \right\rangle_i . \tag{8}$$

The probability distribution functions $Z_N(\vec{r}_{ij};\ \vec{r}_{iG})$ of $\vec{r}_{ij}$ with $\vec{r}_{iG}$ fixed is given by[13,14]

$$Z_N(\vec{r}_{ij};\ \vec{r}_{iG}) = \frac{t_i{}^{3/2}}{(2\pi)^{3/2} (t_i t_{ij} - t_{i,ij}{}^2)} \exp\left[\frac{-t_i}{2(t_i t_{ij} - t_{i,ij}{}^2)} \left(\vec{r}_{ij} - \frac{t_{i,ij}}{t_i} \vec{r}_{iG} \right)^2 \right] , \tag{9}$$

where

$$\begin{aligned} t_i &= \frac{Nl^2}{3} \left\{ \frac{1}{3} - \frac{i}{N} \left(1 - \frac{i}{N} \right) \right\} , \\ t_{ij} &= \frac{Nl^2}{3} \left| \frac{i}{N} - \frac{j}{N} \right| , \\ t_{i,ij} &= \begin{cases} \dfrac{Nl^2}{6} \left(\dfrac{i}{N} - \dfrac{j}{N} \right) \left(\dfrac{i}{N} + \dfrac{j}{N} - \dfrac{1}{N} \right) & (i > j) \\ \dfrac{Nl^2}{6} \left(\dfrac{j}{N} - \dfrac{i}{N} \right) \left(2 - \dfrac{i}{N} - \dfrac{j}{N} + \dfrac{1}{N} \right) . & (i < j) \end{cases} \end{aligned} \tag{10}$$

Using Eqs. (9) and (10), Eq. (8) can be rewritten as

$$\mathbf{D}^{i}{}_{\mathrm{rot}}=\frac{kT}{\zeta}\begin{pmatrix} 1+\frac{\zeta}{12\pi\eta_0 l}A\left\{1+B\left(1-\frac{r_{iG}{}^2}{5t_i}\right)\right\}+\cdots & 0 & 0 \\ 0 & 1+\frac{\zeta}{12\pi\eta_0 l}A\left\{1+B\left(1-\frac{2r_{iG}{}^2}{5t_i}\right)\right\}+\cdots & 0 \\ 0 & 0 & 1+\frac{\zeta}{12\pi\eta_0 l}A\left\{1+B\left(1-\frac{2r_{iG}{}^2}{5t_i}\right)\right\}+\cdots \end{pmatrix}, \tag{11}$$

where we take x-axis parallel to $\vec{r}_{iG}$, and

$$A=\sqrt{\frac{6N}{\pi}}\left[\left(\frac{1}{2}-x\right)^{1/2}+\left(\frac{1}{2}+x\right)^{1/2}\right],$$
$$B=\frac{71}{2520}\frac{Nl^2}{t_i}\frac{(1/2-x)^{7/2}+(1/2+x)^{7/2}}{(1/2-x)^{1/2}+(1/2+x)^{1/2}}. \qquad \left(x=\frac{i}{N}-\frac{1}{2}\right) \tag{12}$$

Eq. (11) can be interpreted physically as follows: the hydrodynamic interaction effect causes a segment to move easily, if there are many segments moving in the same direction. The smaller the distance r_{iG} is, the more closely crowd the segments, and so the larger become the components of the effective diffusion tensor. Moreover, when the position of the ith segment from the centre of gravity is specified previously, the density distribution of other segments around the ith segment becomes anisotropic, with the result that the radial component of the effective diffusion tensor becomes larger than the transversal ones on account of the effect of hydrodynamic interaction.

If a polymer chain in a solution is under the shear flow, the chain will rotate and be deformed. In this case, we can calculate the intrinsic viscosity of a polymer chain molecule, solving the diffusion equation of the chain. If the diffusion constant of each segment remains constant, the non-Newtonian viscosity does not occur when we use the Rouse model, as is already pointed out[1,5,15]. But if the diffusion constant of a segment becomes an anisotropic effective diffusion tensor with variable components, non-Newtoninan viscosity may occur. However, Eq. (11) cannot be used in the above form. Under the shear flow, the chain is deformed, so that the distribution function in equilibrium (Eq. (9)) used to calculate Eq. (8) is to be replaced by the one of non-equilibrium. This circumstances make it difficult to apply the idea of effective diffusion tensor to the calculation of non-Newtonian intrinsic viscosity. So, hereafter, we may only use the anisotropic property of the effective diffusion tensor, which is essential whether the chain is deformed or not. Thus, we will average the component of the tensor in Eq. (11) on r_{iG}, then we have

$$\mathbf{D}^{i}{}_{\mathrm{rot}}=\frac{kT}{\zeta}\begin{pmatrix} 1+\frac{\zeta}{12\pi\eta_0 l}A\left(1+\frac{2}{5}B\right) & 0 & 0 \\ 0 & 1+\frac{\zeta}{12\pi\eta_0 l}A\left(1-\frac{1}{5}B\right) & 0 \\ 0 & 0 & 1+\frac{\zeta}{12\pi\eta_0 l}A\left(1-\frac{1}{5}B\right) \end{pmatrix}. \tag{13}$$

As A and B are slowly varying functions of i, we will again average Eq. (13) through i, to avoid the complexity which will occur otherwise in carrying out the calculation. Consequently, the averaged effective diffusion tensor, $\mathbf{D}_{\mathrm{rot}}$, becomes in its final form

$$\mathbf{D}_{\mathrm{rot}}=\frac{kT}{\zeta}\begin{bmatrix} 1+0.71\lambda_0 N^{1/2} & 0 & 0 \\ 0 & 1+0.64\lambda_0 N^{1/2} & 0 \\ 0 & 0 & 1+0.64\lambda_0 N^{1/2} \end{bmatrix}, \tag{14}$$

where $\lambda_0=\zeta/\{(6\pi^3)^{1/2}\eta_0 l\}$.

The average of the three diagonal elements is $kT/\zeta(1+2/3\cdot\lambda_0 N^{1/2})$. If we take this mean value for the diffusion constant of each segment, we get the intrinsic viscosity, $[\eta]'$, as follows:

$$[\eta]'=\frac{N_a N^2 l^2 \zeta}{36M\eta_0}\,\frac{1}{1+2/3\cdot\lambda_0 N^{1/2}}\,, \tag{15}$$

the value of which is shown in Table I as a function of $\lambda_0 N^{1/2}$.

§ 3. Non-Newtonian Intrinsic Viscosity

We will now treat the non-Newtonian intrinsic viscosity of polymer solutions. Here we will adopt the Rouse model. In this case, it is convenient to use the normal coordinates ξ_i, η_i, ζ_i $(i=1, \cdots, N-1)$ (the same ones for free-draining case in Zimm's paper[1], non-free-draining effect being taken into account in a different way in our paper), which are linear combinations of x_{iG}, y_{iG}, z_{iG} $(i=1, \cdots, N)$. The coordinates representing the position of the centre of gravity, ξ_0, η_0, ζ_0, do not enter in the following calculation. It is desirable to calculate the effective diffusion tensor in normal coordinates directly. But the functional form of $1/r_{ij}$ in normal coordinates is so complex, that we will try to derive the diffusion tensors in this case from the ones of ordinary x_{iG}, y_{iG}, z_{iG} coordinates. Though it is troublesome to seek the exact new form of diffusion tensors, it will be intuitively understood that the diffusion tensor of Eq. (14) can be used without changing its form for the new coordinates, when we consider the simple rotation of a chain around the centre of gravity, or the uniform radial deformation of the chain. So we may assume for each set of coordinates ξ_i, η_i, ζ_i the diffusion tensor to be of the same form as is given in Eq. (14).

Taking a laminar flow $(gy, 0, 0)$, where g is the shear gradient, we have

$$\begin{aligned}(\xi_i\eta_i)&=\frac{1}{D^r{}_{\mathrm{rot}}}\,\frac{g}{2}\,\langle\xi_i{}^2\rangle(\eta_i{}^2)+3\langle\xi_i{}^2\rangle\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)(\xi_i\eta_i/\rho_i{}^2)\,,\\(\eta_i{}^2)&=\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\,\langle\xi_i{}^2\rangle+3\langle\xi_i{}^2\rangle\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)(\eta_i{}^2/\rho_i{}^2)\,,\end{aligned} \tag{16}$$

where $D^r{}_{\mathrm{rot}}$ and $D^t{}_{\mathrm{rot}}$ are the radial and transversal components of effective diffusion tensor, respectively, $\rho_i{}^2=\xi_i{}^2+\eta_i{}^2+\zeta_i{}^2$, and $\langle\ \rangle$ means the average in equilibrium. $(\ )$ means the average in the steady state. Eqs. (16) are derived from the diffusion equation of Rouse modified by anisotropic diffusion tensors, by multiplying $\xi_i\eta_i$ and $\eta_i{}^2$ to it and averaging, and $\langle\xi_i{}^2\rangle$ is introduced in Eqs. (16) because it comes from the spring constant of Rouse model given by equilibrium mean square separation. If $(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})=0$, non-Newtonian viscosity disappears, and we will calculate $(\xi_i\eta_i)$ in a power series of $(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})$. We may substitute $(\xi_i\eta_i/\rho_i{}^2)_0$ and $(\eta_i{}^2/\rho_i{}^2)_0$ into $(\xi_i\eta_i/\rho_i{}^2)$ and $(\eta_i{}^2/\rho_i{}^2)$ on the righthand term of Eqs. (16), respectively, for the first approximation. The subscript 0 indicates the value evaluated when we assume that $(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})=0$. So we have

$$(\xi_i\eta_i/\rho_i{}^2)_0=\frac{1}{5}s_i-\frac{2}{15}s_i{}^3+\cdots\,, \tag{17}$$

$$\left(s_i=\frac{g}{2}\langle\xi_i{}^2\rangle\frac{1}{D^r{}_{\mathrm{rot}}}\right)$$

$$(\eta_i{}^2/\rho_i{}^2)_0=\frac{1}{3}-\frac{16}{105}s_i{}^2+\cdots\,, \tag{18}$$

and

$$(\xi_i\eta_i)=\frac{g}{2}\langle\xi_i{}^2\rangle^2\frac{1}{D^r{}_{\mathrm{rot}}}\left\{1+\frac{3}{5}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)+\cdots\right\}\left[1-\frac{6}{7}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)\left\{\frac{g}{2}\langle\xi_i{}^2\rangle\frac{1}{D^r{}_{\mathrm{rot}}}\right\}^2+\cdots\right], \tag{19}$$

From $(\xi_i\eta_i)$, we can get in a usual way the intrinsic viscosity $[\eta]$, that is

$$[\eta]=\frac{RT}{gM\eta_0}\sum_i\frac{(\xi_i\eta_i)}{\langle\xi_i^2\rangle}=\frac{RT}{2MD^r{}_{\mathrm{rot}}\eta_0}\{\Sigma\langle\xi_i^2\rangle\}\left\{1+\frac{3}{5}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)+\cdots\right\}$$
$$\times\left[1-\frac{6}{7}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)\frac{1}{D^r{}_{\mathrm{rot}}{}^2}\frac{\Sigma\langle\xi_i^2\rangle^3}{\Sigma\langle\xi_i^2\rangle}\frac{g^2}{4}+\cdots\right]. \tag{20}$$

where one has $\langle\xi_i^2\rangle=\frac{l^2}{3}\frac{N^2}{\pi^2 i^2}$, which leads immediately

$$\sum_i\langle\xi_i^2\rangle=\frac{l^2}{18}N^2, \tag{21}$$

and

$$\sum_i\langle\xi_i^2\rangle^3=\frac{8}{35}\{\Sigma\langle\xi_i^2\rangle\}^3. \tag{22}$$

Then, Eq. (20) can be rewritten as

$$[\eta]=[\eta]_{g\to0}\left[1-\frac{48}{245}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)\left([\eta]_{g\to0}\,\eta_0\frac{M}{RT}\right)^2 g^2+\cdots\right]. \tag{23}$$

Remembering Eq. (14), we have

$$1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}}=(1+0.07\lambda_0N^{1/2})/(1+0.71\lambda_0N^{1/2}). \tag{24}$$

When $\lambda_0\to\infty$, $(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})\sim 0.1$. $[\eta]_{g\to0}$ is nearly the same as $[\eta]'$. $[\eta]_{g\to0}\propto 1/D^r{}_{\mathrm{rot}}\{1+3/5(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})+\cdots\}$ and $[\eta]'\propto 1/D^r{}_{\mathrm{rot}}\{1+2/3(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})+\cdots\}$, where $0<(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})<0.1$.

§ 4. Discussion

Recently, Peterlin-Čopič[16,17] proposed a theory of the non-Newtonian viscosity of dilute polymer solutions. Their idea is essentially similar to that of this paper. But they started from the dumb-bell model, and discussed the anisotropic diffusion tensor according to it. On the other hand, we have started from the concept of the effective anisotropic diffusion tensor of one segment in a chain. In result, Peterlin and Čopič obtained the following result,

$$[\eta]=[\eta]_{g\to0}\left[1-\frac{53}{50}\left(1-\frac{D^t{}_{\mathrm{rot}}}{D^r{}_{\mathrm{rot}}}\right)\left([\eta]_{g\to0}\,\eta_0\frac{M}{RT}\right)^2 g^2+\cdots\right], \tag{25}$$

our result is shown in Eq. (23), where Rouse model is employed.

It is to be noted that $[\eta]/[\eta]_{g\to0}$ is a function of $[\eta]_{g\to0}\eta_0Mg/RT$, this corresponds to the fact that $[\eta]/[\eta]_{\substack{g\to0\\ \omega\to0}}$ is a function of $[\eta]_{\substack{g\to0\\ \omega\to0}}\eta_0M\omega/RT$ in the oscillating field. Though we cannot clarify the behaviour of a chain in the full range of shear gradient, we mayn ow suggest a formula for $[\eta]$ as follows:

$$[\eta]/[\eta]_{g\to0}=\left(1-\frac{[\eta]_{g\to\infty}}{[\eta]_{g\to0}}\right)\frac{6}{\pi^2}\sum_{i=1}^{N}\frac{1}{1+\beta\left[\frac{1}{i^2}\frac{6}{\pi^2}g[\eta]_{g\to0}\,\eta_0\frac{M}{RT}\right]^2}+\frac{[\eta]_{g\to\infty}}{[\eta]_{g\to0}}, \tag{26}$$

presuming the Philippoff-type non-Newtonian viscosity formula. Eq. (26) fits to Eq. (24) with the parameter $\beta=6/7(1-D^t{}_{\mathrm{rot}}/D^r{}_{\mathrm{rot}})(1-[\eta]_{g\to\infty}/[\eta]_{g\to0})^{-1}$, if g is small. This formula is suggested considering of many normal coordinates representing the configuration of a polymer chain.

We will now compare Eqs. (24) and (26) to the experimental data. Eq. (24) with $\lambda_0N^{1/2}\to\infty$ is applied to Čopič's data[17] and Wada's data[18] of non-Newtonian intrinsic viscosity of polystyrene and polymethylmethacrylate, respectively. Broadly speaking, the agreement is satisfactory. Eq. (26) is applied to Sharman-Sones-Cragg's data[19] where $g=0\sim10^4$ sec^{-1}. Many Sharman-Sones-Cragg's data are plotted in log η_r/c vs. g, but approximately holds the relation

$$\log \eta_r/c \simeq \frac{[\eta]}{c} \frac{(1-1/\eta_r{}^0)}{[\eta]_{g\to 0}} + \log \eta_r{}^0/c - \frac{1}{c}\left(1-\frac{1}{\eta_r{}^0}\right),$$

where η_r is the relative viscosity, $\eta_r{}^0$ is η_r at $g\to 0$, and c is the concentration of polymer solution, and hence Eq. (26) can be roughly compared with their data. Though the agreement with each experimental data is not so good, the trend of experimental curves, i.e., the fast decrease of $[\eta]$ followed by slow one with increasing shear rate is reasonably explained by Eq. (26). The tendency of dependence of non-Newtonian viscosity on molecular weight is also satisfactorily explained.

On the Magnetic Properties of Chromium Sulfides*

By Motoyoshi YUZURI, Tokutaro HIRONE, Hiroshi WATANABE,
Seizo NAGASAKI and Seijiro MAEDA

*The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai*

(Received January 7, 1957)

The thermomagnetic properties of chromium sulfide $CrS_{1.17}$ were studied. The spontaneous magnetization of this compound, which is probably of the ferrimagnetic origin, suddenly disappears during cooling at −120°C. A slight heat absorption was observed at this transition point. By X-ray analysis excess diffraction lines besides those of the ideal crystal lattice of the nickel arsenide type were observed at room temperature, which shows a super-lattice structure with parameters of twice c and $2\sqrt{3}$ times of a, a and c being those of the original lattice. It was also found by X-ray analysis that there was no change of the crystal lattice at the magnetic transition temperature, −120°C. This compound showed a ferrimagnetic behavior with the asymptotic Curie temperature at 150°K. A peak in susceptibility *vs.* temperature curve was found by the thermomagnetic measurement in the temperature range from the liquid helium temperature to −120°C. Basing on these data, a short discussion on the nature of the above-mentioned transition is given.

§ 1. Introduction

It was reported by Haraldsen and Neuber¹⁾ that chromium sufide with the composition $CrS_{1.17}$ is ferromagnetic with the Curie temperature of about 30°C and its spontaneous magnetization disappears suddenly during cooling at −120°C and the compound becomes paramagnetic below that temperature. As to the mechanism of the abrupt disappearance of magnetization at −120°C many possibilities could be proposed, *e.g.* the change in crystal structure, the formation or vanishing of ordered arrangement of cations or vacancies in the crystal lattice, or that of ordered arrangement of spins. Because of the lack of thermal and crystallographic data, however, it is difficult to distinguish the most probable one from these possibilities. Hence, in the present studies magnetic, thermal, and X-ray analyses of this compound were undertaken. In the following pages the results of the measurements and a discussion of the nature of the magnetic transition mentioned above are given.

§ 2. Preparation of the Specimens

The specimens used were prepared by the usual ceramic method. Chromium powder (99.3%) and sulfur (99.99%) were mixed in the desired ratios and sealed doubly in an evacuated quartz tube and then heated in an electric furnace. To avoid explosion during heating, the mixtures were heated slowly during 24 hours till 400°C and held at this temperature for 24 hours, then heated till 1,000°C during 24 hours and kept at this temperature for 24 hours. After the reaction was completed, the specimens were cooled at the rate of 30°C per hour down to the room temperature. Sometimes, slight cracks occurred at the inner quartz tube during cooling due to the difference in thermal contraction between the specimens and the quartz tube, but the doubly sealed container mentioned above prevented the specimens from oxidation or decomposition. In order to obtain homogeneous specimens, the reaction products were crushed once more, mixed well and then pressed in a form of small bar under the pressure of about 1.5 tons per square cm and again heated above 900°C for more than 24 hours. Every portion of the specimen thus obtained showed the same thermomagnetic behavior.

* A part of this report is based upon the dissertation (Master Course (1955), Tohoku University) presented by Motoyoshi Yuzuri. This investigation was financed in part by the Grant-in-Aid of the Fundamental Scientific Research of the Ministry of Education.

§ 3. Thermomagnetic Measurements

An automatically recording magnetic balance was used for the measurements of the magnetic susceptibility[2]. The change of the susceptibility, χ, with temperature was measured with samples of various sulfur contents at the magnetic field of about 3,500 Oe. The susceptibility of the compound $CrS_{1.17}$ as measured in the temperature range from the boiling point of liquid nitrogen to 600°C, is shown in Fig. 1. As seen from the figure the reciprocal susceptibility decreases linearly with the fall of temperature in the high temperature range, and then falls rapidly just above the Curie point, below which the saturation in magnetization is observed. Such a behavior suggests that the magnetism of this compound is of ferrimagnetic origin. From the Curie constant obtained from the slope of the $1/\chi$-T curve, the effective Bohr magneton number per Cr ion was calculated to be 4.8. Assuming Lande factor g as 2, the mean spin quantum number S becomes 3.9/2. This observed value of S is considered to be a resonable one, since it may be supposed from the ionic picture of this compound that two kinds of chromium ions, Cr^{2+} and Cr^{3+}, whose spin quantum numbers are 4/2 and 3/2 respectively, coexist in the substance. The specific magnetization at 3,000 Oe below the Curie temperature is also shown in the same figure, which hows that the magnetization disappears suddenly at −120°C as stated above. The change of the specific magnetization σ with the magnetizing field obtained with the sample of $CrS_{1.17}$ is shown is Fig. 2, from which it can be seen that the complete saturation is reached at the field of 8000 Oe. A $\sigma_s - T^{3/2}$ plot made, based on such measurements at various temperatures is shown in Fig. 3, which indicates that the saturation magnetization varies linearly with $T^{3/2}$ below 250°K*. The saturation value at the absolute zero of temperature obtained by extrapolating the linear part of the $\sigma_s - T^{3/2}$ curve, is 0.35 Bohr magneton per Cr atom.

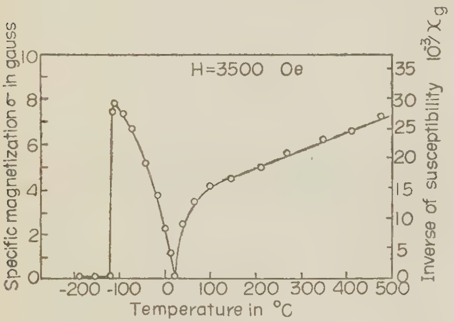

Fig. 1. The thermomagnetic curve of $CrS_{1.17}$.

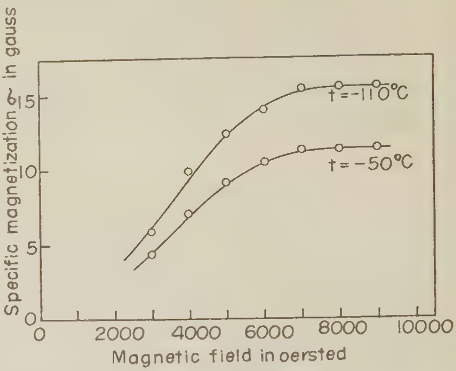

Fig. 2. The curves of specific magnetization versus magnetic field.

The behavior of the susceptibility below the transition temperature is shown in Fig. 4. As can be seen from the figure, there appears a maximum of susceptibility at −170°C. The emergence of this peak, however, was accompanied by a relaxation of the order of an hour. If the specimen was cooled rapidly to the boiling point of nitrogen and then heated without delay, such a peak did not appear. The necessary condition for observ-

* Such a procedure for obstaining absolute saturation value with Bloch's $T^{3/2}$ law is justified in the case of ferrimagnetism by Prof. Kubo.

ng this peak was to keep the specimen at he boiling point of liquid nitrogen for a few ours or to cool it until the liquid helium emperature was reached. The origin of such relaxation phenomenon, however, is not yet lear.

4. Thermal Analysis

The measurement of specific heat in the ow temperature range was carried out by eans of an adiabatic method, the detailed escription of which was given by Nagasaki nd Takagi[3]. In this case a cylindrical essel made of paper was used as the specien container. The result of measurement s shown in Fig. 5. An anomalous peak of pecific heat at about 30°C corresponds to the Curie point of this compound, and the total eat absorption due to the vanishing of ferrimagnetism is 30 cal/mol.* In addition, a ery small peak was observed at about −120°C, corresponding to the vanishing point f magnetization at low temperature side. The total heat absorption under this peak is 7 cal/mol, the excess entropy change at this point being only 0.044 entropy unit.

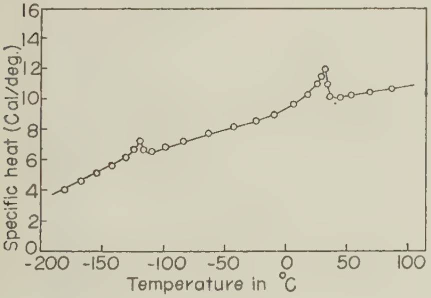

Fig. 5. The curve of the specific heat versus temperature of $CrS_{1.17}$.

§ 5. X-ray Analysis

For the purpose of detecting any change of crystal structure corresponding to the magnetic transition at −120°C, powder diffraction photographs were taken at room temperature and below −120°C. A modefied X-ray camera of the Ubbelohde[4] type was used, the detail of which is as shown in Fig. 6.

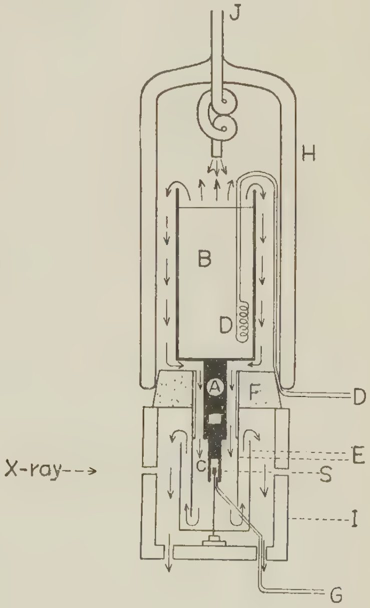

Fig. 6. The low temperature X-ray camera.
A, copper rod; B, copper container for cooling medium; C, copper rod; D, heater; E, cellophane sleeve with glass stiffing; F, corke table; G, thermocouple; H, Dewar vessel; I, cassette; J, glass tube for supply of cooling medium; S, specimen.

The diameter of the camera was 70 mm. Rotating specimen S was cooled by both the cooled copper rod A attached at the bottom of liquid air container and the flow of cooled air evaporated from it. The control of the temperature of the specimen was made by adjusting the contact between the copper rods C and A as well as the flow of cooled air. The evaporation control of liquid air was made by means of adjusting the power supply in the heater D in B, thus the adjustment of temperature of the specimen could range from −100°C to −150°C. As the X-

* not to be observed.

ray scattering occurred by frost adhered to the circumference of the specimen, the freezing of frost was avoided by setting a cylindrical wall of selophan E and flowing cooled air in the direction of arrow sign in the figure. The result of X-ray analysis at room temperature is as shown in Table I. As it shows the compound $CrS_{1.17}$ has the crystal structure of NiAs type and the unit length of a and c axes are 3.45 Å and 5.76 Å respectively, its axial ratio c/a being 1.67. These results coincide with those of Haraldsen. The result of X-ray analysis below −120°C is as shown in Table II; any appreciable change of crystal structure from that at room temperature was not recognized and it was ascertained that the lattice contracts 0.29% and 0.39% along the directions of a and c axes respectively. Such a contraction is probably due to the ordinary thermal contraction, as the thermal expansion coefficient 1.8×10^{-5} in the direction of a axis and 2.2×10^{-5} in that of c axis are sufficient to reproduce such a contraction.

Table II. The result of X-ray analysis at −140°C.

−140°C	3.44 Å	5.74 Å	1.67
	$\Delta a/a=0.29\%$	$\Delta c/c=0.35\%$	

A power photograph at room temperature was also taken by using an X-ray camera with the diameter of 114 mm and the abovementioned results in Table I were confirmed. However, several diffraction lines besides the proper lines of this crystal lattice were recognized in the range of small diffraction angles. These, correspond to a super-lattice structure, whose c axis and a axes are, respectively, twice and $2\sqrt{3}$ times greater an those of the original nickel arsenide pe lattice. According to Haraldsen, the me super-structure* exists the composition ar $CrS_{1.00}$ but not at the composition of $S_{1.17}$.

6. Discussions

Now we discuss the mechanism of abrupt ange of magnetism at −120°C. The pos- bility of the structural change of crystal at is transition point may be excluded because the negligible difference of the X-ray wder patterns found above and below the ansition point and the very small heat sorption observed at this temperature (only cal/mol, cf. § 4 and 5).

It was suggested by Haraldsen and Neuber, at the ordered structure of ions or vacancies as found at the composition $CrS_{1.00}$ (para- agnetic), while, such super-lattice lines anished at the composition $CrS_{1.17}$. They nsidered from these results that the dis- ppearance of the super-structure is respon- ble for the appearance of ferrimagnetism. owever, as reported in section 5, the same iffraction lines corresponding to the above- entioned ordered structure were found by s both for paramagnetic and ferrimagnetic ompounds, and hence such a super-structure considered to have no direct relation to e observed ferrimagnetism and the magnetic ransition at −120°C.

As for the cause of the magnetic transi- ion mentioned above, some kind of the riangular arrangement of the magnetic oment of cations may be considered. In e compound $CrS_{1.17}$ two kinds of cations r^{2+} and Cr^{3+} coexist in the same crystal ttice. In such a case it was concluded pre- iously basing on the molecular field theory[5] at the magnetic moment of each kind of cations orient to different directions respectively, making the so-called triangular spin arrangement in the crystal lattice. It was also inferred from the same theory that more than two stable or metastable directions of the resultant magnetic moment of each kind of cations will occur at a certain temperature during heating or cooling, and an abrupt change of total magnetic moment of the substance will be expected owing to the discontinuous change of the angle between the magnetic moments of cations. The resultant magnetic moment of each kind of cations remain unchanged while the total magnetic moment of the crystal is largely changeable; such a magnetic transition will not be accompanied by any latent heat or heat absorption, this theoretical result coinciding with the fact that a very small heat absorption was observed at the transition. It was also shown previously that a ferrimagnetic behavior of the crystal can be expected from the model of the triangular spin arrangement, and then the above-mentioned abrupt decrease of the reciprocal susceptibility during cooling just above the Curie point is expected from the same point of view.

Preliminary Report on an Electromagnetic Isotope Separator

By Jun OKANO

Department of Physics, Faculty of Science, Osaka University

(Received October 16, 1956)

As a first step towards constructing a high intensity electromagnetic isotope separator, the focussing characteristics of the Smythe type magnetic lens was investigated. And for preliminary experiments of isotope separation, we constructed a small mass separator of this type. The apparatus has the ion radius of 50 cm in the magnet, and has two ion sources which can be operated independently and simultaneously. The ion source was a sort of Finkelstein type and its characteristics was investigated in conjunction with the electrostatic lens system. The maximum ion current on the collector that was attained was about 400 μa and 1 ma for neon and for magnesium respectively.

§ 1. Introduction

In 1934 Smythe et al[1] constructed a mass-spectrometer with a special type of magnetic lens capable of focussing on a collector all the positive ions of the definite mass from a wide area of the ion source. They separated alkaline metals emplying an ion current of 0.1 ma for K^{39}.

From 1938 to 1949 medium size electromagnetic separators were constructed by Walcher.[2] Koch,[3] Bergström[4] et al. The collector currents in these separators were of the order of 10–100 μa. Recently the intensity of the electromagnetic separator has been increased remarkably mainly due to the success in the neutralization of space charge in the ion beam. Bernas[5] constructed a 60° type electromagnetic separator and was able to increase the collector current up to about 10 ma. He used grids of negative potential in order to trap the electrons in the ion beams and succeeded in neutralizing the space charge of positive ions.

Kistemaker and Zilverschoon[6] built a large elcctromagnetic separator and operated the apparatus with a collector current of 1–10 ma. In Oak Ridge[7] and Harwell[8] large scale separators were constructed and the collector currents of these separators were of the order 10–100 ma.

With the recently constructed separators, the ion currents at the collectors are of the order of 1–100 ma. Because the collector current is firstly limited by the area of the source slit through which ions are drawn out, it is necessary to use an exist slit with a large area in order to get a high intensity. In the case of a magnetic lens of first order focussing, increasing the width of the source slit results in the corresponding broadening of the image and decreasing of the resolving power. It follows from this that in order to increase the area of the slit without decreasing the resolving power, an increase of the length of the slit is necessary. However, the increase of the length requires an increase of the magnet pole gap, which may be too expensive. Therefore, it may be more efficient to utilize as an analyzing field of an isotope separator a magnetic lens which is capable of focussing completely on a collector all the ions of the definite mass from a wider source slit.

From this standpoint Smythe type magnetic lens, which is able to focus completely a very wide incident beam of parallel ions on a collector, is considered to be one of the most appropriate as an analyzing field of the isotope separator. We investigated the focussing characteristics of the Smythe type magnetic lens and constructed a small mass separator of this type for preliminary experiments of isotope separation.

Practically, if we use a special type of ion source such as Kunsmann-source, a very wide source slit is available. However, when a more general type of source like arc source is used, it may be difficult to regulate by the electrical lens system the path of ions from the extremely large slit. Then it may be advantageous to employ instead of one source two or more independent sources that are parallel to each other, and to operate them multaneously and superpose the images from hese sources on one collector.

And also it is advantageous to use a multiource, because by adjusting the accelerating oltage slightly it is possible to avoid the roadening of the image due to the imperfecon of the homogeneity of the magnetic field nd because the multisource is beneficial for xchanging the charge material and for inimizing the time for the preparation.

In the following we describe the results of he consideration with respect to some haracteristics of this magnetic lens which re important when it is used as an analyzing ield of the electromagnetic separator and the esults of preliminary experiment of the isoope separation using a small separator of his type.

§ 2. The Characteristics of Smythe Type Magnetic Lens

Let us consider incident ions running parallel to each other and designate the direction of the path of incident ions as the x-axis. And let the mass and energy of the ions be M and eE respectively.

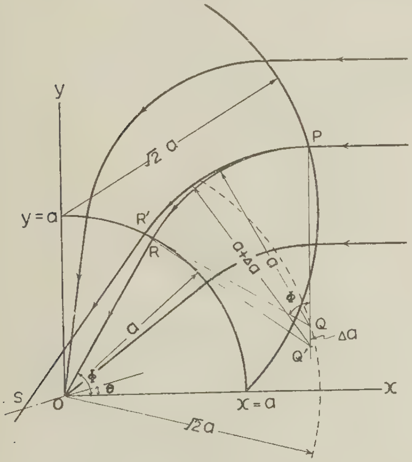

Fig. 1. Focussing property of Smythe-type magnetic lens.

As shown in Fig. 1 ions entering the magnetic field at P will run on a circle with center Q, and radius a, and be deflected by the angle Φ. After leaving the magnetic field at R, the ions pass through the point O. Ions of mass $M+\Delta M$ in the magnetic field run on a somewhat different circle with center Q', and radius $a+\Delta a$ where

$$\Delta a \approx \frac{a}{2}\,\frac{\Delta M}{M} \tag{1}$$

when

$$\frac{\Delta M}{M} \ll 1$$

They leave the magnetic field at R' and pass through the point S on a focal plane which crosses the x-axis at point 0 with an angle θ. The distance $\overline{OS}$ is the mass dispersion, δ_m, for mass difference $\Delta M/M$, and is given by

$$\overline{OS} = \delta_m \approx \frac{\Delta a(1-\cos\Phi+\sin\Phi)}{\sin(\Phi-\theta)} \tag{2}$$

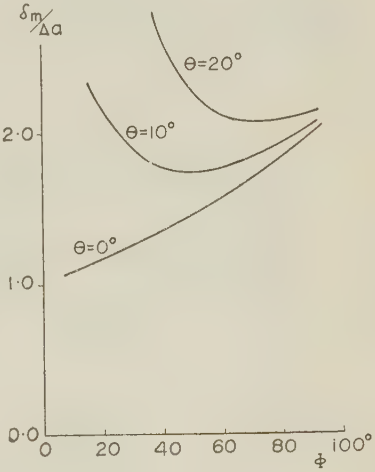

Fig. 2. Mass-dispersion of Smythe-type magnetic lens as a function of Φ. Parameter θ is the angle between the x-axis and the focal plane.

δ_m is plotted as a function of Φ in Fig. 2 for $\theta=0°$, 10° and 20°. As it is desirable to have a constant value of δ_m on a focal plane for the change of Φ, the angle θ for the most appropriate focal plane is determined from the minimum point of the curve plotting δ_m versus Φ. If the part of this magnetic lens, $\Phi=45°\sim90°$ is used, the appropriate value of θ is found between 10° and 25°. θ may also be determined by a graphical method. But in practice the actual focal plane will be somewhat different from that estimated by the above described method mainly due to the effect of the fringing field.

Fig. 3 shows the path of ions emitted from the point P at all angles within the range α. The resultant breadth at the focal plane is

$$\delta_\alpha = a\alpha\left(\frac{\sin\Phi+\cos\Phi}{\sin(\Phi-\theta)}\right), \quad \alpha \ll 1 \tag{3}$$

which determines the breadth of the image due to an imperfection in the parallelity of incident ions. The value of δ_α given by eq. (3) is plotted as a function of Φ in Fig. 4. If Φ increases, δ_α decreases and vanish at $\Phi=135°$ where a first order focussing with respect to α is accomplished but $\Phi=135°$ does not correspond to the practical case because the path of incident ions is tangentially to the boundary of the magnetic field.

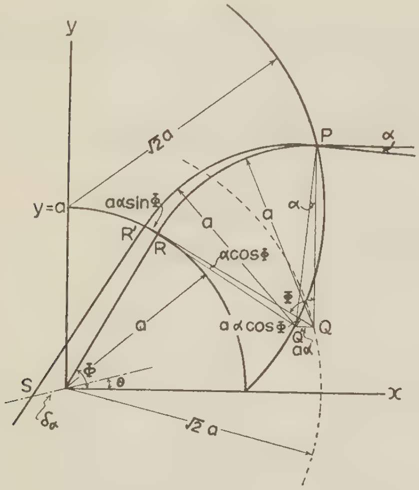

Fig. 3. Arration due to α. (δ_α)

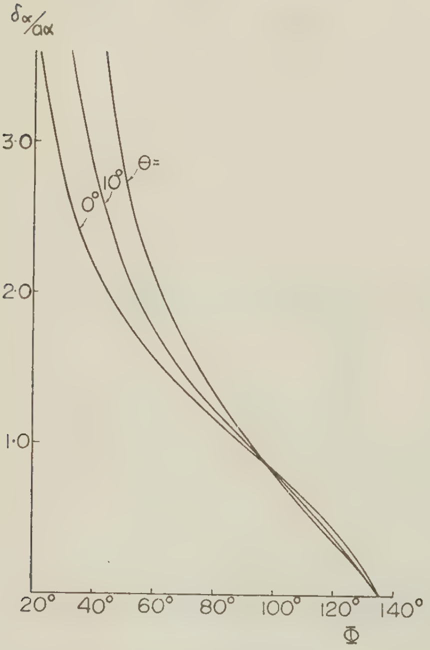

Fig. 4. Values of the aberration due to the imperfection of the parallelity of paths of incident ions as a function of Φ.

In the range of $\Phi=45°-90°$ δ_α is of the order of $a\alpha - 3a\alpha$ when θ is less than 20°.

If the path of incident ions is parallel to the x axis, an incident angle to the magnetic field, that is, the angle between the path of incident ions and a normal to the boundary of the magnetic field at the point of incidence is given by

$$\mathcal{E}'=\Phi-\frac{\pi}{4} \tag{4}$$

When $\mathcal{E}'\not\approx 0$, the magnetic lens has an action of three dimensional focussing. Let us take the Z-axis parallel to the direction of the magnetic field. Then the Z direction focal point is given by

$$G''=a(\operatorname{ctg}\mathcal{E}'-\Phi) \tag{5}$$

where G'' is the distance between the Z direction focal point and the boundary of the magnetic field.

In Fig. 5 G''/a is plotted as a function of Φ showing that it is infinity at $\Phi=45°$ and unity at $\Phi\approx 69° 20'$. And so three dimensional focussing is achieved when $\Phi\approx 69° 20'$. In Fig. 5 the Z-direction magnification factor m_z of the image is also plotted. m_z is larger or smaller than unity according as $\Phi<45°$ or $45°<\Phi<84°$. In the case of an electromagnetic separator the perfect three dimensional focussing is not necessary but it is

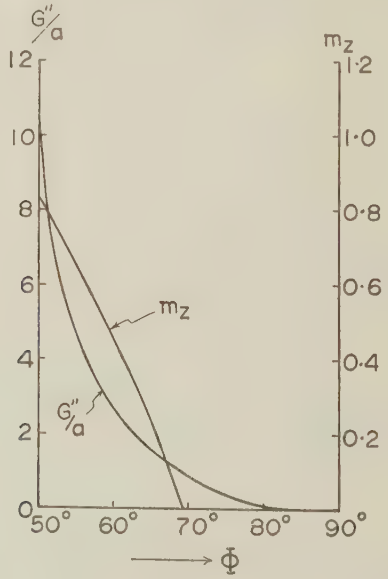

Fig. 5. Z-direction focal length G'' and z-direction magnification factor m_z of Smythe-type magnetic lens as a function of Φ.

desirable that the magnetic lens has Z-direction focussing action and the Z-direction magnification factor of the image is smaller than unity.

Although a Smythe type magnetic lens is considered one of the most appropriate magnetic lens for an analyzing field of an electromagnetic isotope separator, it is necessary to keep in mind the characteristics described above and to select the range of Φ from the practical standpoint.

In order to confirm the practical possibilities of focussing high current ion beam, a preliminary experiment has been carried out with a Smythe type mass-spectrometer which has two sources at $\Phi=53°$ and 67°. In Table I the mass dispersion δ_m, the aberration due to α and Z-direction magnification factor m_z of the image are given for $\Phi=53°$ and 67° assuming that the boundary of the magnetic field is sharp and there is no stray field.

Table I.

	θ \ Φ	53°	67°
δ_m $(\Delta a/a \ll 1)$	10°	$1.75\Delta a$	$1.82\Delta a$
	20°	$2.22\Delta a$	$2.08\Delta a$
$\delta\alpha$ $(\alpha \ll 1)$	10°	$2.05a\alpha$	$1.56a\alpha$
	20°	$2.55a\alpha$	$1.82a\alpha$
m_z		0.73	0.14

§ 3. Apparatus

The mass-spectrometer that was built in this work is shown schematically in Fig. 6.

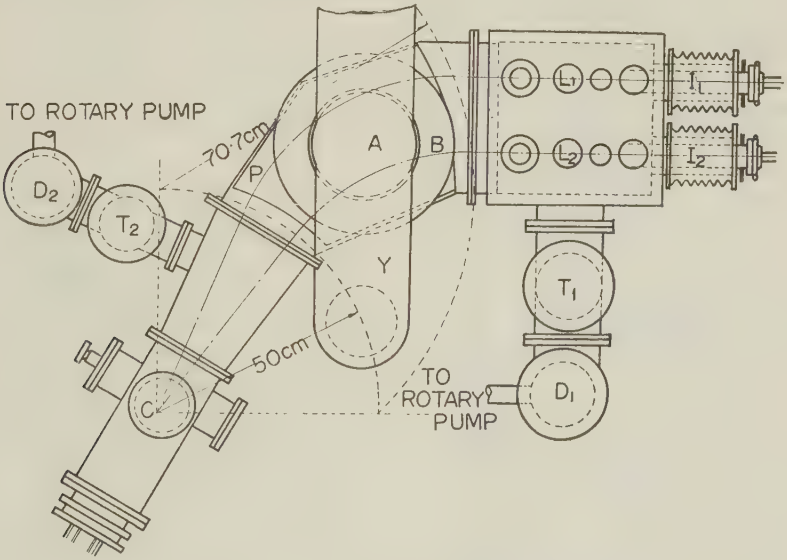

Fig. 6. Schematic diagram of the isotope separator constructed for this work. I_1, I_2: ion source; L_1, L_2: electrostatic lens; Y: yoke; A: core; B: coil; P: pole piece; C: collector; T_1, T_2: liquid air trap; D_1. D_2: diffusion pump.

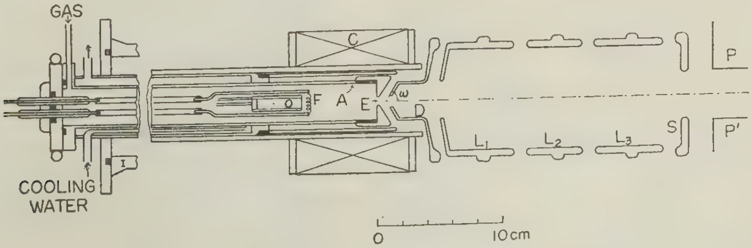

Fig. 7. Schematic diagram of the ion source and the electrostatic lens. I: insulator; O: oven; F: filament; A: anode; E: exit slit; D: draw out electrode; S: electrode for space charge neutralization; L_1, L_2, L_3: electrostatic lens; P, P': pole piece.

Two ion sources are placed 15 cm appart from each other in a casing with openings to a high vacuum pump. Ions are drawn from the plasma of the arc of the ion source by an electric field, and by passing through the electrostatic lens, consisting of three cylinders, a beam of ions is formed. Then the enter the magnetic field where they are deflected by the angle Φ (53° or 67°).

In Fig. 7 the ion source and the electrostatic lens are shown. The ion source is a sort of Finkelstein type. The anode is a copper cylinder, the inside diameter of which is 30 mm. At the end of the anode cylinder a stainless steel diaphragm is mounted which has in the center a hole of 6 mm diameter. From the hole ions are drawn out by an electric field. The filament is a 0.3 mm tungsten wire. When the element to be separated isotopically is a metal, an oven is inserted behind the filament as shown in Fig. 7. The inner wall of the oven is made of molybdenum sheet and the outer wall is an insulator surrounded by tungsten wire as a heater. At the filament side of the oven there is a small hole, of 2 mm diameter, from which metal vapor diffuses to the space where they are ionized by electron impact. Outside of the anode cylinder a coil is mounted which produces an axial magnetic field up to 600 gause in the ionizing space.

The angle ω between the conical surface of the ion draw out electrode and the beam axis, shown in Fig. 7, was determined experimentally so as to produce a high current ion beam with a small divergence. Now we choose $\omega = 60°$ as this angle. The electrostatic lens consists of three stainless steel cylinders, the inside diameter of which is 82 mm. As the diameter of the ion beam in the electrostatic lens is 20–30 mm in this experiment, the spherical aberration of this lens is considered fairly small. At the end of this electrostatic lens near the analyzing magnetic field a diaphram is placed, which has a circular hole of 36 mm diameter at the center. This diaphram is useful for neutralizing the space charge in the ion beam and for protecting the pole face of the magnet from the bombardment of ions. As the ion source and the electrostatic lens have high positive potentials, if there is on potential barrier, electrons in the ion beam escape to the source side, but if a barrier exists which is given by a negative potential supplied to this diaphragm, the electrons are retarded to the collector side, and trapped in the ion beam, compensating the positive space charge in the ion beam.

The radius of the path of ions in the magnetic field is 50 cm. The total weight of the magnet is about 500 kg and the gap between the pole faces is 40 mm. The maximum field is about 2500 gauss which limits practically the number of elements that can be separated with this apparatus. The pole pieces of the magnet are used at the same time as walls of the vacuum chamber.

The collector consists of pockets made of 0.5 mm thick copper sheets, the back side of which is in contact with the brass plate cooled by water as shown in Fig. 8. In front of the collector a shutter is placed. Ion beams are visible clearly at the front of the collector through windows of the collector chamber in two directions; one is vertical and another is horizontal. In practice this is very convenient for adjusting the conditions of the ion source and the electrostatic lens and for watching the intensity and the sharp-

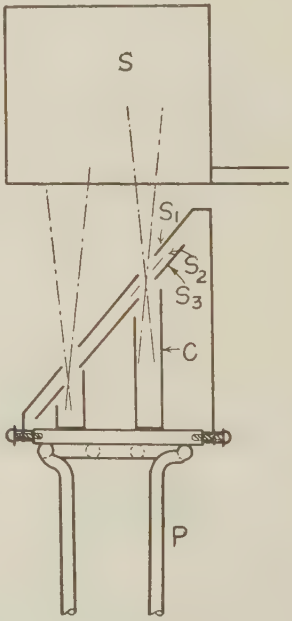

Fig. 8. Collector. S: shutter; S_1: collector cover; S_2: probe for detecting the deviation of the image position; S_3: secondary electron suppressor; C: collector pocket.

ness of the image during a separation run.

Two 6″ oil diffusion pumps are used. One is mounted on the casing of the ion source and another on the chamber placed between the pole chamber and the collector chamber. Liquid air traps are placed between the pumps and the chambers. The effective pumping speed is about 800 liters/sec. The pressure in the vacuum chamber is $(1-3)\times10^{-5}$ mmHg during operation.

The block diagram of the power supply and the control system is shown in Fig. 9. During the process of the adjustment the accelerating voltage is modulated by 60 cycles and the out put current from the collector is driven to the vertical deflection plates of an oscilloscope. A part of the modulated voltage taken from the earth side of the potential divider provides the horizontal deflection. By this device it is possible to observe mass spectra on the oscilloscope screen which gives immediately the information with respect to the sharpness of the image and the beam intensities of all the ions produced in the ion source.

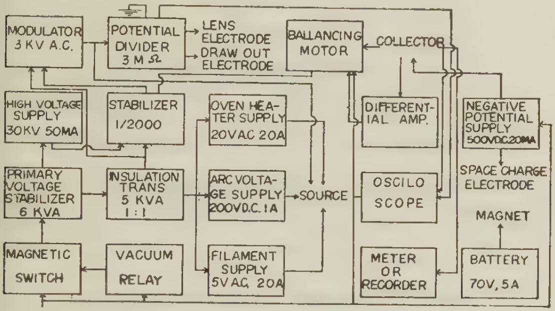

Fig. 9. Block diagram of the power supply and the control system.

During the operation time, a device similar to that used by Zilverschoon et al,6) for an automatic control of the image position was employed in order to compensate for the imperfection of the stabilities of the accelerating voltage and the magnetic field strength.

§ 4. Experimental Results

(1) Ion Source and Eectrostatic Lens

The gas pressure in the ion source 10^{-3}—10^{-4} mmHg. The gas was supplied from the reservoir at the rate of about 4.10^{-3} liters. mmHg/sec. Ion current drawn out of the source decreased exceedingly when the pressure in the source was below 2.10^{-4} mmHg. The optimum magnetic field strength of the source, which was a function of the arc voltage, was between 200 gauss and 500 gaues.

As shown in Fig. 10 the total ion current I_t drawn out of the source, which did not include the current flowing into the ion draw out electrode, increased with the increase of the arc current which was varied by changing filament current. But at some point it reached the maximum, and further increase of the arc current resulted in the decrease of the ion current. This might be caused by the fact that the ion beam diverged with the increase of the arc current and the greater part of the current flowed into the drawing

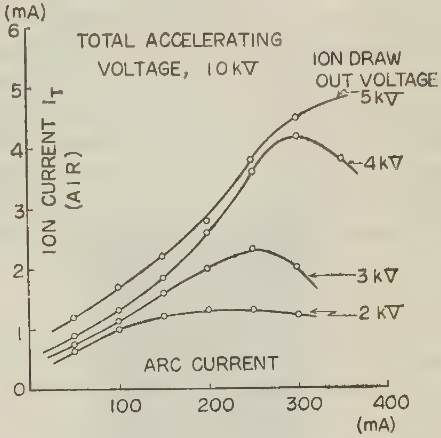

Fig. 10. Total ion current vs. arc current.

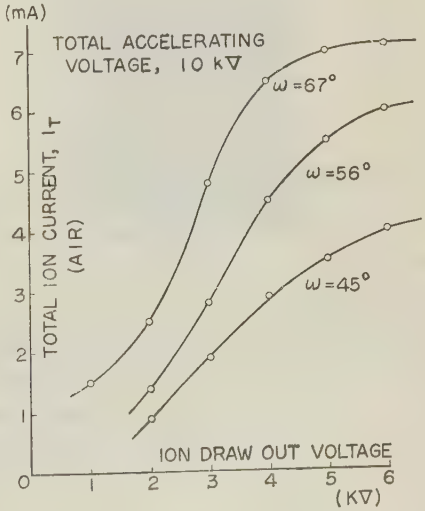

Fig. 11. Total ion current vs. ion draw out voltage.

out electrode. The results shown in Fig. 10 indicate also that the stronger electric field is capable of drawing out the larger ion current within the range of 2–5 kv.

Fig. 11 shows the relation between the total ion draw out voltage for three sorts of angles of the ion draw out electrode which is designated as ω in Fig. 7. The larger ω resulted in higher ion current but in weaker converging action of the ion beam, other conditions being the same. It was desirable to keep the diameter of the ion beam in the electrostatic lens less than one to three times the diameter of the diameter of the electrostatic lens electrode. We chose 60° for ω with a satisfactory result.

Fis. 12 shows the results for the focussing properties of the electrostatic lens. The ion current, which is designated as I_c in Fig. 12, was detected at the Faraday cage about 20 cm distant from the end of the electrostatic lens after passing through the circular slit of 20 mm diameter. Only at optimum conditions of both the lens potential and the ion draw out voltage a shap beam of parallel ions could be formed.

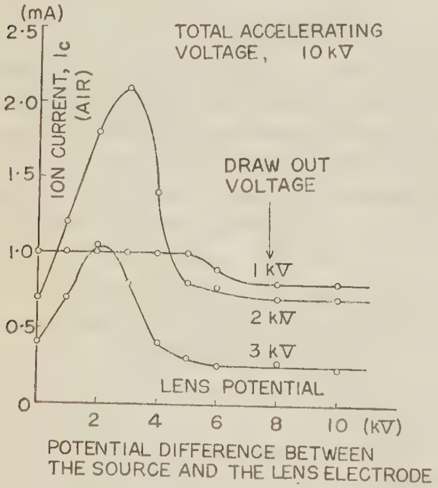

Fig. 12. Variation of ion current with the lens potential.

After adjusting the rats of gass supply, the arc current, the magnetic field of the source, the ion draw out voltage and the lens potential to an optimum condition for producing an intense beam of parallel ions, the accelerating voltage was varied and the ion current I_c was measured in the same way as the case of Fig. 12. The result is shown in Fig. 13. After all, several milliampares of beam current was obtained from our source and lens system. The diameter and the parallelity of the beam could be varied by changing the ion draw out voltage and the lens potential.

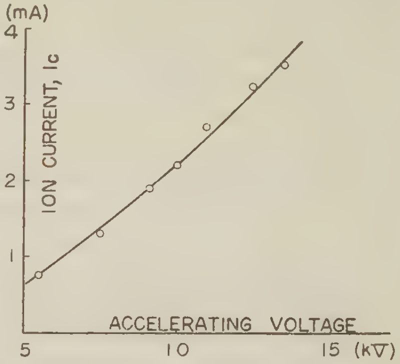

Fig. 13. Ion current vs. accelernting voltage.

(2) Neutralization of Space Change

After these experiments, the sources were mounted on the spectrometer. The image formed at the collector was observed on the oscilloscope screen by the way described previously, or viewed directly through the windows of the collector chamber. At first some tens of microampares of the ion current were obtained at the collector. But increasing the ion current still more resulted in an extremely large divergence of the ion beam due to space charge and therefore in a broadened image.

This result was expected from a rough estimation[3)] of the space charge divergence of the beam by the following relation. Let us consider a beam of parallel ions which has a circular cross section with radius r_0 passing at $Z=0$ and moving into a field free space along the Z axis. After passing through a distance Z, the radius r of the beam gets greater as a result of the mutual repulsion of the ions. The ratio r/r_0 is given by[19)3)]

$$r/r_0 \approx 1.137\cdot 10^{-2}\,(A.J_0^2/E^3)^{1/4}Z \qquad (6)$$

where

A: mass number of ions
E: accelerating voltage in kv
J_0: current density at $Z=0$ in microampare/cm²
Z: distance in cm

This relation has an accuracy of less than 10% in the interval of $1.3 < r/r_0 < 5$.

In Fig. 14 J_0 calculated from Eq. (6) is plotted as a function of A when the accelerating voltage is 10, 20 and 30 kv, Z=100 cm. r/r_0= 1.5. In this experiment an accelerating voltage in the range 10–12 kv was used and length of the path of ions was about 100 cm. And so in the case of ions of neon gas, A=20, it was expected from Fig. 14 to be impossible to obtain an ion current greater than some tens of microampares at the collector as a sharp beam without neutralizing the space charge there.

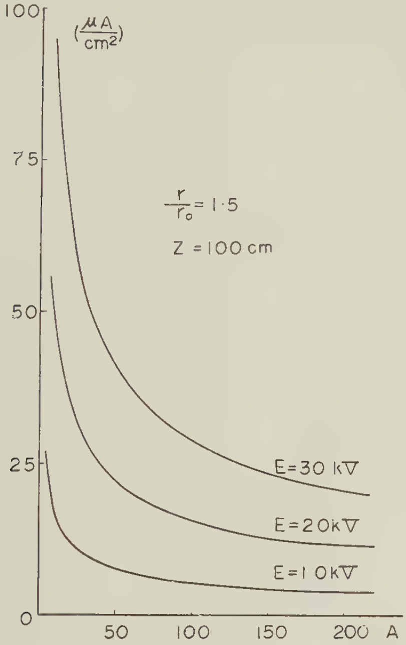

Fig. 14. Space charge divergence of ion beams having circular cross sections.

In order to compensate the space charge of ions by trapping electrons in the ion beam, a negative potential of several hundred volts with respect to the earth was supplied to the diaphram placed at the end of the electrostatic lens system and the potential barrier was prepared to prevent the electrons from escaping into the surce side.

The results were successful and a sharp image was obtained even at several hundred microampares of the collector current. In Fig. 15 are shown photographs of the horizontal view of the neon beam in front of the collector when the negative potential is supplied to the electrode (Fig. 15a) or not (Fig. 15b). The ion current in this case was about 200 microampares for the neon 20 beam, and the ion accelerating voltage was 12 kv. The resolving power was about 60. In Fig. 16 photographs of neon spectra on the oscilloscope screen are shown, taken when the negative potential was varied from 0 volt to −300 volts. When the negative potential increased more than −150 volts, change of

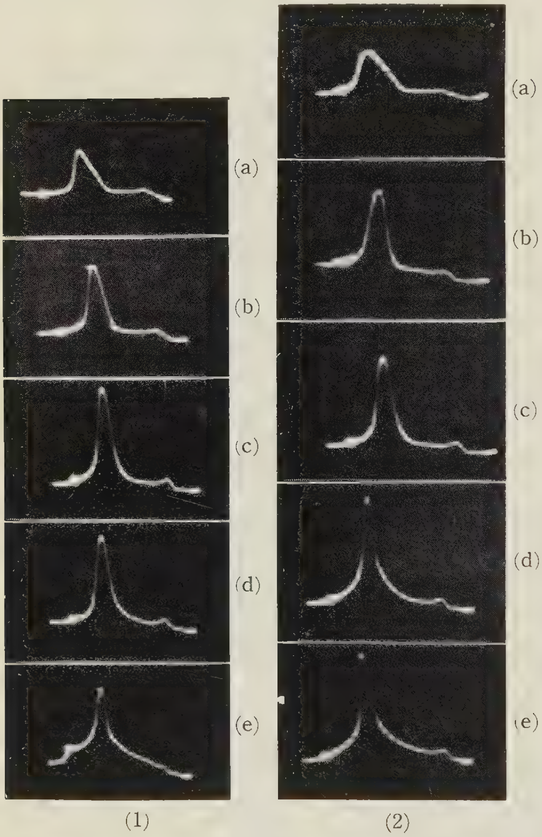
the image form was not remarkable. From the comparison of Fig. 15 a and b or Fig. 16 and d, it is obvious that the neutralization effect is important for getting sharp image and intense ion currents in this experiment.

(3) Characteristic of the Collector Current

In Fig. 17 photographs of mass spectra of neon on the oscilloscope screen showing the variation of the image form with change of the arc current and the magnetic field strength of the ion source are shown. It is seen from the comparison of Fig. 17–1 and 17–2 that the increase of the arc current gives image form somewhat similar to that due to the increase of the magnetic field strength. It is supposed that in both cases the change of the image form is mainly due to the deformation of the equipotential surface near the exit hole of the ion source.



(1) (2)

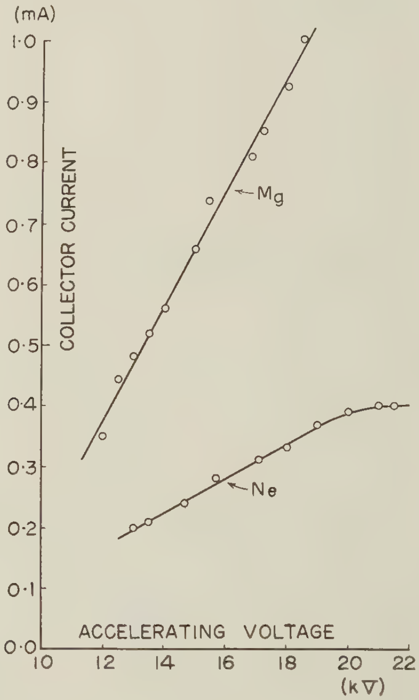

Fig. 18. Collector current vs. accelerating voltage.

The accelerating voltage was raised to about 20 kv and the collector current was measured for neon and magnesium. The results are shown in Fig. 18. Since in the case of magnesium the loss due to scattering by residual gas is smaller than in the case of neon, an ion current two or three times larger is obtained. The maximum collector current obtained from one source was about 1 ma for magnesium and 400 *μa* for neon.

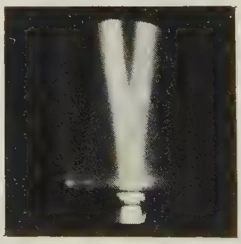

Fig. 19. Neon beams at the front of the collector from two independent sources. ion current (Ne^{20}): 400 μa.

In Fig. 19 is reproduced the photograph of neon beams at the front of the collector showing Ne^{20} beam from two independent sources which are superposed on the collector slit. From the photograph it is possible to determine the focal plane experimentally. The angle θ between the focal plane and the x axis is estimated at 17° by the graphical mathod or by the method of Fig. 2. In this apparatus two sources, which give $\Phi=53°$ and 67° respectively, are used and the experimental results obtained from the photograph give $\theta=25°$ which is somewhat larger than that obtained by the graphical method. In the graphical method or the method of Fig. 2, the boundary of the magnetic field is assumed to be sharp but in practice the radius of the circles of the bounderies are corrected for the fringing field by the length of the pole gap. It is considered that the difference between experimental and graphical θ is mainly due to the imperfection of the correction of the fringing field.

It was observed that the width of the ion beam in the Z-direction at the front of the collector coming from the source of $\Phi=67°$ was smaller than that from the source of $\Phi=53°$, which was reasonable result expected from the Z-direction focussing properties of this magnetic lens discussed in section 2. But no quantitative study on the Z-direction focussing has been carried out as yet.

§ 4. Example of the Separation of Neon and Magnesium

A few experimental separation run will be shown in order to get information for the stability of the instrument.

a. *Neon*

The operating conditions were:

charge material	neon gas
natural abundance	20 90.00% 21 0.27% 22 9.73%
accelerating voltage	15 kV
arc	170 V, 100 ma
source magnetic field	360 gauss
ion draw out voltage	1.5 kV
lens potential	14 kV
negative potential for space charge neutralization	−200 V
pressure in the vacuum chamber	3.10^{-5} mmHg
collector current (total)	200 μa
collector material	0.18 mm thick nickel sheet

The collection method was similar to that of Koch3). After degassing a nickel sheet by high frequency heating in high vacuum at about 800°C, it was mounted in the collector and irradiated to the ion beam for about one hour. Then it was taken out of the collector chamber and set in a small discharge tube as one of the electrodes. The discharge tube was evacuated and sealed off. After these procedures the electrode was heated up to about 800°C. A side tube of the discharge tube was cooled by dry ice and the discharge was started. We could observe the brilliant neon discharge. The volume of the discharge tube was about 10 cc and the neon pressure in the tube was 10^{-1} mmHg. The gas contained in the tube was analyzed by the mass-spectrometer, and the isotopic purities for neon 20 and 22 samples were measured and estimated at 99% and 80% respectively.

b. *Magnesium*

A ribbon of magnesium metal was inserted in the oven which was placed in the anode cylinder of the ion source, and the temperature of the oven was raised gradually up to about 500°C. During this process neon gas was supplied to the ion source as a starting gas and the source was kept at the operating state. When evaporation of magnesium began, the arc current increased suddenly, then the supply of the starting gas was stopped. The operating conditions were:

charge material	metallic magnesium
natural abundance	24 77.4% 25 11.5% 26 11.1%
arc	150 V, 300 ma
source magnetic field	300 gauss
ion draw out voltage	1.2 kV
lens potential	11 kV
negative potential for space charge neutralization	−200 V
pressure in the vacuum chamber	1.10^{-5} mmHg
collector current (total)	300 μa
collector material	0.5 mm thick copper sheet

After a separation run of about 3 hours, the target was taken out of the chamber, and a quantitative chemical analysis was carried out. About 500 micrograms of magnesium 24 were detected from the target. The check of the isotopic purity was not done.

§ 5. Conclusion

A consideration for some properties of the Smythe type magnetic lens was described and a preliminary experiment of the electromagnetic isotope separation was carried out. With an ion exit hole of 6 mm diameter we obtained maximum ion current of the order of 1 ma and the resolving power of about 60 under normal operating condition. In order to get higher resolving power it is necessary to adjust finely the incident direction of ion beams to the magnetic lens, and to move the collector so as to locate it on the actual focal plane. The energy spread of ions drawn out of the source, an imperfection of the alignment of source and lens system, the aberration of the electrostatic lens, a fringing field of the magnetic field, and the scattering of ions by residual gas are considered to have some effects on the broadness of the image, but they were not studied systematically in this experiment.

By increasing the accelerating voltage it is possible to minimize the broadening of the image caused by the energy spread of ions and the scattering by the residual gas. A part of the aberratian of the electrostatic lens may be avoided by an enlargement of the lens diameter. As for the fringing field effect it is necessary to carry out a systematic study.

As shown is Fig. 18 the collector current increases with the increase of the accelerating voltage up to 20 kV. But at about 20 kV it is saturated in the case of neon. This characteristics is similar to a space charge limited current of a diode. The saturation current may be limited mainly by the area of the ion exit hole unless this type of source is employed. It is necessary to use a high enough accelerating voltage to draw out the saturation current and to use as wide an area of the source slit as possible in order to get a high current and to operate an electromagnetic separator most efficiently.

The space charge in the ion beam is compensated successfully by trapping electrons in it and it is considered that the divergence of the ion beam caused by the space charge is no longer a serious obstacle for getting a high current and a sharp image at the collector.

Acknowledgement

The author is indebted to Prof. K. Ogata for his guidance and encouragement throughout this study. The auther wishes to express his gratitude to Prof. T. Hayakawa and Mr. S. Yamashita who kindly carried out the quantitative chemical analysis of the enriched magnesium and to Mr. Y. Kobayashi and Mr. Y. Yoshikawa for their kind help in the mass-spectrometric analysis of the enriched neon gas.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 4, APRIL, 1957

On the Transonic Flow of a Compressible Fluid Past an Axisymmetric Slender Body at Zero Incidence

By Ken-ichi KUSUKAWA

Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received November 20, 1956)

The high subsonic flow past a slender body of revolution placed along the axis of a circular cylindrical wind tunnel at zero incidence is discussed. Neglecting the square of the perturbation velocity q'^2 in comparison with q' and the spatial derivatives of q'^2, making use of a certain transformation of variables, the fundamental equation for determining the perturbation stream function of this transonic flow can be reduced to the equation which is formally equal to the fundamental equation of transonic flow past a two-dimensional body placed along the center line between two parallel flat walls. Considering the transonic similar solution due to von Kármán and the general similarity rule of the axisymmetric transonic flow derived by Oswatisch and Berndt, we can obtain very easily the surface pressure coefficient C_{pax} of an axisymmetric flow, provided the surface pressure coefficient C_{p2} of a two-dimensional flow can be found.

As an example the pressure distribution on the surface of a paraboloid of revolution of finite length at Mach number 1 is obtained.

§ 1. Introduction

As is well known, the so-called linearized theory cannot be applied to the transonic flow of a compressible fluid, because the non-linear term in the fundamental equation becomes to contribute essentially to the character of the solution in the vicinity of the sonic point. In this case it is necessary to consider the fundamental equation of the transonic approximation due originally to von Kármán[1]. While the fundamental equation of the transonic flow in two dimensions can be reduced to a simple linear equation (so-called Tricomi's equation) in the hodograph plane, that of the axisymmetric transonic flow remains non-linear in the hodograph space as well as in the physical space. Owing to this reason there have been few examples of the axisymmetric flow treated by this transonic approximation: the discussion of the singularity of a particular solution at infinity,[2] the flow past a slender cone-cylinder[3] studied by the relaxation method, etc....

In this paper the fundamental equation is represented in a form for determining the perturbation stream function ψ instead of the perturbation velocity potential φ. Considering the fact that at the sonic point the square of the perturbation velocity q'^2 takes a minimum value which is zero and that the spatial derivative of q' may take a finite value where q' vanishes, we may neglect q'^2 in comparison with q' and the spatial derivatives of q'^2. Thus the fundamental equation for determining ψ can be reduced to an equation which is formally equal to the fundamental equation of transonic flow in two-dimensions. Considering the relation between the boundaries of axisymmetric and two-dimensional flows, the transonic similar solution due to von Kármán[1], and the general similarity rule due to Oswatisch and Berndt[4], we can obtain very easily the velocity distribution on the surface of an axisymmetric slender body, provided the velocity distribution on the surface of a corresponding two-dimensional symmetric body is known. The latter can be found, in principle, by solving Tricomi's differential equation.

As an example, we investigate the velocity distribution at Mach number 1 on the surface of a paraboloid of revolution of finite length.

§ 2. Fundamental Equations

We now consider the high subsonic flow past a slender body of revolution which is placed along the centre line (axis) of a circular cylindrical wind tunnel at zero incidence. We shall take the cylindrical coordinates o-xy, where the x-axis is taken along the axis of revolution of the body and y denotes the distance from the axis. If we denote by u, v, the velocity components along the x- and y- directions and by ρ the density of the fluid, the axisymmetric irrotational flow of a compressible inviscid fluid is governed by the equations:

$$\frac{\partial}{\partial x}(\rho y u)+\frac{\partial}{\partial y}(\rho y v)=0\,, \tag{2.1}$$

$$\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}=0\,. \tag{2.2}$$

We shall introduce Stokes's stream function Ψ satisfying (2.1) such that

$$\rho y u=\partial\Psi/\partial y,\quad \rho y v=-\partial\Psi/\partial x\,, \tag{2.3}$$

then using Bernoulli's equation

$$(a^2/\rho)d\rho+q\,dq=0\,, \tag{2.4}$$

where $a=(dp/d\rho)^{1/2}$ is the local speed of sound and q is the magnitude of the velocity, Eq. (2.2) bocomes

$$\begin{aligned}(1-u^2/a^2)\Psi_{xx}-2(uv/a^2)\Psi_{xy}\\ +(1-v^2/a^2)\Psi_{yy}-\Psi_y/y=0.\end{aligned} \tag{2.5}$$

Instead of the velocity components u, v, we shall make use of the magnitude q and the angle of inclination θ of the velocity vector such that

$$u=q\cos\theta,\quad v=q\sin\theta\,.$$

For a slender obstacle we may assume that θ is very small, so that Eqs. (2.3) and (2.5) can be respectively approximated to

$$\rho y q=\partial\Psi/\partial y,\quad \rho y q\theta=-\partial\Psi/\partial x\,, \tag{2.6}$$

$$(1-q^2/a^2)\frac{\partial^2\Psi}{\partial x^2}+\frac{\partial^2\Psi}{\partial y^2}-\frac{1}{y}\frac{\partial\Psi}{\partial y}=0\,. \tag{2.7}$$

Since we deal with the transonic flow in the present paper, the perturbation analysis may be carried out as follows. Taking conveniently the magnitude q of the flow velocity and the density ρ of the fluid at the sonic point as their units, the magnitude of the perturbation velocity q', the perturbation density ρ' and the perturbation stream function ψ are defined as

$$q'=q-1,\quad \rho'=\rho-1,\quad \psi=\Psi-y^2/2\,. \tag{2.8}$$

Neglecting higher order terms, we obtain the following relations

$$\rho q=1-\Gamma q'^2,\quad 1-q^2/a^2=-2\Gamma q' \tag{2.9}$$

where $\Gamma=(\gamma+1)/2$, γ being the ratio of the specific heats. By the use of Eqs. (2.8) and (2.9), the equations (2.6) and (2.7) become respectively

$$-\Gamma q'^2=\frac{1}{y}\frac{\partial\psi}{\partial y},\quad \theta=-\frac{1}{y}\frac{\partial\psi}{\partial x}\,, \tag{2.10}$$

$$\pm 2\sqrt{\Gamma}\sqrt{-\frac{1}{y}\frac{\partial\psi}{\partial y}}\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}-\frac{1}{y}\frac{\partial\psi}{\partial y}=0\,, \tag{2.11}$$

where the positive and negative signs refer respectively to the sub- and the supersonic local velocities.

Now, at infinity upstream the velocity is equal to the uniform velocity U, and on the surface of the obtacle and the tunnel wall the gas must flow tangentially along the surfaces. Thus the perturbation stream function must satisfy the following conditions:

$$\left.\begin{aligned}\frac{1}{y}\frac{\partial\psi}{\partial y}&=-\Gamma(1-U)^2\\ \frac{\partial\psi}{\partial x}&=0\end{aligned}\right\}\ \text{at}\quad x=-\infty\,, \tag{2.12}$$

$$\psi+\frac{y^2}{2}=\Psi=0 \tag{2.13}$$

on the surface of the obstacle,

$$\frac{\partial\psi}{\partial x}=0\qquad\text{at } y=L\,, \tag{2.14}$$

where L denotes the radius of the wind tunnel. In the extreme case, where $1/L$ tends to zero, the obstacle can be considered to be placed in an unbounded uniform flow.

§ 3. Transformation of Variables

Introducing the following transformation of the variables:

$$x=l\xi,\quad \frac{3}{2}y^{2/3}=k\eta,\quad \psi=k^{-3}\omega(\xi,\,\eta), \tag{3.1}$$

where l and k are constants Eq. (2.11) is transformed to

$$\pm 2\sqrt{\Gamma_1}\sqrt{-\frac{\partial\omega}{\partial\eta}}\frac{\partial^2\omega}{\partial\xi^2}+\frac{\partial^2\omega}{\partial\eta^2}+\frac{8}{9}k^6\Gamma q'^2\eta=0\,, \tag{3.2}$$

in which

$$\sqrt{\Gamma_1}=\sqrt{\Gamma}/l^2\,. \tag{3.3}$$

The boundary conditions (2.12), (2.13) and (2.14) are respectively transformed to

$$\left.\begin{aligned}\frac{9}{4}k^{-6}\eta^{-2}\frac{\partial\omega}{\partial\eta}&=-\Gamma(1-U)^2\\ \frac{\partial\omega}{\partial\xi}&=0\end{aligned}\right\}\ \text{at}\ \xi=-\infty\,, \tag{3.4}$$

$$\frac{4}{27}k^6\eta^3+\omega=0\quad\text{on curve C, say,} \tag{3.5}$$

$$\frac{\partial\omega}{\partial\xi}=0 \quad \text{at} \quad \eta=L_1, \tag{3.6}$$

where the curve C in the ξ,η-plane should correspond to the meridian curve of the body of revolution, and

$$L_1=\frac{3}{2k}L^{2/3} \tag{3.7}$$

§ 4. Approximate Solution of Eq. (3.2)

The solutions of Eq. (3.2) subject to the boundary conditions (3.4) at infinity upstream must take the following form:

$$\lim_{\xi\to-\infty}\omega=-\frac{4}{27}k^6\Gamma(1-U)^2\eta^3\,. \tag{4.1}$$

We now discuss the orders of magnitude of various terms in Eq. (3.2). In the first term $\sqrt{-\partial\omega/\partial\eta}$ is of the order of $\eta q'$, and the second term is of the order of $\partial(\eta^2 q'^2)/\partial\eta$. At the sonic point the square of the perturbation velocity q'^2 takes a minimum value which is equal to zero. On the other hand the spatial derivative of q' may take a finite value where q' vanishes. Therefore q'^2 can be neglected in comparison with q' and the spatial derivatives of q'^2. Thus the last term in Eq. (3.2) can be safely neglected in comparison with other terms except at a great distance from the obstacle, where the solution must take the form (4.1), and therefore the last term becomes larger than the first. Consequently, except at a great distance from the obstacle, Eq. (3.2) can be approximated to

$$\pm2\sqrt{\Gamma_1}\sqrt{-\frac{\partial\omega_1}{\partial\eta}}\frac{\partial^2\omega_1}{\partial\xi^2}+\frac{\partial^2\omega_1}{\partial\eta^2}=0\,, \tag{4.2}$$

where ω_1 represents ω to this approximation. If we suppose that ω_1 satisfies the following boundary conditions:

$$\left.\begin{aligned}&\frac{\partial\omega_1}{\partial\eta}=-\Gamma_1(1-U_1)^2\\&\frac{\partial\omega_1}{\partial\xi}=0\end{aligned}\right\}\quad \text{at} \quad \xi=-\infty\,, \tag{4.3}$$

$$\frac{4}{27}k^6\eta^3+\omega_1=0 \qquad \text{on curve C,} \tag{4.4}$$

$$\frac{\partial\omega_1}{\partial\xi}=0 \quad \text{at} \quad \eta=L_1\,, \tag{4.5}$$

where Γ_1 and L_1 were defined in Eqs. (3.3) and (3.7), and U_1 denotes an undetermined constant, the function

$$\omega^*=\omega_1+\Gamma_1(1-U_1)^2\eta-(4/27)k^6\Gamma(1-U)^2\eta^3$$

has the character of the solution at infinity expressed by Eq. (4.1). Considering the condition (4.5), it can be readily seen that the function ω^* satisfies the boundary condition (3.6) at the wall of the wind tunnel.

As mentioned above, Eq. (3.2) can be approximated by Eq. (4.2) near the obstacle, and their solution ω and ω_1 satisfy the same boundary conditions (3.5) and (4.4) respectively at the obstacle. Thus the solution ω can be approximately replaced by ω_1, and so by ω^*, if the following conditions can be satisfied near the obstacle:

$$\left|\frac{\partial\omega_2}{\partial\eta}\right|\ll\left|\frac{\partial\omega_1}{\partial\eta}\right|,\qquad \left|\frac{\partial^2\omega_2}{\partial\eta^2}\right|\ll\left|\frac{\partial^2\omega_1}{\partial\eta^2}\right|, \tag{4.6}$$

where

$$\omega_2=\Gamma_1(1-U_1)^2\eta-(4/27)k^6\Gamma(1-U)^2\eta^3\,.$$

It will be seen in consideration of Eq. (4.4) that ω_2 is of the order of $(1-U)^2\omega_1$ on the obstacle. Neglecting the terms of the order of $(1-U)^2$ and $(1-U_1)^2$, the conditions (4.6) are satisfied except at the sonic point, where

$$q'^2=(9/4)k^{-6}\eta^{-2}(\partial\omega/\partial\eta)\doteqdot(9/4)k^{-6}\eta^{-2}(\partial\omega_1/\partial\eta)$$

vanishes, but $(\partial\omega_2/\partial\eta)$ may take a finite value. To satisfy the relations (4.6) at the vicinity of the sonic point, we must add the following conditions:

$$\partial\omega_2/\partial\eta=\Gamma_1(1-U_1)^2-(4/9)k^6\Gamma(1-U)^2\eta^2=0$$
$$\text{at} \quad \eta=\eta_s \tag{4.7}$$

where η_s denotes the sonic point on the surface of the obstacle.

Especially, when the obstacle has a sharp shoulder at the point of maximum thickness, the velocity of fluid attains the local sound velocity at this point: $\eta_s=c\tau$, where c and τ denote the chord length and the half thickness ratio of the obstacle respectively. Thus in this case Eq. (4.7) can be expressed in the following form:

$$\begin{aligned}(1-M_1)^2/\Gamma_1&=\frac{4}{9}k^6c^2\tau^2(1-M)^2/\Gamma\\&=\frac{4}{9}k^6\tau^2\left(\frac{\Gamma_1}{\Gamma}\right)^{1/2}(1-M)^2/\Gamma\,,\end{aligned} \tag{4.8}$$

or

$$(1-M)=(3/2)\Gamma^{3/4}(1-M_1)/(k^3\tau\Gamma_1^{3/4})$$

where

$$1-M=\Gamma(1-U) \text{ and } 1-M_1=\Gamma_1(1-U_1)\,.$$

By this equation (4.8) the arbitrary constant U_1 is determined.

§ 5. Corresponding Two-dimensional Fluid Flow

Now we shall consider the two-dimensional symmetric transonic flow past a thin obstacle which is placed along a centre line between two parallel flat walls. Taking the cartesian coordinates o-$\xi\eta$, where the ξ-axis is taken along the axis of symmetry of the obstacle, the two-dimensional nearly parallel flow of a compressible fluid is governed by

$$(1-Q^2/a^2)\frac{\partial^2\Omega}{\partial\xi^2}+\frac{\partial^2\Omega}{\partial\eta^2}=0\,, \tag{5.1}$$

where Q and a denote the magnitude of the two-dimensional flow velocity and the local speed of sound respectively, and Ω is the stream function satisfying the following relations:

$$\rho Q=\partial\Omega/\partial\eta\,,\quad \rho Q\Theta=-\partial\Omega/\partial\xi \tag{5.2}$$

in which Θ is the angle of inclination of the velocity.

As in the axisymmetric case, taking the magnitude of the flow velocity and the density ρ of the fluid at the sonic point as their units conveniently, the magnitude Q' of the perturbation velocity, the perturbation density ρ' and the perturbation stream function Ω, are defined as follows,

$$Q'=Q-1,\quad \rho'=\rho-1,\quad \Omega_1=\Omega-\eta\,. \tag{5.3}$$

Neglecting higher order term, Eqs. (5.1) and (5.2) become respectively

$$\pm2\sqrt{\Gamma^*}\sqrt{-\frac{\partial\Omega_1}{\partial\eta}}\,\frac{\partial^2\Omega_1}{\partial\xi^2}+\frac{\partial^2\Omega_1}{\partial\eta^2}=0\,, \tag{5.4}$$

$$-\Gamma^*Q'^2=\frac{\partial\Omega_1}{\partial\eta}\,,\quad -\Theta=\frac{\partial\Omega_1}{\partial\xi}\,, \tag{5.5}$$

where $\Gamma^*=(\gamma^*+1)/2$, and γ^* denotes the ratio of specific heats of a gas considered here.

Since Eq. (5.4) is formally equal to Eq. (4.2), the solution of Eq. (4.2) subject to the boundary conditions (4.3), (4.4) and (4.5) can be recognized to be the perturbation stream function of the two-dimensional symmetric transonic flow of an imaginary gas, the ratio of the specific heats of which is determined by Eq. (3.3).

The condition (4.3) means that this two-dimensional flow has a uniform velocity U_1 at infinity upstream. While the boundary condition (4.5) is readily recognized to be the condition at the two parallel flat walls a distance $2L_1$ apart, the boundary condition (4.4) at the obstacle represents that the curve C cannot be the surface of an obstacle in the two-dimensional fluid flow, because the gas does not flow tangentially along the curve C but crosses it. (In fact, the condition that the gas flows tangentially along the curve C should be expressed by $\eta+\omega_1=0$.)

Instead of the boundary curve C, we shall consider a symmetric curve C_1 on which the following condition is satisfied:

$$\left(\frac{d\eta}{d\xi}\right)_{c_1}=\pm\tau h(\xi_1)\,, \tag{5.6}$$

where ξ_1 denotes ξ/c, and c is the chord length of the obstacle. Remembering the transformation (3.1), the corresponding chord length in the xy-plane is cl. If this chord length in the xy-plane is conveniently taken to be unity, we obtain

$$\left.\begin{aligned} c&=1/l\\ \text{and}\quad x&=\xi_1\end{aligned}\right\} \tag{5.7}$$

Integrating Eq. (5.6), we obtain

$$\eta_{c_1}=c\tau H(\xi_1)\qquad\text{on curve } C_1 \tag{5.8}$$

with

$$H(\xi_1)=\int_0^{\xi_1}h(\xi_1)$$

where τ denotes the half thickness ratio $\eta_{\max}/c$, and then the maximum value of the given function $H(\xi_1)$ becomes unity.

Instead of the boundary condition (4.4) on the curve C, we shall take the following one on the curve C_1 such that

$$\left(\frac{\partial\omega_1}{\partial\xi}\right)_{c_1}=-\Theta=-(\tau^m\Gamma_1{}^n)\tau h(\xi_1)\ \text{on}\ C_1 \tag{5.9}$$

where m and n denote certain constants. This condition (5.9) also represents that the gas does not flow tangentially along the curve C_1 except when both m and n vanish.

In the flow pattern given by the solution of Eq. (4.2) subject to the boundary conditions (4.3), (4.5) and (5.9), we shall find the form of the curve C on which the condition (4.4) is satisfied. From Eq. (4.4), we obtain

$$\begin{aligned}\left(\frac{d\eta}{d\xi}\right)_c&=\left\{-\frac{\partial\omega_1}{\partial\xi}\Big/\left(\frac{4}{9}k^6\eta^2+\frac{\partial\omega_1}{\partial\eta}\right)\right\}_c\\ &=\left\{-\frac{\partial\omega_1}{\partial\xi}\Big/\frac{4}{9}k^6\eta^2(1-\Gamma q'^2)\right\}_c\\ &\qquad\qquad\text{on curve C}\end{aligned} \tag{5.10}$$

As the order of q'^2 can be safely neglected, Eq. (5.10) is reduced to

$$\left(\eta^2\frac{d\eta}{d\xi}\right)_c=-\frac{9}{4k^6}\left(\frac{\partial\omega_1}{\partial\xi}\right)_c \quad \text{on curve C} \qquad (5.11)$$

If both the thickness ratios of the curves C and C$_1$ are very small, we may assume in the first approximation that at the two points having the same abscissa on the curves C and C$_1$, the values of $\partial\omega_1/\partial\xi$ will take almost the same values. Thus putting

$$\left(\frac{\partial\omega_1}{\partial\xi}\right)_c\doteqdot\left(\frac{\partial\omega_1}{\partial\xi}\right)_{c_1}\equiv-(\tau^m\Gamma_1{}^n)\tau h(\xi_1)\,, \qquad (5.12)$$

Eq. (5.11) becomes

$$\left(\eta^2\frac{d\eta}{d\xi}\right)_c=\frac{9}{4k^6}(\tau^m\Gamma_1{}^n)\tau h(\xi_1) \quad \text{on C} \qquad (5.13)$$

Integrating this equation, we obtain

$$\eta^3=\frac{27}{4k^6}(\tau^m\Gamma_1{}^n)c\tau H(\xi_1) \quad \text{on C} \qquad (5.14)$$

where

$$H(\xi_1)=\int_0^{\xi_1}h(\xi_1)d\xi_1$$

In compliance with Eq. (5.12), we shall take the thickness ratio of the curve C to be equal to that of the curve C$_1$, then

$$\frac{27}{4k^6}(\tau^m\Gamma_1{}^n)\tau c=c^3\tau^3 \quad \text{where } c=1/l\doteqdot(\Gamma_1/\Gamma)^{1/4},$$

and therefore the value of k can be determined as a function of τ, Γ_1 and Γ such that

$$k^6=(27/4)\tau^{m-2}\Gamma_1{}^{n-1/2}\Gamma^{1/2}\,, \qquad (5.15)$$

Then Eq. (5.14) becomes

$$\eta_c=c\tau H^{1/3}(\xi_1)\,. \quad \text{on C} \qquad (5.16)$$

Thus it is seen that the solution of Eq. (4.2) subject to the boundary conditions (4.3), (4.5) and (5.9) also satisfies the condition (4.4) on the curve C, which is represented by Eq. (5.16).

By the use of the transformation (3.1), we can find the meridian curve of the obstacle, which is corresponding to the curve C in the $\xi\eta$-plane, such that

$$y=tH^{1/2}(x) \qquad (5.17)$$

with

$$t=\sqrt{8/27}k^{3/2}c^{3/2}\tau^{3/2}=(2/\sqrt[4]{27})\tau^{1+m/4}\Gamma_1{}^{1/4+n/4}\Gamma^{-1/4}\,, \qquad (5.18)$$

where t denotes the half thickness ratio of this obstacle.

From the same transformation (3.1), we obtain the magnitude q' of the perturbation velocity on the surface of the obstacle:

$$q'=k^{-2}(\Gamma_1/\Gamma)^{1/2}Q_c'/y_c{}^{2/3}\,, \qquad (5.19)$$

where the sufix c represents the quantities on the curve C. By the use of Eqs. (5.17) and (5.7), we obtain

$$y_c=tH^{1/2}(x)=tH^{1/2}(\xi_1)\,. \qquad (5.20)$$

As both the curves C and C$_1$ in the $\xi\eta$-plane have the same thickness ratio, $Q_c'(\xi)$ can be approximately obtained in the following form:

$$Q_c'(\xi)\doteqdot Q_{c_1}'(\xi)+(\partial Q_c'/\partial\eta)(\eta_c-\eta_{c_1})\,. \qquad (5.21)$$

As the flow is irrotational, we obtain the relation

$$\frac{\partial Q_{c_1}'}{\partial\eta}=\frac{\partial\Theta_c}{\partial\xi}\cdot \qquad (5.22)$$

Remembering the boundary condition (5.9), we obtain

$$\partial\Theta_{c_1}/\partial\xi=(\tau^m\Gamma_1{}^n)(\tau/c)h'(\xi_1)\,. \qquad (5.23)$$

Substituting (5.8), (5.16) and (5.23) into (5.21), we obtain

$$Q_c'(\xi)=Q_{c_1}'(\xi)+\tau^{m+2}\Gamma_1{}^nh'(\xi_1)\{H^{1/3}(\xi_1)-H(\xi_1)\} \qquad (5.24)$$

Substitution of Eqs. (5.24) and (5.20) into Eq. (5.19) yields

$$\begin{aligned}q_c'=(1/\sqrt{3})\tau^{-m/2}\Gamma_1{}^{1/2-n/2}\Gamma^{-1/2}[Q_{c_1}'(\xi_1)\\+\tau^{2+m}\Gamma_1{}^nh'(\xi_1)\{H^{1/3}(\xi_1)-H(\xi_1)\}]H^{-1/3}(\xi_1),\end{aligned} \qquad (5.25)$$

where

$$x=\xi_1\,.$$

If the values of constants m and n are determined, we can find the perturbation velocity of the transonic axisymmetric fluid flow on the surface of a obstacle whose meridian curve is represented by Eq. (5.17), provided the perturbation velocity Q' of the corresponding two-dimensional transonic fluid flow can be known.

The character of the singularity at infinity in the transonic axisymmetric fluid flow is essentially different from that in the transonic two-dimensional fluid flow. This is represented as the difference between the transonic similarity laws' in both cases: The perturbation velocities q' and Q' of the axisymmetric and of the two-dimensional transonic fluid flows, which are connected by the relation (5.25), must satisfy respectively their own "transonic similarity laws", and by this fact we shall obtain the formulae for determining the constants m and n.

§ 6. Transonic Similarity Law

We shall consider again the two-dimensional transonic fluid flow which was discussed in § 5. Taking ω_1 in Eq. (4.2) as the perturbation stream function Ω_1 of the two-dimensional transonic flow, the fluid flow should be governed by Eq. (4.2). The boundary conditions are given by Eqs. (4.3), (4.5) and (5.9). Since the half thickness ratio τ of the curve C_1 is considered to be very small, the boundary condition (5.9) can be assumed to be satisfied on the ξ-axis within the accuracy considered here. Therefore, instead of Eq. (5.9) we can use

$$\frac{\partial\omega_1}{\partial\xi}=-\Theta=-(\tau^m\Gamma_1{}^n)\tau h(\xi_1) \text{ at } \eta=\pm 0\,. \quad (6.1)$$

Introducing the following affin transformation:

$$\left.\begin{aligned}&\xi=c\xi_1\,,\quad \eta=c\tau^{-p}\Gamma_1{}^{-q}\eta_1\,,\\&\omega_1=(c\Gamma_1{}^{-1})\tau^{-p}\Gamma_1{}^{-q}(1-M_1)^2F(\xi_1,\eta_1),\end{aligned}\right\} \quad (6.2)$$

where M_1 and c denote respectively the Mach number of the flow at infinity and the chord length of the curve C_1 and p, and q are certain constants, Eq. (4.2) becomes

$$\pm 2\frac{|1-M_1|}{\tau^{2p}\Gamma_1{}^{2q}}\sqrt{-\frac{\partial F}{\partial\eta_1}}\frac{\partial^2F}{\partial\xi_1{}^2}+\frac{\partial^2F}{\partial\eta_1{}^2}=0\,, \quad (6.3)$$

and the boundary conditions (4.3), (4.5) and (6.1) respectively become

$$\frac{\partial F}{\partial\eta_1}=-1,\quad \frac{\partial F}{\partial\xi_1}=0,\quad \text{at } \xi_1=-\infty, \quad (6.4)$$

$$\frac{\partial F}{\partial\xi_1}=0 \quad \text{at } \eta_1=L_1\tau^p\Gamma_1{}^q/c \quad (6.5)$$

and

$$\frac{\partial F}{\partial\xi_1}=-\frac{\tau^{m+p+1}\Gamma_1{}^{n+q+1}}{(1-M_1)^2}h(\xi_1) \quad \text{at } \eta_1=\pm 0. \quad (6.6)$$

The dependence of the preceding equations on τ, Γ_1 and M_1, can be eliminated by setting

$$\frac{1-M_1}{\tau^{2p}\Gamma_1{}^{2q}}=K_1\,, \quad (6.7)$$

$$\frac{\tau^{m+p+1}\Gamma_1{}^{n+q+1}}{(1-M_1)^2}=K'\,, \quad (6.8)$$

where K_1 and K' are constants. Eliminating $(1-M_1)$ from Eqs. (6.7) and (6.8), we obtain

$$K'K_1{}^2=\frac{\tau^{m+p+1}\Gamma_1{}^{n+q+1}}{\tau^{4p}\Gamma_1{}^{4q}}\,, \quad (6.9)$$

which shows that these equations hold for arbitrary values of τ, Γ_1 and M_1 only if

$$p=\frac{m+1}{3},\quad q=\frac{n+1}{3}, \quad (6.10)$$

in which case

$$K_1=(1-M_1)\tau^{-(2/3)(m+1)}\Gamma_1{}^{-(2/3)(n+1)}\,, \quad (6.11)$$

and

$$K'=\frac{1}{K_1{}^2}\,. \quad (6.12)$$

Substituting

$$f_1(\xi_1,\ \eta_1)=K_1{}^2F(\xi_1,\ \eta_1)\,, \quad (6.13)$$

Eq. (6.3) becomes

$$\pm 2\sqrt{-\frac{\partial f_1}{\partial\eta_1}}\frac{\partial^2 f_1}{\partial\xi_1{}^2}+\frac{\partial^2 f_1}{\partial\eta_1{}^2}=0\,, \quad (6.14)$$

and the boundary conditions (6.4), (6.5) and (6.6) respectively become

$$\frac{\partial f_1}{\partial\eta_1}=-K_1{}^2,\quad \frac{\partial f_1}{\partial\xi_1}=0 \quad \text{at } \xi_1=-\infty\,, \quad (6.15)$$

$$\frac{\partial f_1}{\partial\xi_1}=0 \quad \text{at } \eta_1=L_1\tau^p\Gamma_1{}^q/c\,, \quad (6.16)$$

$$\frac{\partial f_1}{\partial\xi_1}=-h(\xi_1) \quad \text{at } \eta=\pm 0 \quad (6.17)$$

The equation (6.14) and the boundary conditions (6.15) and (6.17), except for (6.16) depend merely on K_1. If the distance $2L_1$ between the two parallel walls can be expressed as a function of K_1 such that

$$L_1\tau^p\Gamma_1{}^q/c=\lambda_1(K_1)\,, \quad (6.18)$$

the value of $\lim\limits_{\eta\to 0}(\partial f_1/\partial\eta_1)$ should depend on ξ_1 and K_1 for given functional forms of $h(\xi_1)$ and $\lambda_1(K_1)$. Therefore putting

$$\lim_{\eta_1\to 0}(\partial f_1/\partial\eta_1)=-\Phi(\xi_1,\ K_1)\,,$$

from Eq. (5.5), we obtain the perturbation velocity at $\eta=0$ such that

$$\begin{aligned}Q'^2&=-\frac{1}{\Gamma_1}\left(\frac{\partial\omega_1}{\partial\eta}\right)=-\frac{(1-M_1)^2}{\Gamma_1{}^2}\frac{\partial F}{\partial\eta_1}\\&=\frac{-(1-M_1)^2}{\Gamma_1{}^2K^2}\frac{\partial f_1}{\partial\eta_1}=\frac{(1-M_1)^2}{\Gamma_1{}^2K^2}\Phi(\xi_1,\ K_1),\end{aligned}$$

or

$$\begin{aligned}Q'&=\pm\frac{|1-M_1|}{\Gamma_1K_1}\sqrt{\Phi(\xi_1,\ K_1)}\\&=\pm\tau^{(2/3)\cdot(m+1)}\Gamma_1{}^{(1/3)\cdot(2n-1)}\sqrt{\Phi(\xi_1,\ K_1)}\,. \quad (6.19)\end{aligned}$$

where the negative and positive signs refer to the sub- and the supersonic regions respectively.

In a special case for $m=n=0$, Eq. (6.19) becomes

$$Q'=\pm\tau^{2/3}\Gamma_1{}^{-1/3}\sqrt{\Phi(\xi_1,\ K_1)}\,, \quad (6.20)$$

and the boundary condition (6.1) can be reduced to

$$(\partial\omega_1/\partial\xi)_{c_1}=-\Theta=\tau h(\xi_1) \quad \text{at } \eta=\pm 0\,, \qquad (6.21)$$

which represents that the gas flows along the curve C_1. This result represents von Kármán's two-dimensional transonic similarity law[1]. Substituting Eq. (6.19) into Eq. (5.25), we obtain the magnitude q' of the perturbation velocity of transonic axisymmetric fluid flow on the surface of the body of revolution as

$$\begin{aligned} q' = \mp & \frac{1}{\sqrt{3}}\tau^{2/3+m/6}\Gamma_1^{1/6+n/6} \\ & \times\Gamma^{-1/2}\sqrt{\Phi(\xi_1, K_1)}\,H^{-1/3}(\xi_1) \\ & +\frac{1}{\sqrt{3}}\tau^{2+m/2}\Gamma_1^{1/2+n/2}\Gamma^{-1/2}h'(\xi_1) \\ & \times\{1-H^{2/3}(\xi_1)\}\,, \end{aligned} \qquad (6.22)$$

where the negative and positive signs refer respectively to the sub- and the supersonic local velocities. By the use of Eq. (5.18), Eq. (6.22) can be represented in the following form

$$\begin{aligned} q' = \mp & \frac{3}{4}t^2\tau^{-(4+m)/3}\Gamma_1^{-(1+n)/3}\sqrt{\Phi(\xi_1, K_1)}\,H^{-1/3}(\xi_1) \\ & +\frac{3}{4}t^2h'(\xi_1)\{1-H^{2/3}(\xi_1)\} \end{aligned} \qquad (6.23)$$

where

$$t^2=\frac{4}{3\sqrt{3}}\tau^{(4+m)/2}\Gamma_1^{(1+n)/2}\Gamma^{-1/2}\,. \qquad (5.18)$$

On the other hand the similar solutions of the axisymmetric transonic flow governed by Eqs. (2.10) and (2.11) can be obtained by introducing the following affin transformations:

$$\left.\begin{aligned} & x=x_1\,, \quad y=\frac{1}{t\sqrt{\Gamma}}y_1 \\ & \psi=t^2g(x_1,\ y_1) \end{aligned}\right\} \qquad (6.24)$$

By the use of this transformation, Eq. (2.11) becomes

$$\pm 2\sqrt{-\frac{1}{y_1}\frac{\partial g}{\partial y_1}}\frac{\partial^2 g}{\partial x_1^2}+\frac{\partial^2 g}{\partial y_1^2}-\frac{1}{y_1}\frac{\partial g}{\partial y_1}=0\,. \qquad (6.25)$$

Considering the obstacle to be slender, the boundary condition on the surface of the obstacle (2.13) can be replaced by the following condition:

$$-\frac{\partial\psi}{\partial x}=y\theta=\frac{1}{2}\frac{dy^2}{dx}=\frac{t^2}{2}\frac{dH(x)}{dx} \quad \text{at } y=0, \qquad (6.26)$$

where $y=tH^{1/2}(x)$ represents the meridian curve of the body of revolution. The boundary conditions (2.12), (6.26) and (2.14) are transformed respectively to

$$\left.\begin{aligned} & \frac{1}{y_1}\frac{\partial g}{\partial y_1}=-K_1^2\,, \\ & \frac{\partial g}{\partial x_1}=0 \end{aligned}\right\} \quad \text{at } x_1=-\infty\,, \qquad (6.27)$$

$$-\frac{\partial g}{\partial x_1}=\frac{1}{2}\frac{dH(x_1)}{dx}=\frac{1}{2}h(x_1) \quad \text{at } y_1=0\,, \qquad (6.28)$$

$$\frac{\partial g}{\partial x_1}=0 \quad \text{at } y_1=t\sqrt{\Gamma}\,L\,, \qquad (6.29)$$

where

$$K=(1-M)/t^2\Gamma\,. \qquad (6.30)$$

As the equation (6.25) and the boundary conditions (6.27) and (6.28) contain only one parameter K, there exists a similar solution $g(x_1,\ y_1,\ K)$, if the radius L of the circular wind tunnel can be expressed as a function of the transonic parameter K such that

$$Lt\sqrt{\Gamma}=\lambda(K)\,. \qquad (6.31)$$

Thus the magnitude q' of the perturbation velocity at a position $(x_1,\ y_1)$ can be found in the following similar form:

$$q'=\pm\sqrt{-\frac{1}{\Gamma}\frac{1}{y}\frac{\partial\psi}{\partial y}}=\pm t^2\sqrt{-\frac{1}{y_1}\frac{\partial g}{\partial y_1}} \qquad (6.32)$$

Putting

$$\sqrt{-\frac{1}{y_1}\frac{\partial g}{\partial y_1}}=f(x_1,\ y_1,\ K)\,, \qquad (6.33)$$

Eq. (6.32) can be described shortly as

$$q'=\pm t^2 f(x_1,\ y_1,\ K)\,. \qquad (6.34)$$

It should be noted here that this function $f(x_1,\ y_1,\ K)$ has singularities along the axis of the body, and that a point (x_1, y_1) which corresponds to one point on the surface of the body of revolution for one value of t, can never remain at the surface for any other value of t. Oswatisch and Berndt[4] considered the character of the affin transformation (6.24) and found the general similarity law. According to this law, the perturbation velocity $q'_{\text{surf.}}$ on the surface of a body of revolution of thickness ratio $2t$, is represented by the following form:

$$\begin{aligned} q'_{\text{surf.}}/t^2-\frac{d^2H}{dx^2}\log\sqrt[4]{\Gamma}\,t= & f(x_1,\ K) \\ & -\frac{d^2H}{dx^2}\log\sqrt[4]{\Gamma_0}\,t_0\,, \end{aligned} \qquad (6.35)$$

with

$$\Gamma=\frac{\gamma+1}{2}\,, \quad \Gamma_0=\frac{\gamma_0+1}{2}$$

where γ_0 and t_0 denote the ratio of the specific heats of a standard gas and a standard thickness ratio respectively, and where $f(x_1, K)$ denotes a similar solution (6.33).

Putting especially,

$$\sqrt[4]{\Gamma}\, t = \sqrt[4]{\Gamma_0}\, t_0 \tag{6.36}$$

Eq. (6.35) can be reduced to Eq. (6.34).

Comparing Eqs. (6.23) and (5.18) with (6.35) and (6.36) respectively, we can determine the values of constants m and n such that

$$m=-4\,, \quad n=-1\,. \tag{6.37}$$

By the use of these values, Eqs. (6.23) and (5.18) become respectively

$$\begin{aligned} q'_{\text{su.f.}} = &\mp \frac{3}{4} t^2 \sqrt{\Phi(\xi_1,\, K_1)} H^{-1/3}(\xi) \\ &+ \frac{3}{4} t^2 \frac{d^2H}{d\xi_1{}^2}(1-H^{2/3}(\xi_1)) \end{aligned} \tag{6.38}$$

$$t\Gamma^{1/4} = 2/\sqrt[4]{27} \tag{6.39}$$

and

$$\xi_1 = x\,.$$

Considering the similarity law (6.35), we obtain the perturbation velocity $q'_{\text{surf.}}$ on the surface of a body of revolution for general values of $t\sqrt[4]{\Gamma}$ such that

$$\begin{aligned} q'_{\text{surf.}} = &\mp \frac{3}{4} t^2 \sqrt{\Phi(x,\, K_1)} H^{-1/3}(x) \\ &+ \frac{3}{4} t^2 H''(x)\{1-H^{2/3}(x)\} \\ &- H''(x) \log\{2/(27\Gamma)^{1/4} t\}\,, \end{aligned} \tag{6.40}$$

where negative and positive signs refer to the sub- and the supersonic local fluid velocities respectively.

Substituting Eqs. (6.39) and (4.8) into Eq. (6.30), and remembering Eqs. (6.11), (6.37) and and (5.15), we obtain the following relation between the transonic parameters K and K_1:

$$\left.\begin{aligned} K &= \frac{1-M}{t^2\Gamma} = \frac{3}{2}\frac{(1-M_1)}{k^3\tau}\left(\frac{\Gamma}{\Gamma_1}\right)^{3/4}\frac{\sqrt{27}}{4}\Gamma^{-1/2} \\ &= (3/4)\tau^2(1-M_1) = (3/4)K_1\,, \end{aligned}\right\} \tag{6.41}$$

substituting Eqs. (6.39) and (3.7) into Eq. (6.31), remembering Eqs. (6.18), (6.37) and (5.15), we obtain the following relation between the functional forms $\lambda(K)$ and $\lambda_1(K_1)$:

$$\left.\begin{aligned} \lambda(K) &= Lt\sqrt{\Gamma} \\ &= \frac{2}{3}\sqrt{\frac{2}{3}}\, k^{3/2} L_1{}^{3/2} \frac{2}{4\sqrt{27}} \Gamma^{-1/4}\sqrt{\Gamma} \\ &= \frac{4}{3\sqrt{3}} [L_1\tau^{-1}/(\Gamma_1/\Gamma)^{1/4}]^{3/2} \\ &= \frac{4}{3\sqrt{3}} \lambda_1{}^{3/2}(K_1) \end{aligned}\right\} \tag{6.42}$$

By the use of the relations (6.40), (6.41) and (6.42), we can obtain the velocity distribution over the given body of revolution placed along the axis of a circular cylindrical wind tunnel (in the extreme case, in the uniform flow extended to infinity) if we want to find the entire axisymmetric flow pattern of a imaginary gas (whose gas constant must be determined by the relation (6.39)) past a slender body represented by Eq. (5.17) placed along the axis of a circular cylindrical wind tunnel, we need to find the two-dimensional transonic flow governed by Eq. (4.2) subject to the boundary conditions (4.3), (4.5) and (6.1), where we must put $m=-4$ and $n=-1$. However, the velocity distribution on the surface of the body of revolution can be readily obtained, provided the functional form

$$\Phi(\xi_1,\, K_1) \equiv \Phi\left(x,\, \frac{4}{3}K\right)$$

is known. Fortunately this function $\Phi(\xi_1, K_1)$ can be found from the velocity distribution of a real gas over the corresponding two-dimensional body, (which is given by solving Eq. (4.2) subject to the boundary conditions (4.3), (4.5) and (6.1), where we may put $m=0$ and $n=0$.) Thus we can obtain the velocity distribution represented by Eq. (6.38) and the relation between the functional forms $\lambda(K)$ and $\lambda_1(K_1)$ represented by Eq. (6.42), if there exists the relation (6.39) between the half thickness ratio t of the obstacle and the gas constant Γ. Considering the general similarity law expressed by Eq. (6.35), this result can be modified to the general form (6.40), which is useful for general values of Γ and t. It is worth while to mention here that the similarity law is not completely consistent with a Prandtl-Meyer expansion at the shoulder.

The pressure coefficient C_p on the surface of an obstacle considered here is given by

$$C_p = \frac{p-p_\infty}{(1/2)\cdot\rho_\infty U^2} = -2\{q'_{\text{surf.}} - q_\infty'\} \tag{6.43}$$

By the use of Eqs. (6.40) and (6.43), we obtain the pressure coefficient over a body of revolution such that

$$\left.\begin{aligned} C_p/t^2 = &\pm \frac{3}{2}\sqrt{\Phi\left(x,\, \frac{4}{3}K\right)} H^{-1/3}(x) \\ &- \frac{3}{2} H''(x)\{1-H^{2/3}(x,\} \\ &+ 2H''(x) \log\{2/\sqrt[4]{27\Gamma}\, t)\}\,, \end{aligned}\right\} \tag{6.44}$$

where the positive and negative signs refer to the sub- and the supersonic local fluid velocities respectively.

Corresponding two-dimensional formula becomes

$$C_{p_2}\Gamma_1^{1/3}\tau^{-2/3}=\pm 2\sqrt{\Phi(\xi_1,\ K_1)}-2K_1\,, \qquad (6.45)$$

with

$$K_1=(1-M_1)/\tau^{2/3}\Gamma_1^{2/3}\,,$$

where the double signs have the same meaning as in the former case.

The head drag coefficient C_d of a body of revolution is obtained by

$$C_d=\frac{1}{A_b}\int_0^1 2\pi C_p\left(\frac{dy}{dx}\right)y\,dx\,, \qquad (6.46)$$

where A_b denotes the area of the base section.

Substitution of Eqs. (6.44) and (5.17) into Eq. (6.46) yields

$$\left.\begin{aligned}C_D/t^2=&\int_0^1\left(\frac{3}{2}\sqrt{\Phi}\,H^{-1/3}+\frac{3}{2}H''H^{2/3}\right)H'\,dx-\left(\log\frac{(27)^{1/4}}{2}+\frac{3}{4}\right)(H'(1)^2-H'(0)^2)\\&+\{\log(\Gamma^{1/4}t)^{-1}\}\{H'(1)^2-H'(0)^2\}-2K\,.\end{aligned}\right\} \qquad (6.47)$$

§7. A Numerical Example

As is mentioned above, to find the velocity distribution on the surface of an axisymmetric obstacle, we need to obtain that on the surface of a certain two-dimensional obstacle which is symmetric with respect to the free-stream velocity.

As a typical example of two-dimensional transonic flows, the flow past a finite wedge at Mach number 1 was dealt with by Guderley and Yoshihara[5]. Starting from this solution, we shall obtain a certain axisymmetric flow. In this case, the function $H(\xi_1)$ in Eq. (5.8) becomes

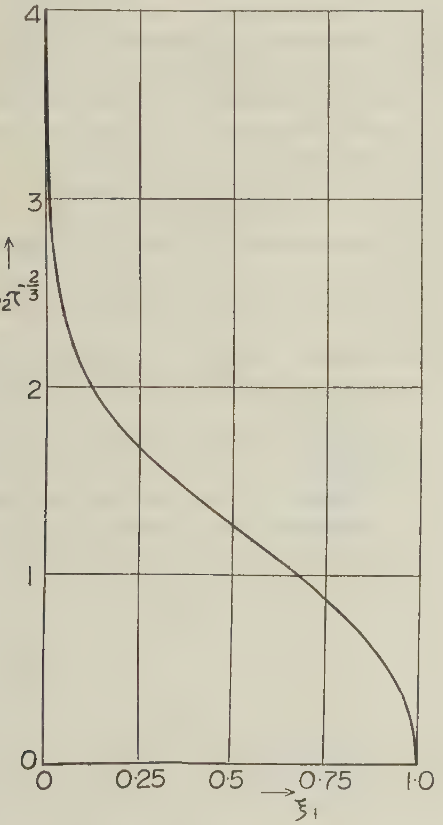

Fig. 1. Pressure distribution over a finite wedge at $M=1$, for $\gamma=1.4$ (Ref. (5)).

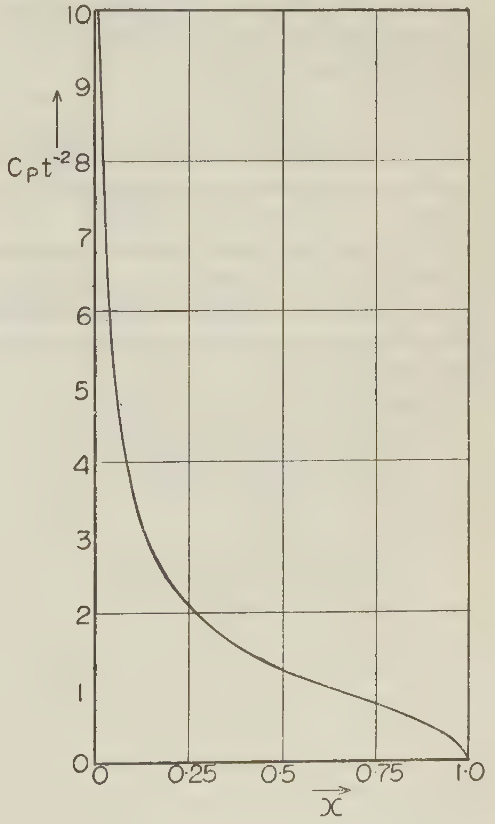

Fig. 2. Pressure distribution over a paraboloid of revolution of finite length at $M=1$.

$$H(\xi_1)=\begin{cases}\xi_1 & \text{for } 0\leqq\xi_1\leqq 1\\ 1 & \text{for } 1<\xi_1\,.\end{cases} \tag{7.1}$$

By the use of Eq. (5.17), the corresponding body of revolution is given by

$$y=\begin{cases}t\sqrt{x} & \text{for } 0\leqq x\leqq 1\\ t & \text{for } 1\leqq x\end{cases} \tag{7.2}$$

which represents a paraboloid of revolution of finite length. Guderley and Yoshihara calculated the function

$$C_{p_2}\tau^{-2/3}=2\Gamma_1{}^{(-1/3)}\sqrt{\Phi(\xi_1,\ 0)}$$

which is shown in Fig. 1. In this case the term of $H''(x)$ in Eq. (6.44) vanishes and we can obtain the pressure coefficient over the paraboloid in the following simple form:

$$C_p/t^2=\frac{3}{2}\sqrt{\Phi(x,\ 0)}/x^{1/3} \qquad \text{for } 0\leqq x\leqq 1. \tag{7.3}$$

This pressure distribution is shown in Fig. 2.

Integrating Eq. (6.46) graphically, we obtain the head drag coefficient of the paraboloid of revolution of finite length as

$$C_d=1.73\,t^2\,, \tag{7.4}$$

where t denotes the half thickness ratio.

Miles[6] evaluated the wave drag on a slender body in sonic flight by matching the result of the linearised theory with the asymptotic solution of Guderley and Yoshihara[7] along the sonic line. The head drag coefficient of a body of revolution of finite length is given by

$$\left.\begin{aligned} C_D/t^2=\frac{H'(1)^2}{4}&\left[\log\left\{1.786\left[\int_0^1 H(x)\,dx\right]^3\right.\right.\\ &\left.\left.\Big/H'(1)\right\}+\frac{7}{2}\right]\\ &+H'(1)^2\log\left(\Gamma^{1/4}t\right)^{-1}\,,\end{aligned}\right\} \tag{7.5}$$

where the meridian curve of the body is represented by

$$y=tH^{1/2}(x)\,. \tag{5.17}$$

Putting $K=0$ in Eq. (6.47), it should be compared with Miles's result (7.5). When the body of revolution considered has pointed nose, $H'(0)$ in Eqs. (6.47) and (7.5) vanishes. Thus for the pointed body both equations have the same coefficient in the term of $\log(\Gamma^{1/4}t)$. However, when $H'(0)$ does not vanish, their coefficients are quite different. Then it is probable that Miles's formula (7.5) fails for a body of revolution with a bluff nose. It seems to be the very reason for this failure that the solution of the linearized equation in the extreme case of $M=1$ is recognized as the extreme form of the solution of the hyperbolic equation for the supersonic flow rather than that of the elliptic equation for the subsonic flow, and that it cannot include the contribution of the bluff nose.

More interesting examples will be dealt with in another paper to be published shortly.

The writer wishes to express his heartiest gratitude to Professor I. Imai for many useful suggestions and kind advice.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 4, APRIL, 1957

On the Transonic Flow of a Compressible Fluid Past a Nearly Axisymmetric Slender Body

By Ken-ichi KUSUKAWA

Department of Physics, Faculty of Science, Tokyo Metropolitan University

(Received November 20, 1956)

The transonic flow of a compressible inviscid fluid past a nearly axisymmetric slender body is dealt with by dividing the perturbation velocity potential into two parts:—the one is governed by the fundamental equation of an axisymmetric transonic flow, and the other is determined by the two-dimensional Laplace's equation in the plane perpendicular to the free-stream velocity vector.

As the axisymmetric transonic flow can be dealt with by a new approximation offered in a previous paper[3], and the solution of the two-dimensional Laplace's equation is easily found, the present problem can be solved.

As examples the flow past an elliptic paraboloid of finite length is discussed and the head drag and the lift coefficients of a paraboloid of revolution of finite length are obtained.

§ 1. Introduction

As is well known, the nearly parallel flow of a compressible inviscid fluid past a slender obstacle of general cross section can be dealt with by the so-called slender body theory[1),2)], unless there exists any transonic region. But this method cannot be applied to the transonic flow, because the approximation of linearization of the equation, on which this method is based, fails in the transonic region.

In this paper we shall deal with the transonic flow of a compressible inviscid fluid past a nearly axisymmetric slender body. The perturbation velocity potential is divided into two parts:—the one refers essentially to the magnitude of the velocity of a transonic fluid flow, but is not sensitively influenced by the sectional form of the body, and the other is essentially determined by the sectional form of the body, but scarecely contributes to the magnitude of the fluid velocity. Thus the approximate equation for determining the former can be reduced to the fundamental equation for the transonic axisymmetric fluid flow, and that for determining the latter can be reduced to the two-dimensional Laplace's equation in the plane parpendicular to the free stream velocity vector.

As the two-dimensional Laplace's equation can be easily solved for any boundary condition corresponding to the form of the body, we can find the perturbation velocity potential of transonic flow past a slender body of general cross section, provided the transonic fluid flow past a suitable axisymmetric body can be known. An approximate method for solving the latter problem was offered by the present writer[3)], and we shall apply a solution given by this method to the numerical examples, which will be discussed in § 4.

§ 2. Fundamental Equations

We shall take the cartesian coordinates where the x-axis is taken along the uniform velocity. Taking conveniently the magnitude of the velocity and the density of the fluid at the sonic point as their units, the perturbation velocity components u', v' and w' along x, y and z-axis, the perturbation density ρ' and the perturbation velocity potential φ are defined as follows:

$$\left.\begin{aligned} &u'=u-1=\frac{\partial\varphi}{\partial x}, \quad v'=\frac{\partial\varphi}{\partial y}, \quad w'=\frac{\partial\varphi}{\partial z}, \\ &\rho'=\rho-1 \end{aligned}\right\} \qquad (2.1)$$

Assuming the flow to be nearly parallel, the equation for determining φ becomes

$$\left(1-\frac{u^2}{c^2}\right)\frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial y^2}+\frac{\partial^2\varphi}{\partial z^2}=0\ , \qquad (2.2)$$

where c denotes the local speed of sound.

By the use of (2.1) and Bernoulli's theorem:

$$(c^2/\rho)d\rho+qdq=0\ ,$$

where q denotes the magnitude of the velocity, we obtain approximately the following relation:

$$1-u^2/c^2=-(\gamma+1)u' \qquad (2.3)$$

wehre γ denotes the ratio of the specific heats.

Substituting Eq. (2.3) into Eq. (2.2), we obtain

$$-(\gamma+1)\frac{\partial\varphi}{\partial x}\frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial y^2}+\frac{\partial^2\varphi}{\partial z^2}=0\,, \tag{2.4}$$

which is the fundamental equation in the transonic approximation due originally to von Kármán[4].

Introducing the cylindrical coordinates such that

$$y=r\cos\theta\,,\qquad z=r\sin\theta\,,$$

Eq. (2.4) becomes

$$-(\gamma+1)\frac{\partial\varphi}{\partial x}\frac{\partial^2\varphi}{\partial x^2}+\frac{\partial^2\varphi}{\partial r^2}+\frac{1}{r}\frac{\partial\varphi}{\partial r}+\frac{1}{r^2}\frac{\partial^2\varphi}{\partial\theta^2}=0\,. \tag{2.5}$$

We shall expand the perturbation velocity potential φ into Fourier series as

$$\varphi=u_0(x,r)+\sum_{n=1}^{\infty}u_n(x,r)\cos(n\theta+\beta_n)\,, \tag{2.6}$$

where β_n are arbitrary constants.

At a great distance from the obstable φ must become $U(1-x)$, where U denotes the free-stream velocity, therefore the flow pattern becomes asymptotically axisymmetric. Since the body considered is nearly axisymmetric, we can assume the following relation between the values of u_0 and u_n (for $n\geqq1$) near the obstacle:

$$O(u_n)/O(u_0)=O(\varepsilon)\ll O(1)\qquad\text{for }n\geqq1 \tag{2.7}$$

As the body is very slender, the magnitudes of the axial and radial components of the velocity can be assumed to be of the order of $O(\varepsilon)$ according to the usual perturbation theory:

$$\left.\begin{aligned}O\left(\frac{\partial\varphi}{\partial x}\right)&=O\left(\frac{\partial u_0}{\partial x}\right)=O(\varepsilon)\,,\\ O\left(\frac{\partial\varphi}{\partial r}\right)&=O\left(\frac{\partial u_0}{\partial r}\right)=O(\varepsilon)\,.\end{aligned}\right\} \tag{2.8}$$

On the other hand the order of a diameter of the body denoted by $O(r)$ is also assumed to be of the order of $O(\varepsilon)$:

$$O(r)=O(\varepsilon) \tag{2.9}$$

Thus from Eqs. (2.7), (2.8) and (2.9), we obtain the following order estimations near the obstacle:

$$\left.\begin{aligned}O\left(\frac{\partial^2u_0}{\partial x^2}\right)&=O\left(\frac{\partial u_0}{\partial x}\right)=O(\varepsilon)\\ O\left(\frac{\partial^2u_n}{\partial x^2}\right)&=O\left(\frac{\partial u_n}{\partial x}\right)\\ &=O\left(\frac{\partial u_0}{\partial x}\right)\cdot O(\varepsilon)=O(\varepsilon^2)\\ O\left(\frac{\partial^2u_0}{\partial r^2}\right)&=O\left(\frac{1}{r}\frac{\partial u_0}{\partial r}\right)\\ &=O\left(\frac{\partial u_0}{\partial r}\right)\Big/O(r)=O(1)\\ O\left(\frac{\partial^2u_n}{\partial r^2}\right)&=O\left(\frac{1}{r}\frac{\partial u_n}{\partial r}\right)=O(u_n/r^2)\\ &=O\left(\frac{\partial u_n}{\partial r}\right)\Big/O(r)\\ &=O\left(\frac{\partial u_0}{\partial r}\right)O(\varepsilon)/O(\varepsilon)=O(\varepsilon)\end{aligned}\right\} \tag{2.10}$$

Substituting Eq. (2.6) into Eq. (2.5), and remembering Eq. (2.10), Eq. (2.5) can be reduced to

$$\begin{aligned}&-(\gamma+1)\frac{\partial u_0}{\partial x}\frac{\partial^2u_0}{\partial x^2}+\frac{\partial^2u_0}{\partial r^2}+\frac{\partial u_0}{r\partial r}\\ &+\sum_{n=1}^{\infty}\cos(n\theta+\beta_n)\left\{\frac{\partial^2u_n}{\partial r^2}+\frac{\partial u_n}{r\partial r}-\frac{n^2}{r^2}u_n\right\}\\ &+O(\varepsilon^3)=0\,.\end{aligned} \tag{2.11}$$

Neglecting the terms of the order of $O(\varepsilon^3)$, we can obtain the following equations for determining u_0 and u_n:

$$-(\gamma+1)\frac{\partial u_0}{\partial x}\frac{\partial^2u_0}{\partial x^2}+\frac{\partial^2u_0}{\partial r^2}+\frac{\partial u_0}{r\partial r}=0\,, \tag{2.12}$$

$$\frac{\partial^2u_n}{\partial r^2}+\frac{\partial u_n}{r\partial r}-\frac{n^2}{r^2}u_n=0\,.\qquad\text{for }n\geqq1 \tag{2.13}$$

Eq. (2.12) is formally equal to the fundamental equation for the transonic axisymmetric flow of a compressible fluid.

§ 3. Solutions and Boundary Conditions

As is well known, the general solutions of Eqs. (2.13) are given by

$$u_n=a_n(x)r^n+b_n(x)r^{-n}\,,\qquad\text{for }n\geqq1\,, \tag{3.1}$$

where $a_n(x)$ and $b_n(x)$ are arbitrary functions of x.

Thus the perturbation velocity potential φ is represented by

$$\varphi=u_0(x,r)+\sum_{n=1}^{\infty}\{a_n(x)r^n+b_n(x)r^{-n}\}\cos(n\theta+\beta_n)\,. \tag{3.2}$$

We shall consider the boundary conditions which φ must satisfy. Since $\partial\varphi/\partial x$ tends to $(U-1)$ as $x\to\infty$ or $r\to\infty$, we obtain

$$u_0(x,r)=(U-1)x\qquad\text{at infinity,} \tag{3.3}$$

and

$$a_n=0\qquad\text{for all }n\geqq1\,. \tag{3.4}$$

On the surface of the obstacle, the gas must flow tangentially along the surface. If the surface of the obstable is expressed by

$$R=F(x,\theta)\ , \tag{3.5}$$

this function $F(x, \theta)$ can be expanded into Fourier series as

$$R=F_0(x)+\sum_{n=1}^{\infty} F_n(x)\cos(n\theta+\alpha_n) \tag{3.6}$$

where α_n are certain constants.

We shall consider the following three points on the surface of the obstacle:

$$\mathrm{A}(x,\ R,\ \theta)\ ,\qquad \mathrm{B}(x,\ R+\Delta R,\ \theta+\Delta\theta)$$

and

$$\mathrm{C}(x+\Delta x,\ R+\Delta R,\ \theta)\ .$$

Since both the vectors $\overrightarrow{\mathrm{AB}}$ and $\overrightarrow{\mathrm{AC}}$ exist on the tangential plane of the surface at the point A, and the velocity vector should also be on this plane, we obtain the following condition:

$$\begin{vmatrix} 0 & \partial R/R\partial\theta & 1 \\ 1 & \partial R/\partial x & 0 \\ 1 & \partial\varphi/\partial r & \partial\varphi/r\partial\theta \end{vmatrix}=0 \tag{3.7}$$

Neglecting the higher order terms, Eq. (3.7) is reduced to

$$\partial\varphi/\partial r=\partial R/\partial x \qquad \text{at } r=R\equiv F(x,\theta)\ . \tag{3.8}$$

Substituting Eqs. (3.2) and (3.6) into Eq. (3.8), we obtain

$$\left.\begin{aligned} &\frac{\partial u_0}{\partial r}-\sum_{n=1}^{\infty}\frac{nb_n(x)}{r^{n+1}}\cos(n\theta+\beta_n) \\ &=\frac{dF_0}{dx}+\sum_{n=1}^{\infty}\frac{dF_n(x)}{dx}\cos(n\theta+\alpha_n) \\ &\qquad\qquad \text{at}\quad r=R\equiv F(x,\theta)\ . \end{aligned}\right\} \tag{3.9}$$

As the sectional form $R=F(x, \theta)$ is not very different from a circle, the boundary condition (3.8) at $r=R\equiv F(x, \theta)$ can be assumed, within the accuracy of the order of the usual slender body theory, to be satisfied at $r=F_0(x)$. Thus Eq. (3.8) can be approximated to

$$\left.\begin{aligned} &\left(\frac{\partial u_0}{\partial r}\right)_{r=F_0(x)}-\sum_{n=1}^{\infty}\frac{nb_n(x)}{F_0^{\,n+1}(x)}\cos(n\theta+\beta_n) \\ &=\frac{dF_0}{dx}+\sum_{n=1}^{\infty}\frac{dF_n(x)}{dx}\cos(n\theta+\alpha_n)\ . \end{aligned}\right\} \tag{3.10}$$

From this equation, we obtain the following conditions:

$$\left(\frac{\partial u_0}{\partial r}\right)_{r=F_0(x)}=\frac{dF_0(x)}{dx}\ , \tag{3.11}$$

and

$$\left.\begin{aligned} &\beta_n=\alpha_n \\ &b_n(x)=-\frac{F_0^{\,n+1}(x)}{n}\frac{dF_n(x)}{dx}\ . \end{aligned}\right\} \tag{3.12}$$

By the use of the conditions (3.3), (3.4), (3.11) and (3.12), the perturbation velocity potential φ of the transonic flow past a slender obstacle expressed by Eq. (3.6) is readily given by

$$\varphi=u_0(x,r)-\sum_{n=1}^{\infty}\frac{F^{n+1}(x)}{nr^n}\frac{dF_n(x)}{dx}\cos(n\theta+\alpha_n)\ , \tag{3.13}$$

provided the perturbation velocity potential $u_0(x, r)$ of the transonic flow of free-stream velocity U past an axisymmetric body expressed by $R=F_0(x)$ can be known.

§ 4. Examples

As examples we shall consider the following two cases. The one is the transonic flow of a compressible fluid past a slender elliptic paraboloid of finite length at zero angle of attack at $M_\infty=1$, and the other is the transonic flow past a slender paraboloid of revolution of finite length with small angle of attack at $M_\infty=1$.

(1) Elliptic Paraboloid

We shall consider an elliptic paraboloid of unit length expressed by

$$\left.\begin{aligned} &x=\frac{y^2}{a^2}+\frac{z^2}{b^2}\ ,\qquad 0\leq x\leq 1\ , \\ &e=\sqrt{a^2-b^2}/a\ , \end{aligned}\right\} \tag{4.1}$$

where a, b and e denote the semi-major and semi-minor axes and the eccentricity of the base section respectively.

Introducing the cylindrical coordinates such that

$$y=R\cos\theta\ ,\qquad z=R\sin\theta\ , \tag{4.2}$$

Eq. (4.1) can be expanded into the e^2-power series as

$$R=b\sqrt{x}\left(1+\frac{e^2}{2}\cos^2\theta+\frac{1.3}{2!\,2^2}e^4\cos^4\theta+\cdots\right) \tag{4.3}$$

After some elementary calculations Eq. (4.3) is reduced to Fourier series as

$$\left.\begin{aligned} &R=b\sqrt{x}\,(A_0+A_1\cos 2\theta \\ &\qquad\qquad +A_2\cos 4\theta+\cdots) \\ &\text{where} \\ &A_0=1+\frac{e^2}{4}+\frac{9}{64}e^4+\cdots\ , \\ &A_1=\quad\ \frac{e^2}{4}+\frac{12}{64}e^4+\cdots\ , \\ &A_2=\qquad\quad \frac{3}{64}e^4+\cdots\ . \end{aligned}\right\} \tag{4.4}$$

In our case it is sufficient, within the accuracy of the approximation in Eq. (3.10), to take terms up to e^2.

Comparing Eq. (4.4) with Eq. (3.6), we obtain

$$\left.\begin{aligned} &F_0(x)=A_0b\sqrt{x}\ , \quad F_1(x)=0\ , \\ &F_2(x)=A_2b\sqrt{x}\ , \quad F_n(x)=0 \ \text{for}\ n\geq 3\ . \end{aligned}\right\} \tag{4.5}$$

By the use of this equation, Eq. (3.13) becomes

$$\varphi=u_0(x,\ r)-\left\{\frac{A_0{}^3A_1b^4}{4}\frac{x}{r^2}\cos 2\theta\right\}\ . \tag{4.6}$$

Thus the axial, radial and tangential components $v_x{}'$, $v_r{}'$, $v_\theta{}'$ of the perturbation velocity are respectively represented by

$$v_x{}'=\frac{\partial\varphi}{\partial x}=\frac{\partial u_0}{\partial x}-\frac{A_0{}^3A_1b^4\cos 2\theta}{4r^2}\ , \tag{4.7}$$

$$v_r{}'=\frac{\partial\varphi}{\partial r}=\frac{\partial u_0}{\partial r}+\frac{A_0{}^3A_1b^4\cos 2\theta}{2r^3}\ , \tag{4.8}$$

$$v_\theta{}'=\frac{\partial\varphi}{r\partial\theta}=\frac{A_0{}^3A_1b^4x\sin 2\theta}{2r^3}\ . \tag{4.9}$$

For the sake of finding the velocity components on the surface of the elliptic paraboloid, putting approximately

$$r=R\doteqdot F_0(x)=A_0b\sqrt{x}\ ,$$

Eqs. (4.7) and (4.8) are reduced to

$$(v_x{}')_s=\left(\frac{\partial u_0}{\partial x}\right)_{r=F_0(x)}-\frac{A_0b^2A_1\cos 2\theta}{4x}\ , \tag{4.10}$$

$$(v_\theta{}')_s=\frac{bA_1\sin 2\theta}{2\sqrt{x}}\ . \tag{4.11}$$

The values of A_0 and A_1 for $a=0.1$, $b=0.09$, $e=(19)^{1/2}/10$, and those for $a=0.1$, $b=0.08$, $e=6/10$ are given in Table I.

Table I. The values of A_0 and A_1.

a	b	e	A_0	A_1
0.1	0.09	$(19)^{1/2}/10$	1.0475	0.0475
0.1	0.08	6/10	1.09	0.09

By an approximate method offered in the previous paper[3)], we can find the value of $(\partial u_0/\partial x)$ at $r=F_0(x)$, which represents the axial component of the perturbation velocity over a paraboloid of revolution of unit length and thickness ratio $t=2A_0b$. Thus by the use of Eq. (4.8), we can calculate the values of the axial and tangential components $v_x{}'$, $v_\theta{}'$ of the velocity on the surface of the elliptic paraboloid.

In the case of $a=0.1$ and $b/a=9/10$, the distributions of the tangential velocity components $v_\theta{}'$ at several chordwise stations are shown in Fig. 1, and the chordwise distributions of the axial component $v_x{}'$ in the several meridian planes are shown in Figs. 2–5. For comparison, there are also shown in these figures the distributions of the axial component $v_x{}'$ over the surface of the paraboloids of revolution whose meridian curves are the same as those of the elliptic paraboloid in every meridian planes. It is due to the influence of tangential flows, that at small values of θ, the absolute values of $v_x{}'$ on the elliptic paraboloid are smaller than those over the paraboloid of revolution, and at values near 90° the latter ones are smaller than the formers.

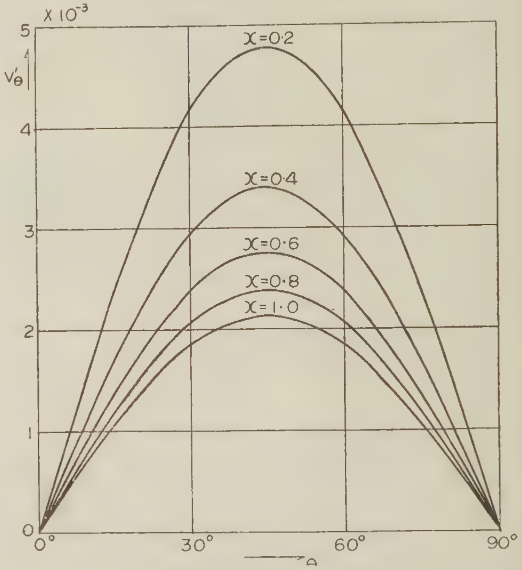

Fig. 1. The distribution of the tangential velocity component $v_\theta{}'$ over an elliptic paraboloid of $a=0.1$ and $b/a=9/10$.

In the case of $a=0.1$ and $b/a=8/10$, the distributions of the tangential component $v_\theta{}'$ of the velocity at several chordwise stations are shown in Fig. 6, and the chordwise distributions of the axial component $v_x{}'$ in the several meridian planes are shown in Figs. 7–10.

As the pressure coefficient C_p on the surface in the approximation considered here is given by

$$C_p=\frac{p-p_\infty}{p_\infty U^2/2}=-2v_x{}'\ , \tag{4.12}$$

we can find readily the values of C_p from those of $v_x{}'$, and they are also shown in Figs. 2–5, 7–10.

Since Prandtl-Meyer's expansion occurs locally at the shoulder of the finite elliptic para-

Figs. 2–5. Chordwise distributions of the pressure and the axial perturbation velocity component v_x' over an elliptic paraboloid of $a=0.1$ and $b/a=9/10$ in the several meridian planes.

The full-and the dotted lines refer to the elliptic paraboloid and the corresponding paraboloid of revolution.

boloid, the pressure coefficient C_p must, in principle, vanish there. In fact, the calculated values of the pressure coefficient at the shoulder become of such a vanishingly small order as 2/10000 in our case, therefore this approximate method is justified from this view point.

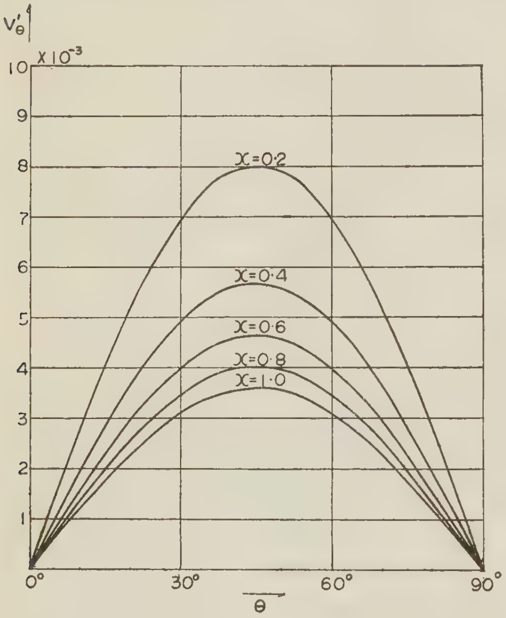

Fig. 6. The distributions of the tangential velocity component v_θ' over an elliptic paraboloid of $a=0.1$ and $b/a=8/10$.

(2) Paraboloid of Revolution at Small Incidence

We shall consider a slender paraboloid of revolution of unit length such that

$$x_1=\frac{y_1^2}{a^2}+\frac{z^2}{a^2}\,, \qquad 0\leqq x_1\leqq 1 \tag{4.13}$$

where a denotes the radius of the base section.

We shall introduce the angle of attack α. Taking the cartesian coordinates $o-x\,y\,z$ where the x-axis is taken along the free stream velocity, we obtain the following relations:

$$\begin{aligned} x_1&=x\cos\alpha-y\sin\alpha\,,\\ y_1&=x\sin\alpha+y\cos\alpha\,. \end{aligned} \tag{4.14}$$

Substitution of Eq. (4.14) into Eq. (4.13) gives

$$\begin{aligned} ax^2\cos\alpha-a^2y\sin\alpha&=(y^2+z^2)\\ &+(x^2-y^2)\sin^2\alpha+2xy\sin\alpha\cos\alpha\,. \end{aligned} \tag{4.15}$$

Introducing the cylindrical coordinates such that

$$y=R\cos\theta\,, \qquad z=R\sin\theta\,, \tag{4.16}$$

Eq. (4.15) becomes

$$R=\frac{1}{2A}[-B\pm\sqrt{B^2+4AC}\,]\,,$$

where

$$\left.\begin{aligned} A&=1-\sin^2\alpha\cos^2\theta\,,\\ B&=a^2\sin\alpha\cos\theta+x\sin 2\alpha\cos\theta\,,\\ C&=a^2x\cos\alpha-x^2\sin^2\alpha\,. \end{aligned}\right\} \tag{4.17}$$

Since $R\geqq 0$, neglecting the terms of the order smaller than $O(\alpha)$, Eq. (4.17) is reduced to

$$R=a\sqrt{x}-(1/2)(a^2+2x)\alpha\cos\theta\,. \tag{4.18}$$

Comparing this equation with Eq. (3.6), we obtain

$$F_0(x)=a\sqrt{x}\,, \qquad F_1(x)=-\frac{1}{2}(a^2+2x)\alpha\,. \tag{4.19}$$

Thus by the use of Eq. (3.13), we can obtain the perturbation velocity potential:

$$\varphi=u_0(x,\,r)+\alpha a^2x\cos\theta/r\,, \tag{4.20}$$

Then the axial and the tangential components v_x', v_θ' of the perturbation velocity on the surface of the obstacle are respectively given by

$$(v_x')_s=\left(\frac{\partial u_0}{\partial x}\right)_{r=F_0(x)}+\frac{\alpha a}{\sqrt{x}}\cos\theta\,, \tag{4.21}$$

$$(v_\theta')_s=-\alpha\sin\theta\,, \tag{4.22}$$

where $\partial u_0/\partial x$ at $r=F_0(x)$ represents the axial component of the velocity over the same paraboloid of revolution at zero incidence. The pressure coefficient C_p on the surface of the body is readily given by

$$C_p=-2v_x'=-2\left(\frac{\partial u_0}{\partial x}\right)_{r=F_0(x)}-2\frac{\alpha a}{\sqrt{x}}\cos\theta\,. \tag{4.23}$$

The head drag coefficient C_d of the obstacle is obtained as

$$C_d=\frac{1}{A_b}\iint C_p(dR/dx)Rd\theta dx\,, \tag{4.24}$$

where A_b denotes the area of the base section.

Substitution of Eq. (4.23) into Eq. (4.24) gives

$$C_d=\frac{1}{A_b}\left\{\iint C_{p_0}\frac{dR}{dx}Rdxd\theta+\iint C_{p_1}\frac{dR}{dx}Rd\theta dx\right\},$$

where

$$C_{p_0}=-2\left(\frac{\partial u_0}{\partial x}\right)_{r=F_0(x)}\,, \qquad C_{p_1}=-\frac{2\alpha a}{\sqrt{x}}\cos\theta\,. \tag{4.25}$$

Since the function C_p is symmetric with respect to the axis of revolution x_1, the first term in the right-hand side of Eq. (4.25) is calculated by

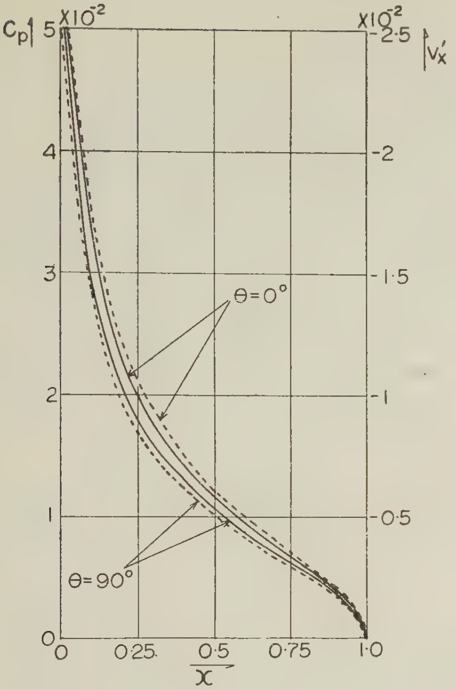

Fig. 7.

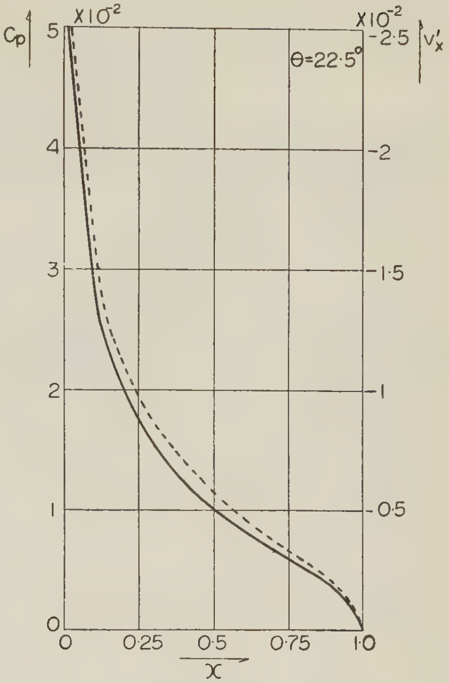

Fig. 8.

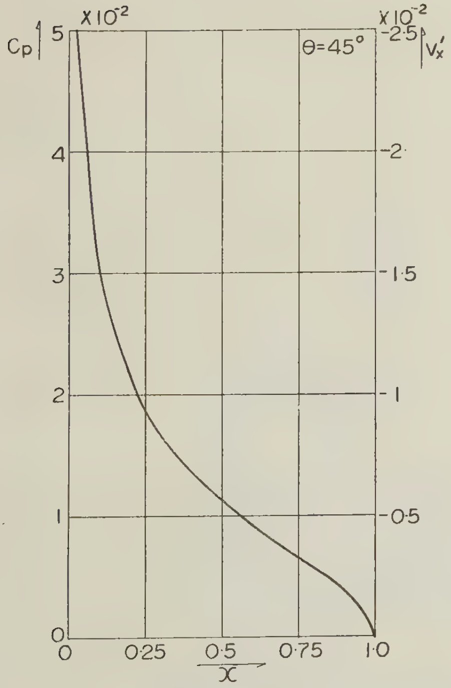

Fig. 9.

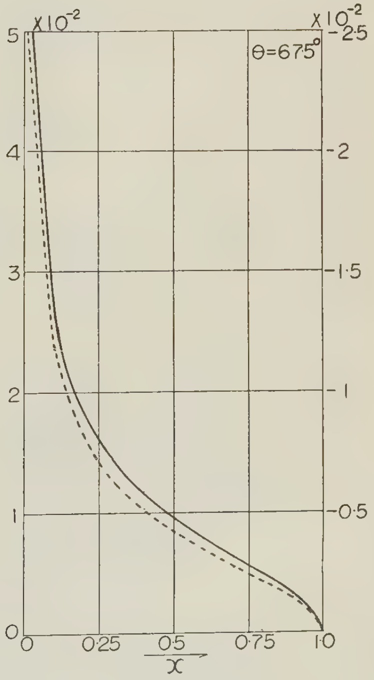

Fig. 10.

Figs. 7–10. Chordwise distributions of the pressure and the axial perturbation velocity component v_x' over an elliptic paraboloid of $a=0.1$ and $b/a=8/10$ in the several meridian planes.

The full-and the dotted lines refer to the elliptic paraboloid and the corresponding paraboloid of revolution.

$$\left\{\frac{1}{A_b}2\pi\int_0^1 C_{p0}\frac{dR}{dx_1}R(x_1)dx_1\right\}\cos\alpha$$
$$=\left(\int_0^1 C_{p_0}dx_1\right)\cos\alpha\ .$$

Neglecting the terms of the order of $O(\alpha^2)$, the second term is reduced to

$$-\iint\frac{2\alpha a\cos\theta}{\sqrt{x}}\frac{1}{2}\left(\frac{dR}{dx}\right)^2 d\theta dx$$
$$=-a^3\alpha\iint\frac{\cos\theta}{\sqrt{x^3}}d\theta dx=0\ .$$

Thus we obtain the head drag coefficient:

$$C_d=C_{d_0}\cos\alpha=C_{d_0}+O(\alpha^2)\ , \qquad (4.26)$$

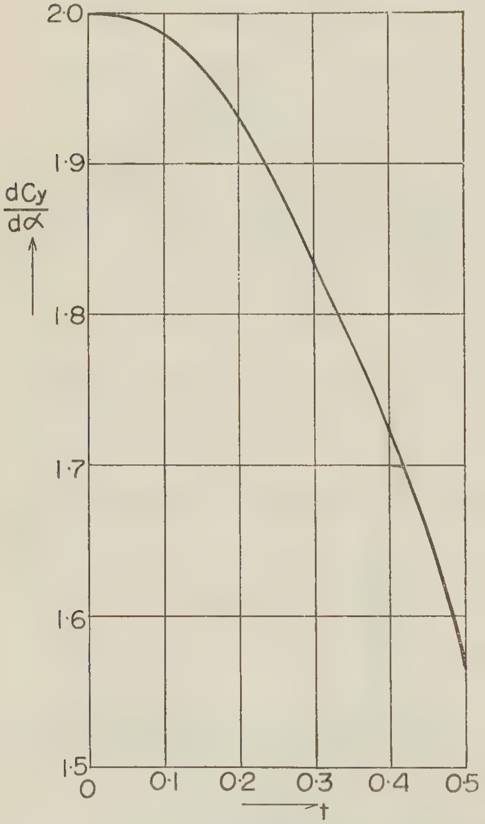

Fig. 11. The variation of $(dC_y/d\alpha)_{\alpha=0}$ for a finite paraboloid with the half thickness ratio t.

where $C_{d_0}=\int_0^1 C_{p_0}dx_1$ represents the head drag coefficient of the paraboloid of revolution of unit length at zero incidence. According to the previous paper[3)], C_{d_0} is given by

$$C_{d_0}=1.73t^2 \qquad (4.27)$$

where t denotes the half thickness ratio, so that it is the same as a in this case.

It is seen from Eq. (4.26) that the influence of the angle of attack α to the drag coefficient C_d is of the order of $O(\alpha^2)$.

As the lift is seriously influenced by the under pressure at the base, it cannot be estimated without the knowledge of the base pressure. Then we shall consider here the y-component P_y of the resultant of the pressure acting on the head of the obstacle such that

$$P_y=-\iint C_pR\cos\theta d\theta dx$$
$$=-\left[\iint C_{p_0}\cos\theta R d\theta dx+\iint C_{p_1}R\cos\theta d\theta dx\right]$$
$$=-\left[2\pi\int C_{p_0}R\frac{dR}{dx_1}dx_1\right]\sin\alpha$$
$$+\left[\iint\frac{2\alpha a}{\sqrt{x}}\cos^2\theta(a\sqrt{x})d\theta dx\right]$$
$$=-A_bC_{d_0}\sin\alpha+2\alpha A_b=A_b\alpha(2-C_{d_0}) \qquad (4.28)$$

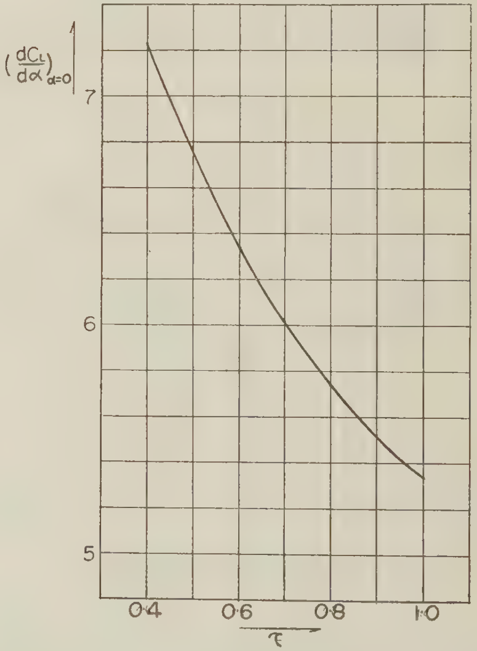

Fig. 12. The variation of $(dC_L/d\alpha)_{\alpha=0}$ for a double wedge with the thickness ratio τ. (Ref. (5)).

Introducing the non-dimensional coefficient $P_y/A_b=C_y$, we obtain

$$C_y=P_y/A_b=(2-C_{d_0})\alpha\ . \qquad (4.29)$$

Substitution of Eq. (4.27) yields

$$C_y=(2-1.73t^2)\alpha\ , \qquad (4.30)$$

and we obtain

$$(dC_y/d\alpha)_{\alpha=0}=2-1.73t^2\ , \qquad (4.31)$$

where t denotes the half thickness ratio of the paraboloid of revolution. The variation of $(dC_y/d\alpha)_{\alpha=0}$ with the half thickness ratio t is shown in Fig. 11.

Guderley and Yoshihara[5] investigated theoretically the transonic flow past a double wedge with small angle of attack α, at $M_\infty=1$ and calculated the lift coefficient C_L. For comparison the variation of $(dC_L/d\alpha)_{\alpha=0}$ with the thickness ratio τ of the double wedge is shown in Fig. 12.

Finally it will be of interest to mention here that by the slender body theory[1],[6], the lift coefficient of the pointed slender body of revolution in the supersonic fluid flow is given by

$$C_L=2\alpha+O(t^3\log^2 t)\ . \qquad (4.32)$$

It is the reason for the difference between Eqs. (4.30) and (4.32), that the surface velocity of a paraboloid of finite length in sonic flight is subsonic, while that of a pointed body at $M>1$ is supersonic.

The writer wishes to express his heartiest gratitude to professor I. Imai for his many useful suggestions and kind advice.

Experimental Studies of the Lift on Two Equal Circular Cylinders placed side by side in a Uniform Stream at Low Reynolds Numbers

By Sadatoshi TANEDA

Kobe University of Mercantile Marine

(Received December 26, 1956)

Lifts acting on two equal circular cylinders placed side by side in a uniform stream were measured by means of lamp scale and mirror method at Reynolds numbers from 0.01 to 1.6. The results obtained are as follows:

1. Each cylinder experiences a repulsive force.
2. The value of lift coefficient decreases monotonously as the Reynolds number is increased.
3. When the Reynolds number is sufficiently small, the value of lift coefficient increases first and then decreases as the ratio of the distance between two cylinders to the diameter of the cylinder increases.

These results are in good agreement with the theoretical conclusions which are led from the Oseen's linearized equations of motion.

The photographs of the actual flow pattern were also taken.

§ 1. Introduction

In a recent paper[1], the forces acting on two parallel circular cylinders of equal diameter with their axes in a plane perpendicular to a uniform flow have been discussed by Fujikawa on the basis of Oseen's linearized equations of motion, and several interesting results were obtained. The present author was interested especially in the conclusions that when two equal cylinders are placed side by side they repulse each other, and that when Reynolds number is small, the lift increases first and then decreases with the increase of the distance between the two cylinders. However, so far as is known to the author, there has been no experimental verification up to the present.

In the present experiments, the lifts acting on two equal circular cylinders placed side by side were measured for several cases when the ratio of the distance between the axes of the two cylinders to the diameter of the cylinder is equal to 4.6, 10, 18 and 50, the Reynolds number of the flow varying from 0.01 to 1.6. To obtain the flow with such a low Reynolds number, the glycerine-water solutions were used as the viscous fluid. And the lift, which was extremely small (order of 10^{-1} dyne), were sensibly detected by means of lamp scale and mirror method. The results were in good agreement with the theoretical one based on the Ossen's equations.

§ 2. Apparatus

The experiments were carried out with the moving metal vessel of 200 mm in length, 100 mm in width and 80 mm in depth. The general arrangement of the apparatus is shown in Fig. 1. The vessel is filled with the glycerine-water solution, and is set on the small carriage which is advanced uniformly along the straight rails by means of lead screw. The value of Reynolds number can be varied by changing the density of the glycerine-water solution.

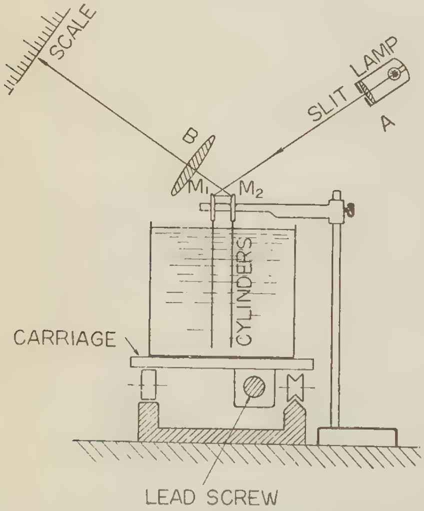

Fig. 1. Schematic diagram of the apparatus.
A, **B**: Convex lenses, $\mathbf{M}_1$, $\mathbf{M}_2$: Plane mirrors.

The two cylinders are hung as a pendulum on a horizontal bracket by means of needle edges so as to be free to swing only across the stream (see Fig. 2). When the vessel is at rest, the following adjustments have to be made:

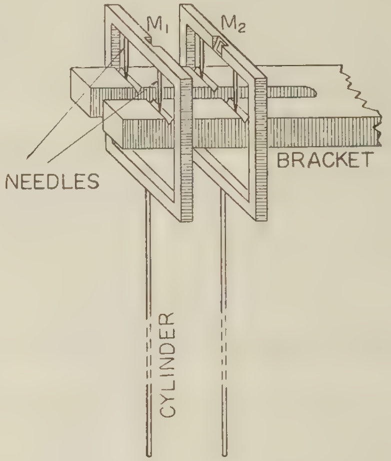

Fig. 2. Sketch of the pendulums.

1. The plane containing the two cylinders has to be made perpendicular to the direction about which the vessel is moved.
2. The two cylinders have to be inclined slightly each other so as to be exactly parallel when the vessel is in motion.
3. The ray of light from the lamp has to be thrown on to a scale after reflections in the mirrors $\mathbf{M}_1$ and $\mathbf{M}_2$ which are attached to the pendulums facing each other.
4. The image of the light source has to be formed on the mirror $\mathbf{M}_1$ by means of lens **A**.
5. The image of the slit has to be formed on the scale by means of lens **B**.

Then the vessel is set in motion, and the small inclination of the pendulum which is caused by the lift is measured by reading the movement of a spot of light on the scale.

The fine brass wires of four different sizes were used as the models, their diameters being 0.30 mm, 0.40 mm, 0.60 mm and 0.77 mm respectively. It must be noted that steel wire cannot be used as the model because it is strongly affected by the weak magnetism existing in the apparatus. The distance between two cylinders was varied from 1 mm to 15 mm at the interval of 1 mm.

On the other hand, the actual flow pattern around the two circular cylinders was photographed by means of aluminium dust method with the glass water tank of 100 cm in length, 20 cm in width and 30 cm in depth. A general description of the apparatus and an account of the photographic technique were given in the previous paper²⁾, and so need not be repeated here.

§ 3. Notations

m: mass of pendulum

l: distance between needle edge and center of gravity of the pendulum

l^*: distance between needle edge and center of lift

g: acceleration of gravity

x: displacement of spot of light on the scale

a: distance between two mirrors $\mathbf{M}_1$ and $\mathbf{M}_2$

b: distance from middle point of $\mathbf{M}_1$ and $\mathbf{M}_2$ to lens **B**

c: distance between lens **B** and scale

f: focal length of lens **B**

D: distance from middle point of $\mathbf{M}_1$ and $\mathbf{M}_2$ to scale

L: lift

C_L: lift coefficient

ρ: density of glycerine-water solution

d: diameter of cylinder

U: speed of carriage

s: span of cylinder (submerged portion of cylinder)

h: distance between axes of two cylinders

ν: kinematic viscosity of glycerine-water solution

R: Reynolds number based on diameter of the cylinder (Ud/ν)

§ 4. Results and Discussion

If the inclination of the pendulum is sufficiently small, then we have from the condition for balance of the forces

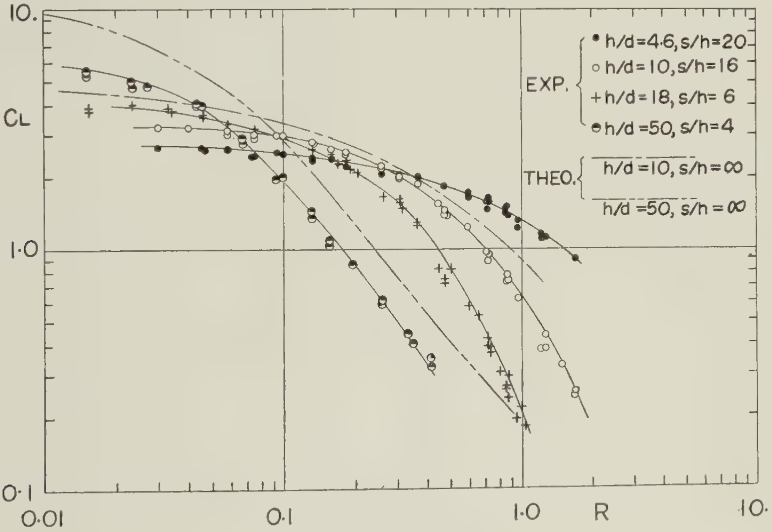

Fig. 3. Lift coefficient.

$$\frac{Dx}{\left(\frac{fb}{f-b}+c\right)\left(1-\frac{b}{f}\right)}=2\,\frac{Ll_1^*}{m_1gl_1}(a+D)+2\frac{Ll_2^*}{m_2gl_2}D\,.$$

Hence

$$L=\frac{Dgx}{2\left(\frac{fb}{f-b}+c\right)\left(1-\frac{b}{f}\right)\left\{\frac{l_1^*(a+D)}{m_1l_1}+\frac{l_2^*D}{m_2l_2}\right\}}\,,$$

and therefore

$$C_L=\frac{L}{d\rho U^2s}=\frac{Dgx}{2\rho dU^2s\left(\frac{fb}{f-b}+c\right)\left(1-\frac{b}{f}\right)\left\{\frac{l_1^*(a+D)}{m_1l_1}+\frac{l_2^*D}{m_2l_2}\right\}}\,.$$

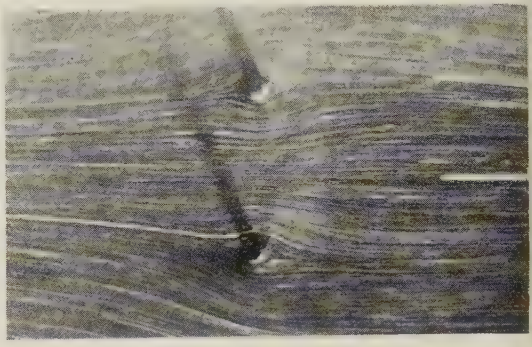
Thus by measuring the value x, the lift coefficient C_L can be calculated. In the present experiments, the inclination of the pendulum which was caused by the lift was less than 1/200. When the Reynolds number R is higher than about 1.5, the lift is too small to be accurately measured by means of this method. On the other hand, when R is lower than about 0.02, the influence of the vessel wall is not so small as can be neglected. Therefore the measurements were made only at Reynolds numbers from 0.01 to 1.6.

Fig. 3 shows the experimental results, together with the theoretical values for the two cases $h/d=10$ and 50. The general conclusions drawn from the experiments are summarized as follows:

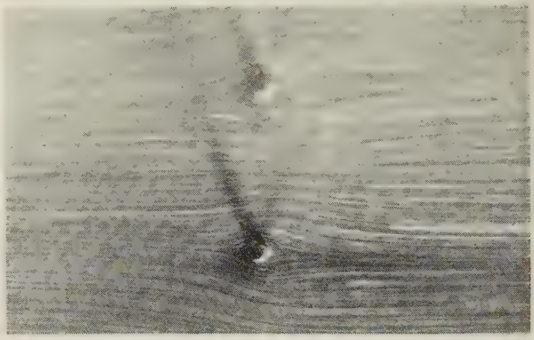
1. Two cylinders repulse each other.
2. Lift coefficient decreases monotonously as the Reynolds number is increased.
3. When Reynolds number is small, the value of lift coefficient increases first and then decreases as the ratio of the distance between the axes of the two cylinders to the diameter of the cylinder is increased.

These conclusions are in complete agreement with the theoretical. However, the observed lift coefficient is slightly lower than the theoretically calculated, the discrepancy being probably due to the end effect and the wall effect. The theoretical calculations apply to an unlimited field of fluid around the two cylinders of infinite length, while the experiments were made in a tank of finite size using the cylinders of finite length.

Photographs of the actual velocity field around the two equal parallel circular cylinders are shown in Fig. 4. It will be noticed that the wakes produced by two cylinders repulse each other.



(a) $R=0.486$, $s/h=12$.



(b) $R=1.46$, $s/h=12$.

Fig. 4. Photographs showing flow pattern around the two equal parallel circular cylinders placed side by side in a uniform stream.

The author is indebted to Professor Hikoji Yamada for his valuable advice and encouragement in the course of this work. Thanks are also due to Dr. Hiroomi Fujikawa for his kind suggestions.

Expansion Formulae for the Forces acting on Two Equal Circular Cylinders placed in a Uniform Stream at Low Values of Reynolds Number

By Hiroomi Fujikawa

Junior College of Engineering, University of Osaka Prefecture, Neyagawa nr. Osaka

(Received December 30, 1956)

As a continuation of a previous paper¹⁾, a further discussion is made on the steady slow motion of a viscous fluid past two parallel circular cylinders of equal radius with their axes in a plane perpendicular to a uniform flow, confining ourselves to the case when the two cylinders are in close proximity to each other.

Expansion formulae in powers of Reynolds number R for the drag and lift acting on one of the cylinders are obtained correct to the lowest order of Reynolds number R. The coefficients of each term are expressed in power series of $a/2h$ and obtained as far as terms of $(a/2h)^4$, where a denotes the radius of the cylinders and $2h$ the distance between their centres.

Up to the order of $(a/2h)^2$, the results are found to be in complete agreement with expansion formulae for the drag and lift acting on the one cylinder placed near the other, which has been obtained directly by expanding the formulae useful for the case when the distance between the cylinders is great.

§1. Introduction and Summary

In a previous paper¹⁾, the writer treated a steady slow motion of a viscous fluid past two parallel circular cylinders of equal radius a, at a great distance apart, with their axes in one plane perpendicular to a uniform stream and obtained expansion formulae in powers of Reynolds number for the forces acting on one of the cylinders, up to the second term of Oseen's approximation. These formulae are valid for the case when the two cylinders are situated at a great distance apart, but they are not applicable to the case in which the cylinders are adjacent to each another.

Also, the writer expanded formally the above formulae in power series of the ratio $a/2h$ as far as terms of $(a/2h)^2$, where $2h$ is the distance between the centres of the cylinders. However, as was noted in the previous paper, such formal expansion formulae are not suitable for a detailed discussion, especially for the case of two adjacent cylinders. It is therefore desirable to obtain expansion formulae for the drag and lift acting on one of the cylinders correct to the order higher than $(a/2h)^2$.

In the present paper, expansion formulae useful for the case when the two circular cylinders are situated in close proximity to each other are obtained up to the order of $(a/2h)^4$ as well as to the lowest order of Reynolds number R. And it is shown that the expressions thus obtained are in complete agreement, up to the order of $(a/2h)^2$, with those which have been derived formally by expanding the formulae useful for the case when the distance between the two cylinders is great.

Making use of these formulae, detailed numerical discussion is made for several cases when the distance between the axes of the two cylinders is equal to 5/4, 3/2, 5/2, 5 and 10 times their diameter, the Reynolds number of the flow varying from 0 to 0.1. Further, as a limiting case, a similar discussion is made for the drag when the two cylinders touch each other, and compared with Tamada's results²⁾.

Thus, it is ascertained that, on increasing the distance between the two cylinders, the drag on one cylinder increases but the lift—the repulsive force—decreases first and then increases.

OUTLINE OF ANALYSIS

§ 2. Fundamental Solutions

For the sake of reference we shall first reproduce the outline of analysis which is necessary for our present purpose.

We consider two infinitely long parallel circular cylinders C, C_*, of equal radius a, set in a steady uniform stream of velocity U of an incompressible viscous fluid in such a manner that their axes lie in a plane perpendicular to the uniform stream.

Let Ox, Oy be the rectangular co-ordinate axes in the plane of fluid motion, the axis of x being taken along the direction of the uniform stream and the origin coinciding with the centre of the cylinder C. The centre of the other cylinder C_* is situated on the y-axis, its coordinates being denoted by $(0, -2h)$ (Fig. 1).

As is well known, the stream function ψ for the perturbation flow due to the presence of a single circular cylinder placed in an unlimited uniform flow has been given by Filon[3) in the form:

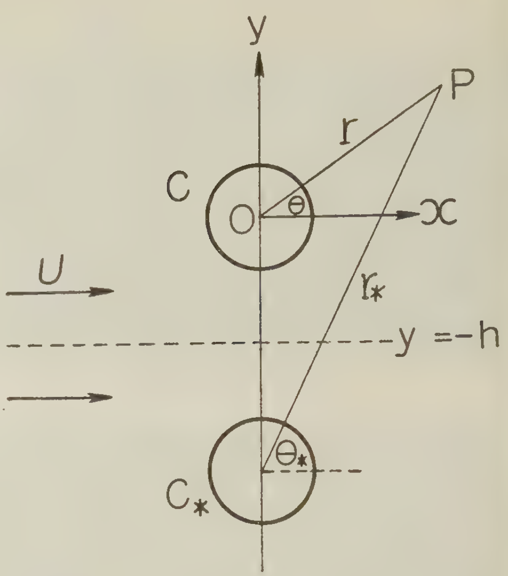

Fig. 1.

$$\psi = \psi_h + \psi_u \,,$$

with

$$\left.\begin{aligned} \psi_h &= \alpha_0 \log r + a_0\theta + \sum_{n=1}^{\infty} r^{-n}(\alpha_n \cos n\theta + a_n \sin n\theta) \,, \\ k\psi_u &= \beta_0 e^{kx} K_0(kr) + b_0 \int_0^{\theta} kr\{K_1(kr) + K_0(kr)\cos\theta\} e^{kr\cos\theta}\, d\theta \\ &\quad + e^{kx} \sum_{n=1}^{\infty} K_n(kr)(\beta_n \cos n\theta + b_n \sin n\theta) \,, \end{aligned}\right\} \tag{2.1}$$

where

$$x = r\cos\theta \,, \qquad y = r\sin\theta \,,$$

a_n, α_n, b_n, β_n being arbitrary real constants, $K_n(kr)$ the modified Bessel function of the second kind[†], and k is connected with the kinematic viscosity ν as

$$k = U/2\nu \,. \tag{2.2}$$

Then, putting

$$\left.\begin{aligned} A_0 = a_0 + i\alpha_0 \,, \qquad A_n = n(a_n - i\alpha_n) \,, \qquad (n \geqq 1) \\ B_n = b_n + i\beta_n \,, \qquad (n \geqq 0) \end{aligned}\right\} \tag{2.3}$$

the conjugate complex velocity W $(=u-iv)$ for the perturbation flow is generally expressed as follows:

$$\left.\begin{aligned} W &= W_h + W_u \,, \\ W_h &= \sum_{n=0}^{\infty} A_n z^{-(n+1)} \,, \\ W_u &= e^{kx}\{C_1 K_0(kr) + \sum_{n=1}^{\infty} (C_{n+1} e^{in\theta} + \overline{C}_n e^{-in\theta}) K_n(kr)\} \,, \end{aligned}\right\} \tag{2.4}$$

[†] The definition of the modified Bessel function used here is identical with those in G. N. Watson's "*A Treatise on the Theory of Bessel Functions*" (Cambridge, 1922).

where C_n's are arbitrary constants connected with B_n's as

$$C_1 = B_0 - \frac{1}{2} B_1 , \qquad C_n = \frac{1}{2}(B_{n-1} - B_n) , \qquad (n \geqq 2) \tag{2.5}$$

and $\overline{C}_n$ denotes the complex conjugate of C_n.

The expression (2.4) for W was first obtained by Prof. I. Imai[1] after integrating a general expression for vorticity.

Now, the conjugate complex velocity W for the perturbation flow due to the presence of the two cylinders in the uniform stream may be written in the following form:

$$W = W_h^{(1)} + W_h^{(2)} + W_u^{(1)} + W_u^{(2)} , \tag{2.6}$$

with

$$\left.\begin{aligned} &W_h^{(1)} = \sum_{n=0}^{\infty} A_n z^{-(n+1)} , \qquad W_h^{(2)} = \sum_{n=0}^{\infty} A_n^* z_*^{-(n+1)} , \\ &W_u^{(1)} = e^{kx}\{C_1 K_0(kr) + \sum_{n=1}^{\infty} (C_{n+1} e^{in\theta} + \overline{C}_n e^{-in\theta}) K_n(kr)\} , \\ &W_u^{(2)} = e^{kx}\{C_1^* K_0(kr_*) + \sum_{n=1}^{\infty} (C_{n+1}^* e^{in\theta_*} + \overline{C}_n^* e^{-in\theta_*}) K_n(kr_*)\} , \end{aligned}\right\} \tag{2.7}$$

where A_n, C_n, A_n^*, C_n^* etc. are arbitrary complex constants and

$$z_* = r_* e^{i\theta_*} = z + 2ih . \tag{2.8}$$

The flow field under consideration must be symmetric with respect to the straight streamline $y = -h$, i.e. $\Im(W) = 0$ along $y = -h$. This condition yields immediately the following relations between the constants in (2.7):

$$A_n^* = \overline{A}_n \qquad (n \geqq 0) , \qquad\qquad C_n^* = \overline{C}_n \qquad (n \geqq 1) . \tag{2.9}$$

§ 3. Determination of the Constants A_n, B_n

We now proceed to the consideration of the remaining boundary conditions at the surfaces of the two cylinders.

The flow is symmetric with respect to the straight streamline $y = -h$ and since the solution (2.6) together with (2.7) and (2.9) already satisfies this condition, it is sufficient to consider the fulfilment of the condition on one cylinder C ($z = a \exp(i\theta)$) only.

The resultant velocity $U + W$ must be zero on the surface of the cylinder, so that the required boundary condition is written as:

$$(W)_{r=a} = -U . \tag{3.1}$$

In order to apply this condition to W given by (2.6), we expand W in a Fourier series in θ on the surface ($r = a$) of the cylinder C. After several calculations, we get the following results† as

$$\left.\begin{aligned} &(W_h^{(1)})_{r=a} = \sum_{n=0}^{\infty} A_n a^{-(n+1)} e^{-i(n+1)\theta} , \\ &(W_h^{(2)})_{r=a} = \sum_{n=0}^{\infty} \sum_{m=0}^{\infty} (-1)^n \frac{(m+n)!}{m!\,n!} \left(\frac{a}{2ih}\right)^n \frac{\overline{A}_m}{(2ih)^{m+1}} e^{in\theta} , \\ &(W_u^{(1)})_{r=a} = \sum_{n=-\infty}^{\infty} \Big\{C_1 K_0 I_n + \sum_{m=1}^{\infty} K_m (C_{m+1} I_{n-m} + \overline{C}_m I_{n+m})\Big\} e^{in\theta} , \\ &(W_u^{(2)})_{r=a} = \sum_{n=-\infty}^{\infty} \Big\{\overline{C}_1 \lambda_{n,\,0} + \sum_{m=1}^{\infty} (\overline{C}_{m+1} \lambda_{n,\,m} + C_m \lambda_{n,\,-m})\Big\} e^{in\theta} , \end{aligned}\right\} \tag{3.2}$$

where

$$\lambda_{n,\,\sigma} = \sum_{s=-\infty}^{\infty} i^{s+\sigma} I_s I_{s-n} K_{s-\sigma}(2kh) , \qquad (\sigma = 0, \pm 1, \pm 2, \cdots) \tag{3.3}$$

---

† For details of the calculation reference should be made to the previous paper[1] of the present writer.

the argument ka of the modified Bessel functions I_n, K_n having been omitted for simplicity.

According to the boundary condition (3.1), every coefficient of $\exp(in\theta)$ $[n=0, \pm 1, \pm 2, \cdots]$ in the expansion should vanish except for the constant term ($n=0$), which must be equal to $-U$.

Thus, we have

$$\left.\begin{aligned}
&\sum_{m=0}^{\infty}(-1)^n \frac{(m+n)!}{m!n!}\left(\frac{a}{2ih}\right)^n \frac{\overline{A}_m}{(2ih)^{m+1}} \\
&\qquad +\mathrm{C}_1 I_n K_0+\sum_{m=1}^{\infty} K_m(\mathrm{C}_{m+1} I_{n-m}+\overline{\mathrm{C}}_m I_{n+m}) \\
&\qquad +\overline{\mathrm{C}}_1 \lambda_{n,\,0}+\sum_{m=1}^{\infty}(\overline{\mathrm{C}}_{m+1}\lambda_{n,\,m}+\mathrm{C}_m \lambda_{n,\,-m})=\begin{cases}-U, & (n=0) \\ 0, & (n=1, 2, \cdots)\end{cases} \\
&A_{n-1}a^{-n}+\mathrm{C}_1 I_n K_0+\sum_{m=1}^{\infty} K_m(\mathrm{C}_{m+1} I_{n+m}+\overline{\mathrm{C}}_m I_{n-m}) \\
&\qquad +\overline{\mathrm{C}}_1 \lambda_{-n,\,0}+\sum_{m=1}^{\infty}(\overline{\mathrm{C}}_{m+1}\lambda_{-n,\,m}+\mathrm{C}_m \lambda_{-n,\,-m})=0\,, \qquad (n=1, 2, \cdots)
\end{aligned}\right\} \tag{3.4}$$

where the argument ka of the modified Bessel functions has been dropped for simplicity. Further, elimination of A_m's from these equations gives

$$\begin{aligned}
&\sum_{m=0}^{\infty}\Bigg[\mathrm{C}_{m+1}\left\{I_{n-m}K_m+\lambda_{n,\,-(m+1)}-\sum_{s=0}^{\infty}(-1)^n \frac{(s+n)!}{s!n!}\left(\frac{a}{2ih}\right)^{s+n+1}(I_{s-m}K_{m+1}+\lambda_{s+1,\,-m})\right\} \\
&\quad +\overline{\mathrm{C}}_{m+1}\left\{I_{n+m+1}K_{m+1}+\lambda_{n,\,m}-\sum_{s=0}^{\infty}(-1)^n \frac{(s+n)!}{s!n!}\left(\frac{a}{2ih}\right)^{s+n+1}(I_{m+s+1}K_m+\lambda_{s+1,\,m+1})\right\}\Bigg] \\
&\qquad\qquad =\begin{cases}-U, & (n=0) \\ 0. & (n=1, 2, \cdots)\end{cases}
\end{aligned} \tag{3.5}$$

Equations (3.5) together with the second equation of (3.4) determine in principle the coefficients A_m's, C_m's and hence the solution of the present problem.

APPROXIMATE SOLUTION FOR THE FLOW AT SUFFICIENTLY SMALL REYNOLDS NUMBER

§ 4. Simultaneous Equations for the Constants b_n and β_n

Now, we shall determine the constants C_m's from the equations (3.5). However, it is difficult in practice to solve these equations exactly. On the other hand, Oseen's equation itself is valid for the whole field of flow only at small Reynolds numbers, and our main interest in the present investigation lies also in such flows. Therefore, in the present paper, we shall treat the case in which the two parameters ka $\left(=\frac{1}{4}R\right)$ and kh are very small.

Separating real and imaginary parts of the equations (3.5), we obtain the system of equation for determining B_n $(=b_n+i\beta_n)$ in the following form:

$$\left.\begin{aligned}
&C_{11}b_0+C_{12}\beta_0+C_{13}\left(\frac{b_1}{2}\right)+C_{14}\left(\frac{\beta_1}{2}\right)+C_{15}\left(\frac{b_2}{2}\right)+C_{16}\left(\frac{\beta_2}{2}\right)+\cdots=-U\,, \\
&C_{i1}b_0+C_{i2}\beta_0+C_{i3}\left(\frac{b_1}{2}\right)+C_{i4}\left(\frac{\beta_1}{2}\right)+C_{i5}\left(\frac{b_2}{2}\right)+C_{i6}\left(\frac{\beta_2}{2}\right)+\cdots=0\,. \\
&\qquad\qquad (i=2, 3, 4, \cdots)
\end{aligned}\right\} \tag{4.1}$$

The coefficients C_{ij}'s involve the functions $I_n(ka)$, $K_n(ka)$ and $K_n(2kh)$. In the previous paper[1], we have developed the analysis under the assumption that $ka \ll 1$, $(kh)^{-1}=O(1)$ and therefore we expanded only the functions $I_n(ka)$ and $K_n(ka)$ up to the order of $(ka)^2$.

However, in the case when $ka \ll 1$ and $kh \ll 1$, with which we are concerned in the present paper, the values of $(kh)^{-n}$ and $K_n(2kh)$ $(n=0, 1, 2, \cdots)$ in C_{ij}'s become very large, and therefore the previous analysis for small values of ka and kh should be modified.

Now, expanding every functions in powers of ka or kh and performing some tedious but traightforward calculations, we find that

$$\left.\begin{aligned}&C_{11},\ C_{13},\ C_{22},\ C_{24},\ C_{32},\ C_{34},\ C_{41},\ C_{43},\ C_{51},\ C_{53},\ C_{62},\ C_{64}=O(1)\ ,\\&C_{12},\ C_{21},\ C_{31},\ C_{42},\ C_{52},\ C_{61}=O(ka)\ ,\\&C_{14},\ C_{16},\ C_{23},\ C_{25},\ C_{33},\ C_{35},\ C_{44},\ C_{46},\ C_{54},\ C_{56},\ C_{63},\ C_{65}=O(k^{-1}a^{-1})\ ,\\&C_{15},\ C_{26},\ C_{36},\ C_{45},\ C_{55},\ C_{66}=O(k^{-2}a^{-2})\ ,\end{aligned}\right\}\tag{4.2}$$

cf. (4.3a)–(4.3c) and (4.5a)–(4.5c)].

These results suggest that the orders of magnitude of b_0, β_0, b_1, β_1, b_2, β_2, $\cdots$ are 1, ka, $ka)^2$, ka, $(ka)^2$, $(ka)^3$, $\cdots$, respectively. Therefore, to the lowest order in ka, we can deternine b_0, β_1, b_2, $\cdots$, separately from β_0, b_1, β_2, $\cdots$, by solving the following system of simulaneous equations:

$$\left.\begin{aligned}&C_{11}b_0+C_{14}(\beta_1/2)+C_{15}(b_2/2)+\cdots=-U\ ,\\&C_{41}b_0+C_{44}(\beta_1/2)+C_{45}(b_2/2)+\cdots=0\ ,\\&C_{51}b_0+C_{54}(\beta_1/2)+C_{55}(b_2/2)+\cdots=0\ ,\\&\qquad\cdots\cdots\cdots\cdots\ ,\end{aligned}\right\}\tag{4.3}$$

vhere

$$\left.\begin{aligned}&C_{11}=\left\{(2S-\tau)-\frac{1}{4}(a/2h)^4+\cdots\right\}+O(k^2a^2)\ ,\\&C_{41}=\left\{\frac{1}{2}(a/2h)^3+\cdots\right\}+O(k^2a^2)\ ,\\&C_{51}=\frac{1}{4}\{(a/2h)^2+2(a/2h)^4+\cdots\}+O(k^2a^2)\ ,\end{aligned}\right\}\tag{4.3a}$$

$$\left.\begin{aligned}&C_{14}=\{(a/2h)^3+\cdots\}(ka)^{-1}+O(ka)\ ,\\&C_{44}=\{1-2(a/2h)^2+4(a/2h)^4+\cdots\}(ka)^{-1}+O(ka)\ ,\\&C_{54}=\{3(a/2h)^3+\cdots\}(ka)^{-1}+O(ka)\ ,\end{aligned}\right\}\tag{4.3b}$$

$$\left.\begin{aligned}&C_{15}=2\{(a/2h)^2-4(a/2h)^4+\cdots\}(ka)^{-2}+O(1)\ ,\\&C_{45}=\{12(a/2h)^3+\cdots\}(ka)^{-2}+O(1)\ ,\\&C_{55}=2\{1-12(a/2h)^4+\cdots\}(ka)^{-2}+O(1)\ ,\end{aligned}\right\}\tag{4.3c}$$

vith

$$S=\frac{1}{2}-\gamma-\log(ka/2)\ ,\qquad \tau=\frac{1}{2}-\log(a/2h)\ ,\tag{4.3d}$$

vhere $\gamma=0.57721\ldots$ is Euler's constant.

Thus, we obtain

$$\left.\begin{aligned}&b_0=-\frac{1}{4}U\Delta\{1-2(a/2h)^2-8(a/2h)^4+\cdots\}+O(k^2a^2)\ ,\\&\beta_1=\frac{1}{4}U\Delta\{(a/2h)^3+\cdots\}(ka)+O(k^3a^3)\ ,\\&b_2=\frac{1}{16}U\Delta\{(a/2h)^2+\cdots\}(ka)^2+O(k^4a^4)\ ,\end{aligned}\right\}\tag{4.4}$$

vhere

$$\Delta=\frac{4}{2S-\kappa-1}\left\{1+2(a/2h)^2+\left(12+\frac{1}{4S-2\kappa-2}\right)(a/2h)^4+\cdots\right\}\ .\tag{4.4a}$$

Then, inserting (4.4) in (4.1), the remaining coefficients β_0, b_1, β_2, $\cdots$ can be determined rom the following equations:

$$\left.\begin{aligned}
&C_{22}\beta_0+C_{23}(b_1/2)+C_{26}(\beta_2/2)+\cdots=C_{20}\,,\\
&C_{32}\beta_0+C_{33}(b_1/2)+C_{36}(\beta_2/2)+\cdots=C_{30}\,,\\
&C_{62}\beta_0+C_{63}(b_1/2)+C_{66}(\beta_2/2)+\cdots=C_{60}\,,\\
&\cdots\cdots\cdots\cdots\,,
\end{aligned}\right\}\qquad(4.5)$$

where

$$\left.\begin{aligned}
&C_{22}=\frac{1}{4}\{4(\tau-1)+4(a/2h)^2-(a/2h)^4+\cdots\}+O(k^2a^2)\,,\\
&C_{32}=\frac{1}{2}\{2(a/2h)-3(a/2h)^3+\cdots\}+O(k^2a^2)\,,\\
&C_{62}=\frac{1}{4}\{3(a/2h)^2-8(a/2h)^4+\cdots\}+O(k^2a^2)\,,
\end{aligned}\right\}\qquad(4.5a)$$

$$\left.\begin{aligned}
&C_{23}=\{2(a/2h)-3(a/2h)^3+\cdots\}(ka)^{-1}+O(ka)\,,\\
&C_{33}=\{1-2(a/2h)^2+6(a/2h)^4+\cdots\}(ka)^{-1}+O(ka)\,,\\
&C_{63}=\{-3(a/2h)^3+\cdots\}(ka)^{-1}+O(ka)\,,
\end{aligned}\right\}\qquad(4.5b)$$

$$\left.\begin{aligned}
&C_{26}=2\{3(a/2h)^2-8(a/2h)^4+\cdots\}(ka)^{-2}+O(1)\,,\\
&C_{36}=\{-12(a/2h)^3+\cdots\}(ka)^{-2}+O(1)\,,\\
&C_{66}=2\{1-12(a/2h)^4+\cdots\}(ka)^{-2}+O(1)\,,
\end{aligned}\right\}\qquad(4.5c)$$

$$\left.\begin{aligned}
C_{20}=\frac{1}{16}&U\Delta(a/2h)^{-1}\{2S-2\tau+1-4(S-\tau+1)(a/2h)^2\\
&-2(8S-9\tau+3)(a/2h)^4+\cdots\}(ka)+O(k^3a^3)\,,\\
C_{30}=\frac{1}{32}&U\Delta\{4(2S-\tau)-3-8(2S-\tau-1)(a/2h)^2\\
&-(64S-32\tau-23)(a/2h)^4+\cdots\}(ka)+O(k^3a^3)\,,\\
C_{60}=\frac{1}{48}&U\Delta\{3(a/2h)-10(a/2h)^3+\cdots\}(ka)+O(k^3a^3)\,,
\end{aligned}\right\}\qquad(4.5d)$$

S, τ and Δ being the same as in (4.3d) and (4.4a) respectively.
Thus, we get

$$\left.\begin{aligned}
&\beta_0=\frac{1}{8}U\Delta\left(S-\tau+\frac{1}{2}\right)(\tau-1)^{-1}(a/2h)^{-1}[1+\Lambda_1(a/2h)^2+\Lambda_2(a/2h)^4+\cdots](ka)+O(k^3a^3)\,,\\
&b_1=\frac{1}{16}U\Delta(\tau-1)^{-1}[\{4S(2\tau-3)-4\tau^2+5\tau+1\}+\cdots](ka)^2+O(k^4a^4)\,,\\
&\beta_2=-\frac{1}{64}U\Delta(\tau-1)^{-1}[(6S-10\tau+7)(a/2h)+\cdots](ka)^3+O(k^5a^5)\,,
\end{aligned}\right\}\qquad(4.6)$$

with the abbreviations

$$\left.\begin{aligned}
&\Lambda_1=\frac{2\tau-1}{\tau-1}-\frac{8S-6\tau+3/2}{S-\tau+1/2}\,,\\
&\Lambda_2=\frac{3}{2}\,\frac{4\tau-5}{\tau-1}+\left(\frac{2\tau-1}{\tau-1}\right)^2-\frac{2\tau-1}{\tau-1}\,\frac{8S-6\tau+3/2}{S-\tau+1/2}+\frac{4S+4\tau-39/4}{S-\tau+1/2}\,.
\end{aligned}\right\}\qquad(4.6a)$$

On the other hand, solving the second equation of (3.4) for $A_0=a_0+i\alpha_0$, and separating the real and imaginary parts, we get the relations

$$\left.\begin{aligned}
&a_0/a=-b_0(ka)^{-1}\\
&\alpha_0/a=b_0\{(a/2h)+O(k^2a^2)\}+\beta_0\{(ka)^{-1}+O(ka)\}\\
&\quad+b_1\left[\left\{-(a/2h)+\frac{1}{2}(a/2h)^3\right\}+O(k^2a^2)\right]+\beta_1\{(a/2h)^2(ka)^{-1}+O(ka)\}\\
&\quad+b_2\{4(a/2h)^3(ka)^{-2}+O(1)\}+\beta_2[\{2(a/2h)^2-3(a/2h)^4\}(ka)^{-1}+O(ka)]\\
&\quad+\cdots\cdots\cdots\cdots\,.
\end{aligned}\right\}\qquad(4.7)$$

Inserting (4.4) and (4.6) into (4.7), we obtain

$$\left.\begin{aligned} a_0 &= \frac{1}{4}Ua\Delta\{1-2(a/2h)^2-8(a/2h)^4+\cdots\}(ka)^{-1}+O(ka)\,, \\ \alpha_0 &= \frac{1}{8}Ua\Delta\left(S-\tau+\frac{1}{2}\right)(\tau-1)^{-1}(a/2h)^{-1}\left[1+\left\{\Lambda_1-\frac{2(\tau-1)}{S-\tau+1/2}\right\}(a/2h)^2\right. \\ &\qquad \left.+\left\{\Lambda_2+\frac{4(\tau-1)}{S-\tau+1/2}\right\}(a/2h)^4+\cdots\right]+O(k^2a^2)\,, \end{aligned}\right\} \tag{4.8}$$

where Λ_1, Λ_2 and Δ are given by (4.6*a*) and (4.4*a*) respectively.

§ 5. The Forces on the Cylinder

We now proceed to the evaluation of the force acting on the cylinder C. As shown in the previous paper[1)], this force may be considered as composed of the drag D and the lift L in the directions of the x and y-axes respectively, which are expressed respectively as

$$D=2\pi\rho U a_0\,, \qquad L=2\pi\rho U\alpha_0\,, \tag{5.1}$$

where ρ is the density of the fluid concerned.

Therefore, making use of the expressions (4.8) for a_0 and α_0, we can obtain expansion formulae for the drag and lift. Thus, correct as far as terms of the lowest order of R, we have the drag and lift coefficients as:

$$\begin{aligned} C_D &= \frac{D}{2\rho U^2 a} \\ &= \frac{4\pi}{R(2S-\kappa-1)}\left\{1+\frac{1}{2(2S-\kappa-1)}\left(\frac{a}{2h}\right)^4\right. \\ &\qquad \left.+O\left(\frac{a^6}{h^6}\right)\right\}+O(R)\,, \end{aligned} \tag{5.2}$$

and

$$\begin{aligned} C_L &= \frac{L}{2\rho U^2 a} \\ &= \frac{\pi}{2\kappa}\,\frac{h}{a}\,\frac{2S-2\kappa-1}{2S-\kappa-1}\left[1+\left(\frac{1}{\kappa}-\frac{8S-5}{2S-2\kappa-1}\right)\right. \\ &\quad \times\left(\frac{a}{2h}\right)^2+\left\{\left(\frac{1}{\kappa}+\frac{1}{2}\right)\left(\frac{1}{\kappa}-4\right)\right. \\ &\quad \left.+\frac{1}{2}\,\frac{1}{2S-\kappa-1}+\left(\frac{1}{\kappa}-\frac{15}{2}\right)\frac{1}{2S-2\kappa-1}\right\} \\ &\quad \left.\times\left(\frac{a}{2h}\right)^4+O\left(\frac{a^6}{h^6}\right)\right]+O(R^2)\,, \end{aligned} \tag{5.3}$$

where as before

$$S=\frac{1}{2}-\gamma-\log\frac{R}{8}\,, \qquad \kappa=-\frac{1}{2}-\log\left(\frac{a}{2h}\right). \tag{5.4}$$

It will be seen that as was noted in the previous paper, these results are in perfect agreement, up to the first two terms, with the formulae which were obtained by considering formally the case $kh \ll 1$ in the previous results for the case of $(kh)^{-1}=O(1)$.

§ 6. Numerical Discussions

Making use of the formulae (5.2) and (5.3), the writer has calculated the values of $C_D/C_D{}^*$ and C_L for various values of the Reynolds number R $(=4ka)$ as well as for various values of the ratio $a/2h$, where $C_D{}^*$ denotes the drag coefficient for a single circular cylinder in an unbounded stream and is given by $C_D{}^*=4\pi/RS$. The results are given in Tables

Table I. Values of $C_D/C_D{}^*$.

I–III and are also shown graphically in Figs. 2 and 3.

The values of C_D/C_D^* for the limiting case when $a/2h=1/2$ are also found to be in good agreement with Tamada's results[2] which are tabulated in the last column of Table I for the sake of reference. Further, the values of C_D/C_D^* and C_L for the case when $a/2h=1/20$ are tabulated for comparison in Table III together with the values calculated by the expansion formulae valid for $kh=O(1)$ which were obtained in the previous paper. In this table, the second and fourth columns with the heading I give the values of C_D/C_D^* and C_L calculated by the formulae in the present paper, while in the third and fifth columns with the heading II are given similar values calculated in the previous paper. In Figs. 2 and 3 the results for the case when $a/2h=1/20$ calculated by the expansion formulae valid for $kh=O(1)$ are also shown by dotted-line curves.

Table III. Values of C_D/C_D^* and C_L $(a/2h=1/20)$.

R	C_D/C_D^*		C_L	
	I	II	I	II
0	0.5000		6.24	
0.0001	0.5923		5.40	
0.001	0.6220		5.13	
0.01	0.6798	0.6793	4.60	4.60
0.02	0.7097	0.7080	4.33	4.34
0.04	0.7516	0.7461	3.95	3.99
0.06	0.7848	0.7737	3.65	3.74
0.08	0.8143	0.7965	3.38	3.53
0.1	0.8418	0.8155	3.13	3.34
0.2		0.8799		2.68
0.4		0.9423		1.88

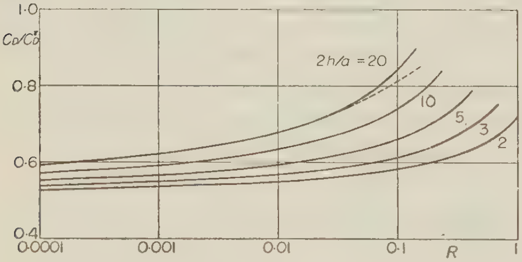

Fig. 2.

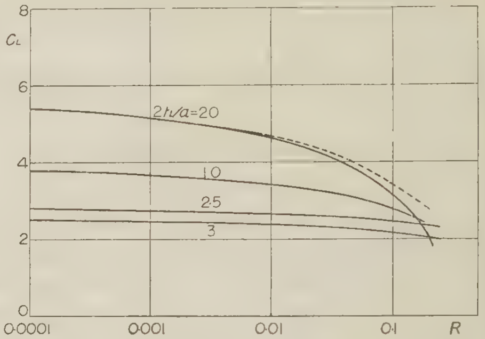

Fig. 3.

From these tables and figures, it will be seen that, as the distance between the cylinders decreases, the values of C_D for a sufficiently small Reynolds number decreases monotonously, while the value of C_L decreases first and then increases.

In conclusion, the writer wishes to express his cordial thanks to Professor S. Tomotika for his continual interest and encouragement throughout this work and especially for his kind inspection of the manuscript.

Also, the writer is much indebted to Professor K. Tamada for his invaluable advices and criticism, and also for his kindness in putting some of his unpublished results at the writer's disposal.

Anomalies of Electrical Properties of Lead Telluride Crystal

By Susumu UCHIYAMA and Kisaburo SHOGENJI
Faculty of Engineering, Nagoya University, Nagoya

(Received January 24, 1957)

It was reported by Putley1) that some PbSe and PbTe crystals reversed the signs of their Hall coefficient in addition to the intrinsic sign reversal. We looked for the sign reversal of PbTe crystals by heat treatment, but could not find it.2) However, a specimen, which was at first a normal p-type one and, after copper being added by evaporation, heat treated in vacuum at 500°K for 3 hours, showed the sign reversal in the extrinsic temperature range. The results obtained are shown in Fig. 1 and are similar to those reported by Putley1). Impurity levels with activation energy of the order of 0.1 ev. are seen, from the slope of resistivity curve, to appear in addition to the ordinary acceptor levels.

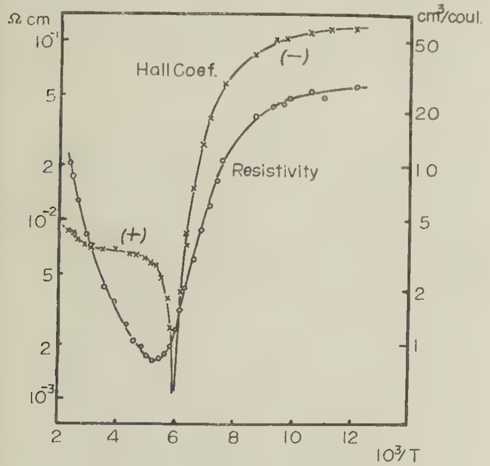

Fig. 1.

Besides the sign reversal some anomalies were found at lower temperatures. At some temperature below the sign reversal temperature, voltage *vs.* current rleation was not symmetrical with respect to the origin, and was not strictly linear even for smaller current. At the same temperature range, voltage drop across the two resistivity probes, for the same current through the specimen, changed by applying a magnetic field transversely. It increased or decreased according to the change of the direction of applied field. The phenomenon cannot be considered to represent magnetoresistive effect, since the change is not proportional to the square of the field but rather proportional to the field itself. The experiments were made with the greatest care. We concluded that the anomalies were not due to any experiment errors but they represented the real peculiarities of the specimen. We thought that these two anomalies arose from the inhomogeneity of the specimen, though the specimen proved to be homogeneous in electrical properties at room temperature. If the number of current carrier varies along the specimen, potential gradient also varies when a current flows. Then potential drop between two probes can be changed by applying a magnetic field, especially when the variation of potential gradient is large near the probes. The potential drop can be increased or decreased by changing the direction of magnetic field. This is, we think, the cause of the anomaly mentioned above. The non-ohmic properties obtained are considered to result from the inhomogeneity too. Moreover a p-n junction might be generated within the specimen at some temperature.

Let us now consider the reason why Hall coefficient changes its sign. Within the scope of our experiments, copper added seems to be responsible for the sign reversal. The surfaces were ground, before measurements, by using emery paper in order to avoid any disturbances due to the surface copper film. Impurity band conduction3) and surface conduction4) can be taken into account as the cause of the sign reversal. Impurity band conduction model proved to have several difficulties in quantitatively explaining the phenomena, although the characteristics obtained were, in several respect, similar to those of germanium with impurity conduction band. But we cannot entirely deny, at present, an occuarence of impurity band conduction, since the data are scanty and there are some uncertainties in the date due to the inhomogeneity.

Researches to get more informations on the cause of the sign reversal are now in progress.

Quasi-static Hysteresis in Barium-titanate Single Crystals

By KIYASU Zen'iti, Kazuo HUSIMI and
Keisuke KATAOKA
Electrical Communication Laboratory, Tokyo

(Received November 5, 1956)

The measurement of hysteresis curve and spontaneous polarization in barium-titanate single crystal have hitherto been carried out by polarization switching method. By this method, we cannot measure these characteristics quantitatively, because there may be asymmetries on the hysteresis loop, and we cannot detect the depolarized point.

The authors have developed a new ultrasonic measuring method which uses the piezoelectric property of ferroelectric materials to determine the absolute polarization. Using this method together with the conventional method we have obtained various important results.

The sample used, 0.14 mm in thickness, with 1 mm² electrode area, is a c-plate which contains a-domain a little, and has been produced by KF-process by Waku in this Laboratory.

After applying a positive half cycle of a sinusoidal field with a peak value of 2 kV/cm and the period of 6 minutes, we obtained minor loops for the field strengths of 0.3, 0.35, 0.4, 0.45 and 0.5 kV/cm. These quasi-static hysteresis loops are shown in Fig. 1.

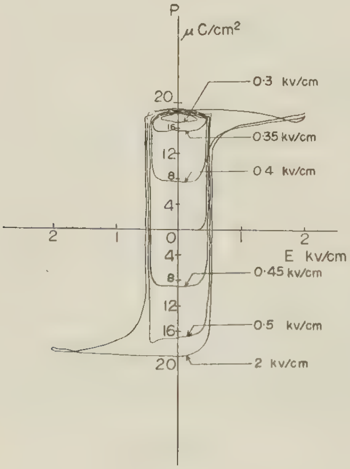

Fig. 1.

After applying 5 kV/cm d.c. field for several times, we measured the polarization at 5 kV/cm d.c. field for 2 seconds. These results are shown in Fig. 2.

1. Maximum slope of the hysteresis loop $\varepsilon_{\max}$ is virtually infinite. $\varepsilon_{\max}$ is found to follow the relaxation formula of Debye's type,

$$\varepsilon^* = \frac{a}{1+j\frac{f}{f_0}} + \varepsilon_\infty$$

with $f_0=0$, instead of the value 29 kc/s reported by Drougard¹⁾, that is, $\varepsilon_{\max}$ is represented by the formula

$$\varepsilon_{\max} = \frac{A}{jf} + \varepsilon_\infty .$$

2. In case of single crystals, the minor loops return to their original spontaneous value without any appreciable depolarization.

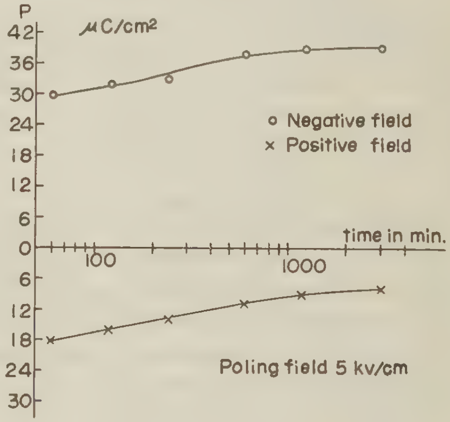

Fig. 2

3. The crystal contains slowly polarizing components which takes several hours to polarize even under a high electric field, whereas it has been believed that the reversal of polarization is completed within a very short time under such a field, although under a low field the polarization may be fairly slow, as Little observed²⁾.

4. There are asymmetries in polarization velocity under positive and negative fields. This characteristic is in the same polarity throughout a single plate crystal, and it is easier to polarize from outer to inner side of a butterfly pair.

5. The value of spontaneous polarization, 37.8×10^{-6} coulomb/cm² at room temperature, is much in excess of Merz's value 24×10^{-6}. The sum of positive and negative polarizations in Fig. 2, on the other hand, is always nearly 48×10^{-6} coulomb/cm² which is just twice the above value. From this we conclude that Merz has measured the high speed component only.

The Thermal Decomposition of Polyvinyl Alcohol Using Mass Spectrometer

By Hideo FUTAMA and Hidejirō TANAKA

Department of Physics, Faculty of Science, Hokkaidō University, Sapporo

(Received November 29, 1956)

It has been known that the thermal decomposition of polyvinyl alcohol (PVA) plays an important role in considering its properties[1]. Using the mass spectrometer (Hitachi RM-AA) which seems to be more convenient than to the customary chemical method[2], we have analysed the thermal decomposition products of PVA. Heating of PVA films is so controlled that the temperature is kept constant for a sufficiently long time and raised step by step.

Decomposed vapours are mainly water and acetaldehyde. Generation of vapours fit the first order reaction with reaction constant k of the order of $10^{-4}\,\mathrm{min}^{-1}$, $m=a[1-\exp(-kt)]$, where t is time and m is the mass of the generated vapour per unit mass of initial PVA. This equation holds for the generation which occurs by raising the tempera-true from $T-\Delta T$ to T and keeping it at T. For example, Fig. 1 shows the generation of acetaldehyde at 200°C. Dotted line is calculated from the equation, where a and k are chosen so as to fit the experimental curve.

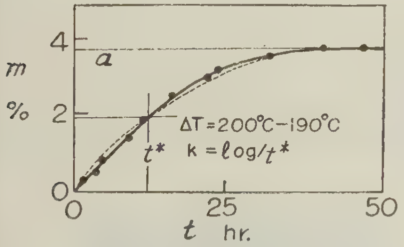

Fig. 1

Saturation value a is the function of T and ΔT, and by making $\Delta T\to O$ we may abtain $a(T,\Delta T)\fallingdotseq f(T)\cdot\Delta T$. Then we can assume the existence of certain distribution function $f(T)$ of the source of decomposed vapour in PVA. Thus it follows

$$a(T,\Delta T)=\int_{T-\Delta T}^{T} f(T)\cdot dT\fallingdotseq f(T)\cdot\Delta T\,.$$

Seeking $a(T,\Delta T)/\Delta T$ experimentally, we can obtain the approximate shape of $f(T)$ as showe in Fig. 2, where ΔT is about 10°C and curves ***A***, ***B*** and ***C*** are found to correspond to water, water and acetaldehyde respectively by the mass spectrometric analysis.

To examine curves ***A*** and ***B*** in Fig. 2, we prepared two samples. One (S_1) is immersed in the vapour of heavy water D_2O solution. Table I shows merely a qualitative tendency of the generation of DHO which consists in the generated aqueous vapour. In the sample (S_1), degree of heavy hydrogen exchange with PVA radical seems to be lower than that in (S_2). Further the curve ***B*** occurs in connection with the decomposition curve ***C***. Thus in Fig. 2, the curve ***B*** seems to correspond to the decomposition or rather to the cross linking (ether bond) in PVA structure, and the curve ***A*** to mere dehydration.

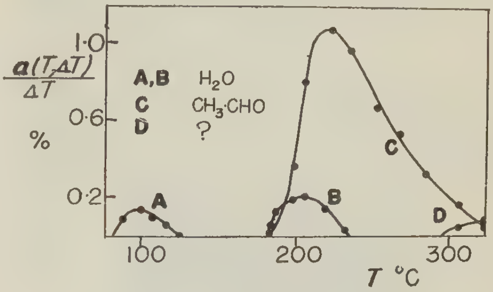

Fig. 2

In Fig. 2, the area of the curve ***B*** indicates 7% of PVA, which means 20% of O atoms in PVA, react into H_2O. The area of the curve ***C*** indicates 60% of PVA, and accumulated plots of a about this curve show 60~70°C lower generation temperature in comparison with more rapid heating[3]. The curve ***D*** in Fig. 2 consists of undetectable vapours which seem to be hydrocarbons. This part and the residue in the furnace indicate 25% of PVA. To detect them is a remaining task.

Table I. Concentration of DHO in the generated aqueous vapour

Sample	***A***	***B***
S_1	30~40%	2~ 3%
S_2	30~40%	40~50%

Resistivity and Hall Coefficient of Semiconductors

By Kisaburo SHOGENJI and Susumu UCHIYAMA
Faculty of Engineering, Nagoya University, Nagoya

(Received January 24, 1957)

Resistivity and Hall coefficient of semiconductors have been already calculated for the case in which the current carriers are scattered by acoustical mode of lattice vibration and ionized impurity centres.[1] We have made the calculation for the case where the current carries are affected by both acoustical and optical modes of lattice vibration. The scattering by impurity centres is neglected in this calculation. Since its effect becomes appreciable at lower temperatures, the calculation made here has some significance at rather high temperatures, especially for semiconductors with high dielectric constant.

The calculation is made on the basis of the following assumptions: *i*) electrons (or holes) which contribute to conduction are free; *ii*) they obey Boltzmann statistics; *iii*) scattering of electrons is due to acoustical and optical modes of lattice vibration, other scattering sources being neglected; *iv*) for scattering by optical mode, relaxation time of Fröhlich and Mott[2] exists. Using conventional notations, conductivity and Hall coefficient are expressed as follows:

$$\left.\begin{aligned} &\sigma=A+(B^2/A), \qquad R=-B/\{H(A^2+B^2)\},\\ &A=-\frac{4\pi e^2}{3}\int_0^\infty lv^3(1+s^{22})^{-1}\frac{\partial f}{\partial\varepsilon}dv,\\ &B=-\frac{4\pi e^2}{3}\int_0^\infty slv^3(1+s^2)^{-1}\frac{\partial f}{\partial\varepsilon}dv,\\ &s=elH/mv. \end{aligned}\right\} \quad (1)$$

Mean free path l of electron is given by

$$\left.\begin{aligned} &1/l=(1/l_a)+(1/l_0),\\ &l_a=3(2\pi mkT)^{1/2}/4e^2n\rho_a,\\ &l_0=(2m\varepsilon)^{1/2}/c^2n\rho_0, \end{aligned}\right\} \quad (2)$$

l_a is mean free path when the acoustical mode only scatters electron and ρ_a is the resistivity at that time; l_0 and ρ_0 correspond to the optical mode. Thus

$$\left.\begin{aligned} &A=\frac{2}{\rho_a}\int_0^\infty\frac{x^4(x+\beta)\exp(-x^2)}{(x+\beta)^2+\gamma}dx,\\ &B=\frac{2\sqrt{\gamma}}{\rho_a}\int_0^\infty\frac{x^4\exp(-x^2)}{(x+\beta)^2+\gamma}dx,\\ &\beta=\frac{3\sqrt{\pi}}{4}\frac{\rho_0}{\rho_a}, \qquad \gamma=\frac{9\pi}{16}\mu_a{}^2H^2, \end{aligned}\right\} \quad (3)$$

μ_a is the mobility corresponding to the acoustical mode. With Eqs. (1) and (3) we can calculate resistivity and Hall coefficient. Fig. 1 shows resistivity at no magnetic field, and ratio of Hall ceofficient to 1/ne. Fig. 2 shows the change of resistivity with magnetic field.

Manganese Impurities in Silver Halides Studied by the Paramagnetic Resonance Absorption

By Hidetaro ABE

Institute of Science and Technology, University of Tokyo, Tokyo

(Received February 8, 1957)

Silver halides, AgCl and AgBr, containing manganese impurities were examined by the method of paramagnetic resonance absorption at room temperature and at $\lambda=3.23$ cm. Specimens were prepared from the mixed melt with cooling velocities of 1°∼50°/min.

Table I. P.R.A. spectra of manganese in silver halides.

Base	AgCl		AgBr
Sort of spectrum	(a) 6 peaks	(b) single	(a) 6 peaks
g-value	2.006 ±0.003	2.000 ±0.003	2.006 ±0.010
Hfs splitting const. A in oer.	87±4	—	83±4
Line shape	≈Gaussian	Lorentzian	—
Line width in oer.	19±3	52±4	60±5
Mole Mn concentration in the sample	$10^{-4}\sim 10^{-2}$	$\sim 10^{-2}$	$10^{-4}\sim 10^{-2}$

The Mn/AgCl system gives two types of spectra as listed in Table I, though sometimes another type of absorption is accompanied which is very broad and weak. Spectrum (a) consists of six clearly resolved lines showing the hfs of Mn, three of which are shown in Fig. 1. Spectrum (b) can be only observed in the specimens having higher Mn concentration. Spectrum (a) should correspond to an impurity state of isolated ions whereas (b) can be explained as being caused by manganese aggregation[1) 2)]. So far as much diluted samples are concerned, it can be concluded from the measured intensity that nearly all the part of added Mn impurities appears to occupy the impurity state (a) and it is stable at room temperature over months. Situation differs somewhat from the case of Mn/NaCl, etc.[1) 3)] at room temperature. The observed hfs shows the crystalline field acting on the Mn ion at room temperature is cubic and the Mn^{++} in AgCl crystal is not accompanied by any Ag vacancy at least in its near neighbours. Mn/NH_4Cl crystal really shows in its P.R.A. spectrum the influence of a heavily distorted crystalline field acting on the Mn ions. In Mn/AgBr system, the six peaks of hfs can be just resolved as in Fig. 2. Assuming that each component line has Gaussian shape, the width of 60 oer. gives the best fit to the observed derivative curves (at 5×10^{-4} mole Mn).

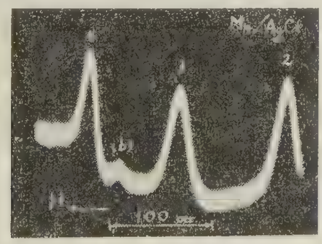

Fig. 1. CRO photo of Mn spectra at 3×10^{-3} mole Mn in AgCl. Large peaks correspond to the 2nd, 3rd and 4th peak of spectrum (a) whereas small peak is the spectrum (b).

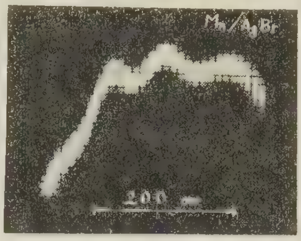

Fig. 2. Low field side of the Mn spectrum at 7×10^{-4} mole Mn in AgBr.

The width of line remains constant within our listed errors, being independent of Mn concentration, which can not be explained by the dipole width. The widths of hfs components in Mn/AgBr and in Mn/AgCl give a ratio of 3.2±0.8. These widths may be, at least mainly, attributed to the nuclear magnetic moments of neighbouring halogens, since the ratio of the nuclear magnetic moment of Br to Cl, $\mu Br/\mu Cl=2.7$, agrees with the above ratio. They are about ten times larger, however, to be explained by the local magnetic field caused by these nuclei. It may be considered that the origin of these widths is attributable to the unresolved substructures due to the halogen nuclei superposed to the main structure of Mn hfs, so that our total Hamiltonian may, presumably, be expressed in the following form:

$$\mathscr{H}=g\beta\boldsymbol{H}\cdot\boldsymbol{S}+A(\boldsymbol{S}\cdot\boldsymbol{I})_{Mn}+\sum A_x(\boldsymbol{S}_x\cdot\boldsymbol{I}_x) \qquad (1)$$

From the observed width of hfs components, the total probability of finding the unpaired spin on some halogen atoms is estimated to be about 0.10.

The author is very grateful to Prof. K. Ôno for his valuable discussions and to Mr. E. Mizuki of the Fuji Photo Film Co. Ltd. for supplying the pure silver halides.

Observation of the Drift of Germanium Surface by Field Effect Experiment

By Makoto KIKUCHI

Electrotechnical Laboratory, Tokyo, Japan

(Received February 22, 1957)

It has been found out that an etched surface of n-type germanium shows "drift" in the room air. Experimental apparatus and measuring circuits are shown in Fig. 1. A chopped light beam is focused on the single crystal germanium rod through a thin mica plate, which is sandwhiched by the specimen and a fine metal mesh. d.c. voltage V_p is supplied to the mesh, and the variation of conductance of the sample and that of photoconductance are measured.

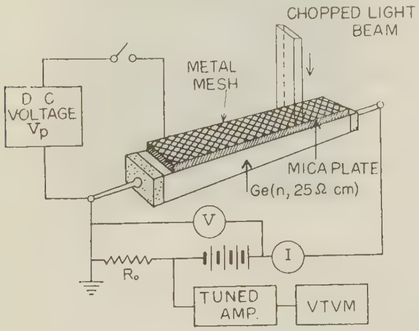

Fig. 1. Schematic representation of experimental apparatus.

At first, the sample was etched with $CP-4$, and after two days, it was again treated with HF for 10 minutes. Measurements were performed after (A) 5 minutes, (B) 17 hours, (C) 24 hours, and (D) 48 hours. Results are shown in Fig. 2. These results were quite well reproducible.

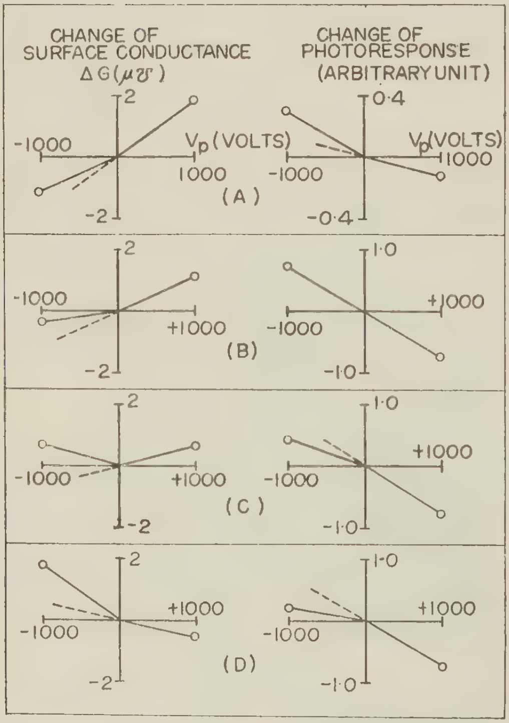

Fig. 2. Experimental results (A) 5 min, (B) 17 hours, (C) 24 hours, (D) 48 hours, after HF treatment.

The surface conductance can be calculated as a function of φ_s (i.e., the difference between the Fermi level and the middle of the energy gap at the surface), using Schrieffer's estimation of the mobility. Relative values of photoresponse may also be estimated from the Stevenson's calculation[1]. These curves are shown in Fig. 3.

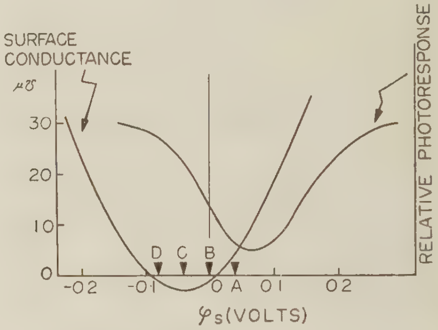

Fig. 3. Variation of surface conductance and photoresponse with φ_s.

From Fig. 2 and 3, we can obtain following conclusions:

1) The situations of the surface (A, B, C and D in Fig. 2) correspond to the positions A, B, C and D on the φ_s axis in Fig. 3, respectively.
2) The etched surface drifts towards the state of less φ_s value in the room air.
3) The maximum of the surface recombination velocity as a function of φ_s calculated by Stevenson must be shifted towards right, as independently pointed out by Harik[2] et al.

It seems likely that the drift of φ_s is caused or accompanied by the building up of oxide layer on the etched surface. We have also obtained some evidences for it.

Detailed discussions and other experimental results will be reported in the near future.

Randomness of Microwave Gas Breakdown Voltage

By Kenji Mitani and Hiroshi Kubo
Yoshida College, University of Kyoto

(Received January 25, 1957)

R. Cooper[1] has made observation of the randomness of the microwave gas breakdown by using pulsed microwave. We have investigated the same phenomenon by continuous microwave, and here the results obtained together with some discussions will be given. The experimental apparatus used is the same as that reported in our previous paper.[2]

In Fig. 1 the curves (a) and (b) show the breakdown probabilities, corresponding respectively to the cases with and without irradiation by γ-rays of RaBr, the breakdown probability meaning the ratio of the number of the breakdowns occuring before a certain voltage V to the total number of breakdowns. Comparing these two curves, it will easily be seen that the case with irradiation by γ-rays has a sharper slope, meaning that in microwave, too, the so called statistical time lag is smaller in the case with irradiation than in the case without it. We find that the microwave breakdown voltage is not uniquely determined. When we take the potential corresponding to the breakdown probability of 50% as the breakdown voltage, as in the case of the direct current breakdown[3], the curves of the microwave breakdown voltage *versus* gas pressure become as shown in Fig. 2. It is found that these curves have the same character as the ones obtained by S. C. Brown and others in microwave[4].

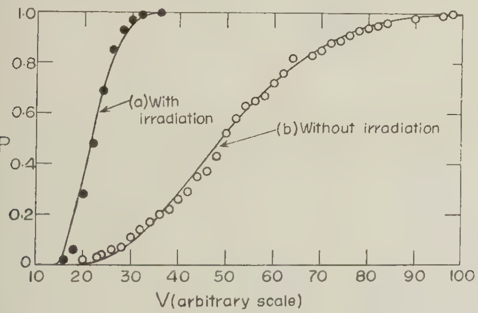

Fig. 1. Effect of irradiation on breakdown probability. ○ and ●: experimental values; ——: calculated curves.

Furthermore, the authors have investigated how these breakdown probability curves are expressed, and it has been found that, except in the range of very small breakdown voltages, these curves can be expressed very nearly by the same equation as that derived by H. Tamagawa[5] in the case of the d.c. breakdown, namely,

$$P(v)=\int_0^v W(v)dv$$
$$=\int_0^v \frac{v}{ak}\exp\left(-\frac{v^2}{2ak}\right)dv=1-\exp\left(-\frac{v^2}{2ak}\right),$$

where P is the breakdown probability, v the over-voltage, and a and k are certain constants. The above equation is based upon such an experimental condition that the applied voltage is raised linearly with respect to the time, and the authors' experiment was also carried out approximately in compliance with this condition. The solid lines in Fig. 1 show the above equation.

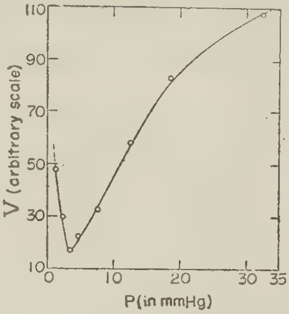

Fig. 2. Breakdown voltage *versus* gas pressure.

As shown by S. C. Brown and others[6], the mechanism of microwave breakdown is different from that of d.c. breakdown, mainly because the diffusion plays a predominant role in the microwave breakdown. Further, we have found from our experiment that the microwave breakdown voltages are distributed in a certain range and the breakdown probability can be expressed approximately by the same expression as in the d.c. breakdown. This result seems to give an important suggestion as to a more detailed breakdown mechanism in microwave, since the curves in Fig. 1 show the existence of the forming time of the avalanche in the microwave breakdown. On the other hand, one of the authors has already shown, in a previous paper[7], that the avalanche can occur in the microwave breakdown, but that its direct detection is very difficult because of its spherical form.

The authors greatfully acknowledge their indebtedness to Professor K. Honda and his coworkers for their encouragement and helpful discussions. The authors' thanks are also due to Professor I. Takahashi for his useful advice and encouragement.

A Possible Fusion Reactor

By Goro MIYAMOTO, Giiti IWATA, Sigeru MORI and Kenji INOUE

Department of Physics, Faculty of Science, University of Tokyo

(Received March 1, 1957)

Perfect focusing properties of an electromagnetic field for ion motion were investigated theoretically[1]) by one of the authors; a mass-spectrometer of such a focusing type, namely, of perfect velocity focusing and total direction focusing for the solid angle 4π, was constructed and tested with electrons. This principle may be applicable to an apparatus for producing effective nuclear reactions, i.e. nuclear fusion reactor.

In the homogeneous magnetic field $(0, 0, -H)$ and the electric field with potential represented by $k/2\cdot(-x^2-y^2+2z^2)$, a charged particle of mass m and charge e moves as the equations,

$$\ddot{x}=\frac{e}{m}kx-\frac{e}{m}\dot{y}H\ ,$$

$$\ddot{y}=\frac{e}{m}ky+\frac{e}{m}\dot{x}H\ ,$$

$$\ddot{z}=-2\frac{e}{m}kz\equiv-\omega^2z\ .$$

By putting $x+iy\equiv\exp(ieHt/2m)\cdot Z$, and transforming into rotating coordinates, the first two equations are transformed into

$$\ddot{Z}=-\left(\frac{1}{4}\frac{e^2}{m^2}H^2-\frac{e}{m}k\right)Z\equiv-s^2\omega^2Z\ .$$

The motion is composed of simple harmonic motions, and if s is selected as a rational number, for example, 1, then the particle can pass through the central point (0, 0, 0) any number of times, even though the particle changes by collisions its velocity and direction at the point.

If we inject ion beams (or a beam), e.g. deuteron beams, in such a way as to make them pass through the central point and compensate the space charge effect by sufficient quantity of electrons, then the ions will come back to that point again and again, till the ion mass changes its value by a nuclear reaction.

Losses of the ions would arise as a result of the neutralization or of the scattering by residual gases or ions outside the central part; especially the multiple Coulomb scattering is fearful.

If the ion density is constant in the small central region $r\leq r_0$ (r: distance from the center), and decreases as $1/r^2$ in the outer region $r_0<r\leq R$, then the occurrence number n of an ion passing the origin is represented approximately by $n^2\sim1/(2\rho\sigma_c r_0)$ where $n\rho$ is the ion density at the center, σ_c is the cross section of the Coulomb scattering. For example, by virtue of $\rho=2.0\times10^{12}i/(r_0^2\sqrt{E})$ and $\sigma_c\sim6\times10^{-13}/E^2$, we have $n^2\sim0.42\,r_0E^{5/2}/i$ where i is the injected total deuteron beams in ampere and E its energy in eV. Numerical expamples are shown in the Table

E (eV)	n	$n\rho$
10^4	4.6×10^4	3.7×10^{15}
10^5	8.1×10^5	2.0×10^{16}
10^6	1.5×10^7	1.2×10^{17}

for $2r_0=1$ and $i=1$. Accordingly the ions have sufficient probability of producing the nuclear reactions near the center. Moreover, if the rational number s is selected specifically, for example, as 4/3 or 4/5 or 7/12 etc. for deuteron mass, then the reaction products T^3 and He^3 are also refocused to the nearly same point again.

When applied static voltage is more than 1 MV and deuteron energy is originally small, then the product ions come to accelerate deuterons by Coulomb collisions near the center, till the nuclear transformation (D^2+T^3) or (D^2+He^3) takes place and T^3 and He^3 are consumed.

This fact suggests the possibility of the chain fusion reaction.

Noise from Ge PN Junction and γ ray Irradiation Effect

By Yoshio INUISHI

Faculty of Engineering, Osaka University

(Received February 18, 1957)

Two kinds of noise exist in Ge PN junction:

a) Shot noise

$$(\overline{\Delta i_s{}^2})_f=2eI\Delta f \qquad (1)$$

b) Flicker-like noise or excess noise or $1/f$ noise

$$(\overline{\Delta i_s{}^2})_f=kI^2\cdot\frac{1}{f}\Delta f \qquad (2)$$

where $\overline{\Delta i_s{}^2}$, I, f and k represent mean square short circuit noise current, mean current, frequency, and a material constant respectively.

In leaky or deteriorated diode, increase in reverse current at Zener voltage is not accompanied[1)3)] corresponding increase in noise current, as is shown in Fig. 1.

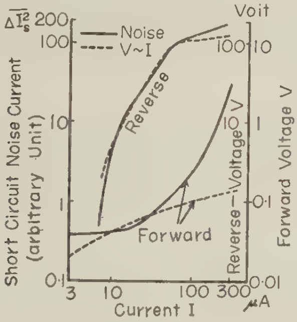

Fig. 1.

Also, carrier injection by light illumination at reversely biased junction does not increase current noise at leaky diode as expected from the increase in reverse current[1) 3)]. These facts suggest us that current through PN junction even over Zener voltage is rather noiseless in comparison with some other kind of excess current which might be produced at surface channel[2) 4)].

To clarify this point, noise from Ge PN junction which shows almost ideal saturation in backward current was investigated. These diodes were provided by the courtesy of G.E. Co., U.S.A.

In Fig. 2 the mean square short circuit noise current and reverse current were plotted as functions of reverse voltage.

In sample No. 1 which shows very clear saturation characteristics, the noise was extremely small and almost equal to the calculated value of shot noise (equation (1)), being nearly independent of applied voltage. Frequency spectrum of noise also supports this view at frequency larger than several KC.

In sample No. 2 at unirradiated state, noise was also small under Zener voltage, being of the same order as calculated shot noise. At Zener voltage, however, abnormal increase in $1/f$ noise current was observed. This might correspond to avalanche noise. These points are under detailed investigation.

No. 2 sample was irradiated by γ ray of 10^6 röntgen dose from CO^{60}, noise and reverse current were measured after irradiation. Reverse current increases and the junction becomes leaky by γ ray irradiation. Noise current also increases remarkably in comparsion with unirradiated samples. These increased noise were proved to obey the equation (2) of flicker-like noise having typical $1/f$ spectrum.

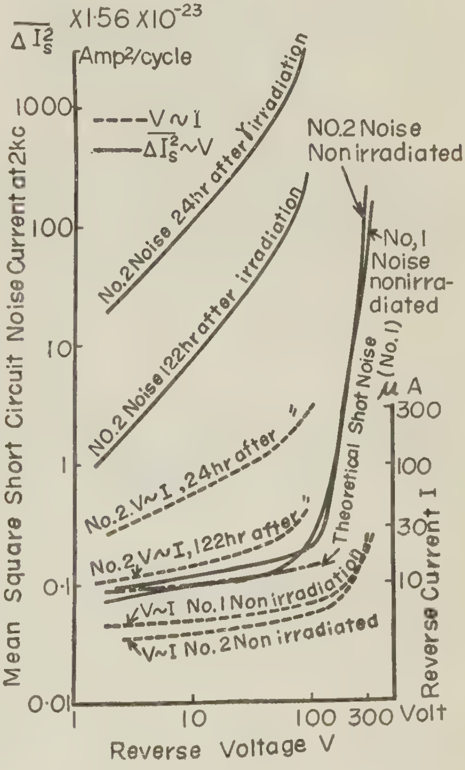

Fig. 2.

Namely γ ray irradiation produce some leaky channel in PN junction which produces remarkable flicker-like noise. In these irradiated sample increase of noise at Zener voltage was masked by the predominant flicker like noise just like the case of leaky diode Fig. 1. Irradiation effect can be annealed even in room temperatures as in shown in Fig. 2.

A Graphical Method for Determining the Coefficient of Viscosity of Newtonian Liquids using an Oscillating Cylinder Viscometer III

By Ali Abdel Kerim Ibrahim (Ph. D.)
Physics Department, Faculty of Science,
Uuiversity of Alexandria
Alexandria, Egypt

(Received December 15, 1956)

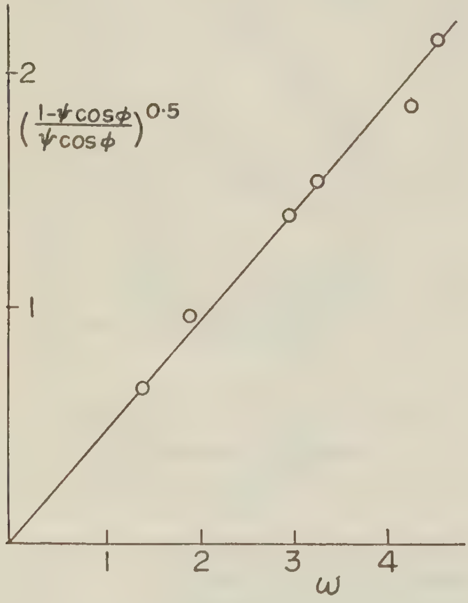

Fig. 1.

If a non-elastic liquid of coefficient of viscosity η in gm. cm.$^{-1}$ sec.$^{-1}$ is filling the annular gap between two coaxial cylinders, the outer being oscillating through very small angles with various frequencies n c.p.s., while the inner is suspended by a delicate copper wire of torsion constant τ then[1],

$$\eta = \frac{1}{\pi} \cdot \frac{d}{L} \cdot \frac{e^{-3d/R}}{a^3} \cdot \frac{I\omega^2-\tau}{\omega}\left(\frac{\psi\cos\phi}{1-\psi\cos\phi}\right)^{0\cdot5} \cdots(1)$$

where, $R=(b+a)/2$ $\omega=2\pi n$
$d=(b-a)/2$

b, is the inner radius in cms. of the outer cylinder, a, is the radius in cms. of an inner cylinder of moment of inertia I in gm. cm^2; and length of immersion L in cms.

$$\psi=\theta_0/\phi_0$$

ϕ_0 being the amplitude of the outer cylinder and θ_0 is that of the inner cylinder. Also, ϕ is the phase angle by which the inner cylinder lags the outer cylinder.

If τ is very small compared with $I\omega^2$, therefore,

$$\eta=k\omega\,[\psi\cos\phi/(1-\psi\cos\phi)]^{0\cdot5} \cdots\cdots\cdots(2)$$

where,

$$k=\frac{I}{\pi} \cdot \frac{d}{L} \cdot \frac{e^{-3d/R}}{a^3}$$

K is an apparatus constant.

Now, if $[(1-\psi\cos\phi)/(\psi\cos\phi)]^{0\cdot5}$ represents the Y-axis, and ω represents the X-axis, then the relation between Y and X is linear and may then be written as,

$$Y=(K/\eta)X \cdots\cdots\cdots\cdots\cdots(3)$$

i.e. a straight line relation from whose slope (K/η) the coefficient of viscosity η may be determined.

The figure shows the results taken by Markovitz[2] et al for standard oil obtained from the national bureau of standards.

The following table gives the results for the liquid under test.

K	(K/η)	η in poise	
		from graph	from table
0.376	0.47×10^{-2}	81	91.6

It is clear from graph and table that my equation represents the facts to a certain degree of accuracy.

Anomalous Electrical Properties of Lead Telluride

By Yasuo Kanai and Riro Nii

The Electrial Communication Laboratory, Musashinoshi, Tokyo

(Received January 25, 1957)

Electrical properties of single crystals of lead telluride (PbTe) were measured from room temperature to liquid air temperature. In some p-type specimens, the same anomaly as previously reported by Putley[1], i.e., the reversal of the sign of the Hall coefficient at low temperature was found. A typical example of such anomalous behaviour is shown in Fig. 1.

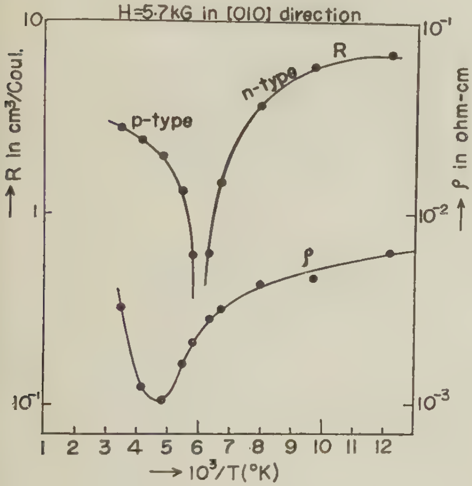

Fig. 1. Resistivity, ρ, and Hall coefficient, R, versus 1/T curves of a single crystal of PbTe. The electric current was applied in the [100] direction.

In such specimens further anomalous phenomena, i.e., the *magneto-conductive phenomena* was observed in the low temperature n-type region. Fig. 2 shows the magetic field dependency of the Hall coefficient and transverse magneto-conductance effect, $-\varDelta\rho/\rho(0)\equiv 1-\rho(H)/\rho(0)$, of the same sample whose electrical properties are shown in Fig. 1. The longitudinal effect of this sample is very small and this magneto-conductive effect varies as $\sin\theta$, where θ is the angle between the direction of electric current and that of magnetic field.

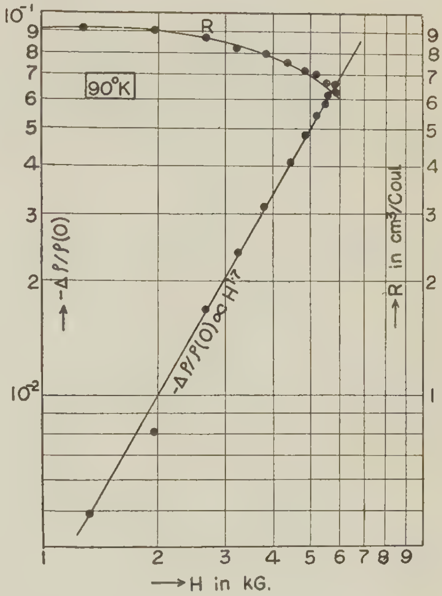

Fig. 2. Hall coefficient, R, and magneto-conductance effect, $-\varDelta\rho/\rho(0)$ versus magnetic field strength curves. Electric current was applied in the [100] direction, and the magnetic field in the [010] direction.

Further systematic investigations on these anomalous properties of PbTe are now in progress.

The authers thank to Mr. S. Uchiyama for valuable discussions.

Cross Section for Displacement of Atoms by Heavy Particle Irradiation

By Takeshi MORIMOTO

Department of Metallurgy, Kyoto University, Kyoto, Japan

(Received January 7, 1957)

The cross section Φ_d of displacement collision by heavy charged high energy particles in the case of $E > ME_{el}/m$ is expressed as follows¹⁾

$$\Phi_d = \frac{2\pi Z^2 z^2 e^4}{M_n V^2 \varepsilon_t}, \tag{1}$$

where Ze and M_n are the nuclear charge and mass of the stopping material, ze, V, E and M are respectively the full charge, the velocity, the kinetic energy and the mass of the incident particle, $\varepsilon_t (\approx 25\,eV)$ is the threshold energy of displacement, m is an electron mass, and $E_{el} = \frac{1}{2} m v^2$ (where v is the electron velocity), the ionization potential.

In the case of low energy, i.e., $E < ME_{el}/m$, the formula (1) is not valid because of the screening effect of the nuclear charge and the electron pick-up of the incident particle. Then, it may be safely said that the incident particle can be regarded electrically neutral rather than ion-like in sufficient low energy. Here, a calculation is presented, assuming that the interaction potential energy between two different neutral atoms $V(R)$ is of the form²⁾

$$V(R) = \frac{Zze^2}{R} \left\{ \frac{a_1^2 \exp(-R/a_2) - a_2^2 \exp(-R/a_1)}{a_1^2 - a_2^2} \right\}. \tag{2}$$

The momentum transfer ΔP in the collision having impact parameter b is given as follows:

$$\Delta P = \frac{2Zze^2}{V(a_1^2 - a_2^2)} \left\{ \frac{a_1^2}{a_2} K_1(b/a_2) - \frac{a_1^2}{a^2} K_1(b/a_1) \right\}, \tag{3}$$

where a_1 and a_2 are the radii of the atomic electron clouds of the incident and stopping atoms respectively, $K_1(x)$ the 1st order modified Bessel function of the second kind. Eq. (3) generally gives the momentum transfer of the interaction between two different atoms. When $a_1 \gg b$ and $a_2 \gg b$ (in high energy range), eq. (3) reduces to

$$\Delta P = \frac{2Zze^2}{Vb}, \tag{4}$$

and we can readily get eq. (1) from eq. (4). The variation of Φ_d for V can be found as shown in Fig. 1, by solving numerically the following eqs. (5) and (6):

$$\Phi_d = \pi b_t^2, \tag{5}$$

$$\frac{2Zze^2}{\Delta P_t (a_1^2 - a_2^2)} \left\{ \frac{a_1^2}{a_2} K_1(b_t/a_2) - \frac{a_2^2}{a_1} K_1(b_t/a_1) \right\} = V, \tag{6}$$

where $\Delta P_t^2 = 2M_n \varepsilon_t$. The low energy treatment mentioned above will be permissible if the condition $MV \geq \Delta P_t$ is fulfilled. This is satisfied by heavy particles to the extent of considerable low energy.

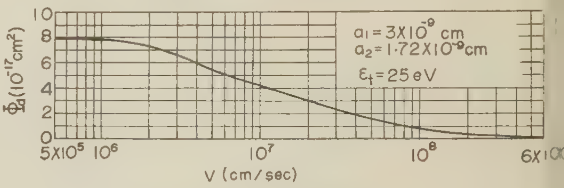

Fig. 1. Cross section for displacement of Atoms by α-Particle Irradiation in Cu.

Nuclear Reactions induced by the 14 MeV Neutrons

By Shinjirō YASUMI

Department of Physics, Kōnan University, Kōbe

(Received December 18, 1956)

The nuclear reactions of Al, Fe, Cu, Zn, Mo and Ag produced by the neutrons from the $T^3(d, n)$ He^4 reaction have been investigated by means of the activation technique. The absolute numbers of activated nuclei in samples were determined by measuring the beta-rays from the samples with a 4π-proportional counter and applying the "method of extrapolation."

By utilizing the variations of neutron energies in the laboratory system, an excitation curve of $Mo^{92}(n, 2n)Mo^{91}$ reaction was obtained. For the cases of Al, Cl, Zn and Ag, only the gradients of excitation curves were also found.

The experimental cross sections were determined as follows: 87.2 mb±8% for $Al^{27}(n, p)Mg^{27}$, 120 mb±12% for $Al^{27}(n, \alpha)Na^{24}$, 144 mb±13% for $Fe^{56}(n, p)Mn^{56}$, 556 mb±5% for $Cu^{63}(n, 2n)Cu^{62}$, 119 mb±12% for $Zn^{64}(n, 2n)Zn^{63}$, 60.2 mb±12% for $Zn^{66}(n, p)Cu^{66}$, 132 mb±16% for $Mo^{92}(n, 2n)Mo^{91}$, 458mb±11% for $Ag^{107}(n, 2n)Ag^{106}$, and 604 mb±11% for $Ag^{109}(n, 2n)Ag^{108}$. Comparing these results with the predictions by the statistical theory of Weisskopf *et al.* it was found that they agreed with each other within about factor 3, but in details, there were some discrepancies between them.

The relative behavior of excitation curve of the $Mo^{92}(n, 2n)Mo$ reaction seems to be consistent with the above theory, though with respect to the absolute values, the theoretical curve lies above the experimental one by about 2.4.

§1. Introduction

A study on the nuclear reactions induced by fast neutrons can provide us powerful informations about the mechanism of the nuclear process.

In recent years, the monoenergetic neutrons from the $T^3(d, n)He^4$ reaction have become easily available by using tritium-loaded zirconium targets[1]. The nuclear reactions by these neutrons have been studied by some workers[2] with the activation method.

Especially, Paul and Clarke[3] carried out these investigations for many nuclei. They found remarkable discrepancies between the theoretical and experimental cross sections of (n, p) and (n, α) reactions for heavy nuclei and suggested the existence of the direct process in these cases. However, the absolute beta-counting method adopted by them seems to be somewhat rough as pointed out by the workers themselves, and may have introduced appreciable errors in their results.

Thus we have attempted to determine more accurately the absolute cross sections and the excitation curves of these reactions by an improved method. The results obtained were discussed from the point of view whether the statistical theory of the nuclear reaction is valid or not for about 14 MeV neutrons.

§2. Experimental Procedures

If a nuclear reaction leads to the formation of an unstable isotope, the resulting activities may provide a means for determining the reaction cross section by absolute beta-counting which determines the total number of active nuclei in the sample. The activation method is still usable also in the case involving K-electron capture, if a fraction of the disintegration through β-emission is known.

(A) *Cross Section*

To determine the cross section, the following three points must be taken into account.

(1) *Number of Neutrons*

The number of neutrons was monitored by the α-particles emitted simultaneously in the T–*d* reaction which were counted by a ZnS-scintillation counter placed at 90° direction with respect to the deuteron beam. The angular distribution of the emitted neutrons is found to be isotropic[4] in the c. m. system at the deuteron energy under consideration.

The samples were irradiated for from several to several ten minutes according to the half-lives of the induced activities. The neutron intensity was obtained from the α-counts in every one minute or thirty seconds interval during irradiations for the purpose of correction for the small fluctuations of the neutron intensity.

In calculating the cross section it was assumed that the neutron intensity was constant in such small intervals. This approximation will introduce inappreciable errors, probably less than 1 per cent.

(2) *Absolute Beta-Counting*

In order to estimate the total number of the active nuclei in the sample plate of finite thickness, the following procedures were used. The net beta-counting rate c/m of a radioactive sample mounted in a given position may be represented as the product of the disintegration rate d/m of the sample multiplied by several factors which express the effects of beta-particle scattering, absorption and the counting geometry, that is, it will be written as follows:

$$c/\mathrm{m}=(d/\mathrm{m})\cdot f_S\cdot f_A\cdot f_B\cdot f_G\ , \tag{1}$$

where

f_S: factor for the effect of the mass of the sample itself in causing both scattering and absorption of beta-particles,

f_A: factor due to the effects of absorption and inscattering into the counter by the counter window and air,

f_B: factor due to the effects of backscattering by the sample holder and the housing,

f_G: geometrical factor.

(a) The correction factor f_S (the “extrapolation method”[5])

Samples of various thickness and the irradiation monitor, which was consisted of the same material and had the same diameter as the samples, were irradiated in juxtaposition, and their activities were counted by two Geiger counters.

The ratio $N_S/N_M\cdot w$ is proportional to the apparent specific activity, where N_S and N_M are the total net counts for the same time interval of a sample and a monitor respectively, w is the thickness of a sample in g/cm². When the curve of $(N_S/N_M\cdot w)$ vs w which represents the self-scattering and absorption of a sample is extrapolated to zero-thickness, the limiting value $\lim\limits_{w\to 0} N_S/N_M\cdot w\equiv S$ may be taken as the true specific activity ($f_S=1$).

(b) The product of the correction factors $(f_A\cdot f_B\cdot f_G)$

These factors were determined by using a 4π-proportional counter of the propan gas flow type.

Two comparatively thin samples of the same material and same thickness were irradiated in juxtaposition at 90° to the direction of the deuteron beam, and the beta-particles from the one sample was counted by an end-window Geiger counter and those from the other sample by the 4π-counter for the same time interval. Then the ratio of their counts $N_{4\pi}/N_G$ corresponds to the reciprocal of the product $(f_A\cdot f_B\cdot f_G)$.

(3) *Assignment of the Nuclear Reactions*

The nuclear reaction was assigned by the half-life of the product nucleus. When more than two reactions occurred simultaneously, the component activities were separated by the analysis of the compound decay curve or from the intensity of residual activity after an appropriate time lapse.

Finally, in order to calculate the cross section, the following equations were used in the cases of “one minute-treatment” and “thirty seconds-treatment”[*] respectively:

for one minute-treatment,

$$\sigma=\frac{M\cdot\left[N_M\Big/\sum\limits_{i=1}^{T} n_{\alpha i}\cdot\exp\{-(T-i+t_0)\lambda\}\right]\cdot S\cdot C_{G'}\cdot C_K}{N_0\cdot\eta\cdot\Omega\cdot[(1-\mathrm{e}^{-\lambda})(1-\mathrm{e}^{-10\lambda})/\lambda]\cdot(4\pi/\omega)}\ , \tag*{(2)$_1^*$}$$

and for thirty seconds-treatment,

---

[*] These referred to the cases in which the neutron intensities were taken to be constant for every one minute or thirty seconds, respectively.

$$\sigma=\frac{M\cdot\left[N_M\Big/\sum_{i=1}^{2T}2n_{\alpha i}\cdot\exp\left\{-\left(T-\frac{i}{2}+t_0\right)\lambda\right\}\right]\cdot S\cdot C_{G'}\cdot C_K}{N_0\cdot\eta\cdot\Omega\cdot[(1-e^{-\lambda/2})(1-e^{-10\lambda})/\lambda]\cdot(4\pi/\omega)}, \qquad (2)_2{}^*$$

where

N_0: Avogadro's number

M: molecular weight of the sample

η: isotopic abundance (%)

S: $=\lim_{w\to 0} N_S/N_M\cdot w$

$C_{G'}$: $=1/(f_A\cdot f_B\cdot f_G)$

Ω: solid angle of the sample under irradiation $=\frac{1}{4}\log\frac{R^2+a^2}{a^2}$

$n_{\alpha i}$: α-counts for one minute or 30 seconds of the i-th interval

T: time of irradiation

t_0: time elapsed from the end of irradiation to the beginning of beta-counting

i: number of the order of each time interval during bombardment (integer)

N_S: beta-counts per 10 minutes on the sample

N_M: beta-counts per 10 minutes on the monitor

C_K: correction factor concerning the branching ratio between the positron emission and the orbital electron capture, namely

$C_K=1$ for the case of β^--activity,
$C_K>1$ for the case of β^+-activity.

ω: solid angle which the α-detector subtends to the neutron source

λ: decay constant

(B) Excitation Curve

The neutron energy E_n in the laboratory system is given by the following equation

$$\sqrt{E_n}=\frac{1}{5}[\sqrt{2E_d}\cos\theta_n+\sqrt{2E_d\cos^2\theta_n+10E_d+20Q}\,], \qquad (3)$$

where E_d is the deuteron energy, θ_n is the emission angle of neutron to the deuteron beam, and Q is the liberation energy of the $T^3(d, n)He^4$ reaction which is equal to 17.6 MeV. At the 0.15 MeV deuteron, E_n varies from 13.3 MeV to 15.0 MeV according to the angle of emission with respect to the deuteron beam. Utilizing this effect, excitation curves near 14.1 MeV were obtained for a few reactions.

Two sheets of fairly thick samples were irradiated at different angles to the deuteron beam. These samples were of the same material and the same thickness, and the relative yield of each specimen is proportional to the relative cross sections at the corresponding neutron energies. Relative counting efficiency of the two Geiger counters used in this experiment was determined previously by a preliminary experiment.

The deuteron energy was kept constant within 2 per cent during the excitation study by stabilizing the exciting current of the beam analyser. Since various deposits on the T–Zr target diminish the deuteron energy considerably after a long bombardment, the excitation curve was always measured with a fresh target.

§ 3. Apparatus

The tritium-loaded zirconium target* was bombarded by the analysed beam of deuterons, which was accelerated by a 0.4 MV-Cockcroft generator. The deuteron energy was about 0.15 MeV and the beam intensity was limited to about 20 microamperes to prevent the local heating. The size of the beam spot was from 2 mm×6 mm to 3 mm×7 mm in an elliptic shape as the target was oblique to the deuteron beam. The total yields for these targets were found as several 10^7 neutrons per second per microampere for 0.15 MeV deuterons.

The target chamber is shown schematically in Fig. 1. The chamber has five irradiation windows covered with 0.2 mm thick copper plates situated respectively at 30°, 60°, 90°,

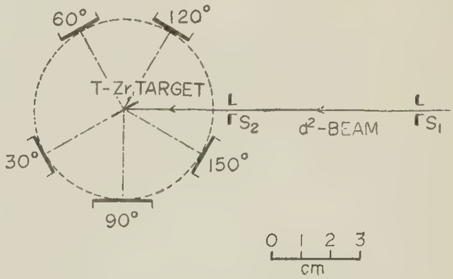

Fig. 1. Schematic drawing of the target chamber.

---

* For the derivation of Eq. (2), see Appendix (1).

* These targets were obtained from A.E.R.E. in England.

120° and 150° to the deuteron beam. For cross section measurements, samples of 20 mm in diameter were irradiated at the 90°-window only, while, for obtaining the excitation curve, samples of 14 mm in diameter were irradiated at all the five windows.

The neutron was monitored by counting α-particles emitted at 90° to the deuteron beam with a ZnS-scintillation counter. The scintillator was made by depositing RCA 33-Z-20A powder in a circular shape directly on the glass wall of a photomultiplier 931A. The thickness of the deposit layer was about 16 mg/cm², which gives the optimum pulse height distribution for the Polonium-α-particles. The scintillator was covered with two very thin aluminium foils (about 120 μg/cm² thick each) to prevent any light from reaching the scintillator.

To determine the discriminator bias the pulse height distribution of the reaction α-particles was measured by a Johnstone-type single channel pulse height analyser⁶⁾. During this measurement the neutron intensity was monitored by a plastic scintillation counter. The noise-level and the α-particle peak were found to be distinctly separated by a wide valley where the counting rate was nearly zero. Hence the bias voltage of the discriminator was set at about the middle point of this valley. The peak due to the proton emitted by the reaction $D^2(d, p)T^3$ was not found in the pulse height distribution curve.

For counting β-rays, we used three end-window type Geiger counters, whose absolute efficiencies were calibrated by a 4π-proportional counter. The counting geometries could be exactly reproducible by means of a proper "jig". All counting systems were placed at adequate distances from the neutron source.

The 4π-counter used is shown in Fig. 2. Propan gas flows through the counter tube at the atmospheric pressure, the flow rate being monitored by a simple flowmeter of the bubble-bottle type⁷⁾. The special feature of this counter is that it is able to put the specimen quickly into the counter without seriously disturbing the operating conditions. Preliminary experiments showed the disturbances of the operating conditions by insertion of samples were found to disappear after one or two minutes at the flow rate of about 60 bubbles per minute.

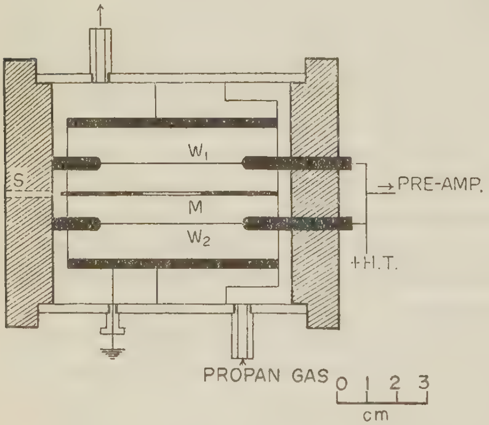

Fig. 2. Construction of the 4π-proportional counter. The plate M is the central separator between the two counters and serves also as a sample holder. It is at the ground potential. W₁ and W₂ are the tungsten wires of 0.05 mm in diameter, which are at positive 4950 volts. One of the end plates made of ebonite has a narrow slit S, which is closed with a strip of "celotape". To insert a sample into the counter, the separator is first taken out through S by removing the celotape strip. Then the sample is placed on the separator, and the latter is taken back into the counter. Finally the slit S should be again closed with the celotape strip.

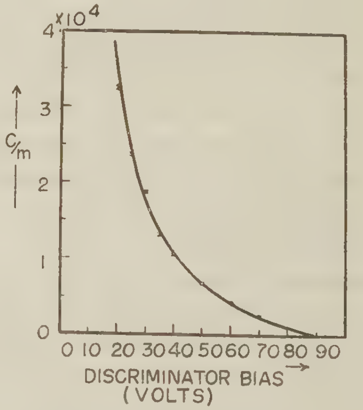

Fig. 3. The integral pulse height distribution of the tritium beta-rays measured by the 4π-proportional counter.

To count nearly all beta-rays emitted from the sample whose maximum energy is about 1 to 3 MeV, the discriminator bias must be set in such a way that the electrons of several keV or more are perfectly detected. For this purpose, the pulse height distribution of the tritium beta-rays was measured by this counter. The results are shown in Fig. 3.

The maximum energy of these beta-rays is about 18 keV, which will be seen from the figure to correspond to 87 volts of the discriminator bias. On the other hand, the noise counting rate per channel above 15 volts was practically negligible. Therefore the bias voltage was set at 20 volts, which corresponds to the electron energy of 4.1 keV.

Hence, the counting efficiency by this counter could be taken to be nearly 100 per cent for beta-rays under consideration. The analysis of the pulse height distribution of beta-rays by the proportional counter is given in Appendix (2).

§ 4. Results

(*1*) *Absolute Cross Section*

All data of the cross section measurements and the final results are tabulated in Table I with their standard errors. The decay constants used for the identification of product nuclei and the calculation of cross sections have been taken from the Table of Isotopes8).

Table I. Data of the cross section measurements and the final results

Reaction	Decay constant λ (min.$^{-1}$)	N_M/Σ*	S	$C_{G'}$	C_K	Cross section** (mb)

* (1) The abbreviation $\Sigma \equiv \left[\sum_{i=1}^{T} n_{\alpha i} \cdot \exp\{-(T-i+t_0)\lambda\}\right]$ is introduced.

(2) All values of (N_M/Σ) correspond to the "one minute-treatment" (see § 2). In the case of the "30 seconds-treatment" the values of $\left[\sum_{i=1}^{2T} 2n_{\alpha i} \cdot \exp\left\{-\left(T-\frac{i}{2}+t_0\right)\lambda\right\}\right]$ were multiplied by the factor $(1-e^{-\lambda/2}/1-e^{-\lambda})$ to reduce to the "one minute-treatment" (cf. eq. $(2)_2$).

** (1) The neutron energy used is 14.1 MeV.

(2) No traces of the reaction $Fe^{54}(n, 2n)Fe^{53}$ was observed with the 14.1 MeV neutrons. This is probably due to the fact that the threshold energy of this reaction is 14.1 MeV11).

The curve of the apparent specific activity vs the sample thickness is shown in Fig. 4 for the case of copper, as an example. In the figure, the arrow indicates the thickness of the sample which was used in the 4π-counter measurement. In all cases these curves have a peak at a certain small thickness. In order to estimate the *S*-value, the curve was linearly extrapolated to zero-thickness inside the peak value by means of the least square calculation.

In the cases of the positron emitters for which the branching ratios of the orbital electron capture are not known, the correction factors C_K are determined from the curves published by Feenberg and Trigg9).

The existence of the shorter half-life activity (65.5 sec.) of Mo^{91} was reported by L.

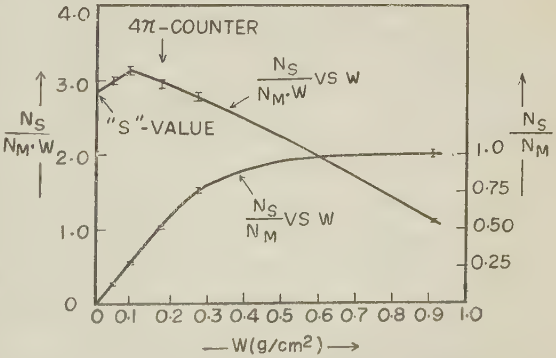

Fig. 4. The curve of the apparent specific activity vs the sample thickness for the case of Cu^{62}.

Katz and others[10] by their betatron experiments. This activity was investigated in the present experiment, but the existence was not found at all at the 14.1 MeV neutrons as reported by Brolley[10].

(2) *Excitation*

Results on the excitation of the reaction $Mo^{92}(n, 2n)Mo^{91}$ are shown in Fig. 5. In the figure the vertical bars show the standard deviations and the horizontal bars show the maximum energy spreads of the neutrons by which each sample is traversed. The solid curve represents the relative excitation function calculated theoretically.

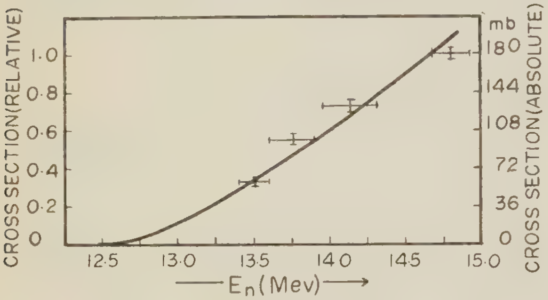

Fig. 5. The threshold behavior of the reaction $Mo^{92}(n, 2n)Mo^{91}$.

Only the gradients of excitation curves, i.e., $d\sigma/\sigma \cdot dE_n$ were measured for the cases of Al, Zn and Ag, because their yields showed no appreciable changes in the energy range considered, and for Cl because of the experimental difficulties due to its low yield. These results are shown in Table II.

Table II. Gradients of excitation curves

Reaction	E_n (MeV)	ΔE_n (MeV)	$\Delta\sigma/\sigma \cdot \Delta E_n \times 100$ (%·MeV^{-1})
$Al^{27}(n, p)Mg^{27}$	14.15	1.31	−21
$Zn^{64}(n, 2n)Zn^{63}$	14.0	1.04	+52
$Cl^{37}(n, p)S^{37}$	14.15	1.28	+ 6
$Ag^{109}(n, 2n)Ag^{108}$	14.15	1.31	−10.2

§ 5. Discussions

It is very interesting to compare the observed cross sections and the excitation curves with the predictions from the existing nuclear theory. The so-called "continuum theory" developed by Weisskopf and his collaborators[12] based on the compound nuclear formalism will be applicable to the present nuclear reaction, where a compound nucleus, if exists, is so highly excited that the conditions of the continuum theory are well fulfilled.

According to Bohr's assumption, the cross section of a nuclear reaction $X(a, b)Y$ can be written in a form

$$\sigma(a, b)=\sigma_C(a)G_C(b)\ , \qquad (4)$$

where $\sigma_C(a)$ is the cross section for the formation of a compound system by the particle a incident upon the target nucleus X and can be found by the wave-mechanical calculations. In the present experiments, however, since the incident particle is the 14 MeV neutron, $\sigma_C(n)$ may be taken to a good approximation to be the cross section for the inelastic collision which can be expressed by $\sigma_{in}(n)=\sigma_{total}-\sigma_{elastic}$. The values of $\sigma_{in}(n)$ used in the present calculations were obtained from the experimental results by Graves and Davis[13].

The second factor $G_C(b)$ is the probability that the compound nucleus C, once formed, decays by emission of a particle b, leaving a residual nucleus Y, and it does not depend on the way in which the compound nucleus has been produced. From the reciprocity theorem and Bohr's assumption, it is given by

$$G_C(b)=\sum_\beta{}' k_\beta^2\sigma_C(\beta)/\sum_\gamma k_\gamma^2\sigma_C(\gamma)\equiv F_b/\sum_c F_c\ , \qquad (5)$$

where $\sigma_C(\beta)$ and $\sigma_C(\gamma)$ are the cross sections for the formation of the compound nucleus through β- and γ-channels, k_β and k_γ being the wave numbers at these channels respectively. The summation $\sum_\beta{}'$ in the numerator of Eq. (5) is to be extended over all the open channels β leading to the emission of the particle b, while the summation $\sum_\gamma$ in the denominator should be extended over all the channels γ into which the compound nuclear system can decay (namely, the summation $\sum_c$ is extended over all particle types c emitted in this reaction).

Now, if we introduce the level density $w(E)$ of the residual nucleus and assume that the decay probabilities from the compound nucleus to various levels of the residual nucleus Y are all the same, i.e., the branching probabilities through β-channels are all equal, then the expression for the F-function will be given as follows:

$$F_b = F_b(\mathcal{E}_{bY}) = \frac{2M_\beta}{\hbar^2}\int_0^{\mathcal{E}_{bY}} \mathcal{E}_\beta \sigma_C(\mathcal{E}_\beta) w_Y(\mathcal{E}_{bY}-\mathcal{E}_\beta)d\mathcal{E}_\beta\ , \tag{6}$$

where M_β is the reduced mass in the channel β; $\mathcal{E}_\beta$ is the channel energy of the emitted particle b; $\mathcal{E}_{bY}$ is the maximum value of $\mathcal{E}_\beta$ and is expressed by the equation $\mathcal{E}_{bY}=\mathcal{E}+Q_{ab}$ using the incident channel energy $\mathcal{E}$ and the Q-value Q_{ab} for the reaction $X(a, b)Y$. $w_Y(E)$ is the level density of the nucleus Y at the excitation E and is given by Weisskopf from thermodynamical consideration, such that

$$w_Y(E) = C \exp\left[2\sqrt{aE}\,\right]\ , \tag{7}$$

where C and a are the constants to be determined to fit the various experimental results. In addition, for C, the following relation holds[14]:

$$4C_{\text{even-even}} = 2C_{\text{even-odd}} = C_{\text{odd-odd}}\ . \tag{8}$$

The Q-values of the (n, p) reactions were derived from the known total β-disintegration energies[15] of the product nucleus, and those for the (n, α) reactions were calculated from the semi-empirical mass data[16]. The values of F-functions can be obtained from the Final Report of the Fast Neutron Data Project[17] and the work of Heidmann and Bethe[18] except for the case of Al.

For Al, there have not yet been published any available data for theoretical estimations, and hence numerical calculations were performed by the author by Eq. (6) making use of the values of σ_C and C given in references (12) and (17) respectively. Further, the values of a were calculated from the semi-empirical formula given by Heidmann and Bethe[18], that is

$$a = \frac{0.14}{4}(A-12)\ \text{MeV}^{-1},$$

for $15<A<70$ where A is mass number.

A very simple formula can be given especially for the $X(n, 2n)Y$ reaction. In this case we may assume that the neutron emission is predominant as soon as it becomes energetically possible. Then the cross section $\sigma(n, 2n)$ will depend on the fraction of the first neutrons emitted from the compound nucleus with such a low energy that the residual nucleus is left with an energy of excitation sufficient to evaporate the second neutron. Then the following formula is obtained for the $(n, 2n)$ cross section:

$$\sigma(n, 2n) = \sigma_{\text{in}}(n)\left[1-\left(1+\frac{\mathcal{E}_c}{\Theta}\right)\exp\left(-\frac{\mathcal{E}_c}{\Theta}\right)\right], \tag{9}$$

where $\mathcal{E}_c$ is the excess energy over the threshold of the $(n, 2n)$ reaction, Θ is the nuclear temperature $\Theta(\mathcal{E}_{bY})$ of the intermediate residual nucleus Y and is put as $\Theta=(\mathcal{E}_{bY}/a)^{1/2}$.

The threshold energies of the $(n, 2n)$ reac-

* This value was neglected in calculations.

tions were obtained from the photoneutron thresholds[19] except for the case of Mo and Ag. The value for Mo was taken from Brolley's results[11] and that for Ag was taken from the semi-empirical mass data[16].

The theoretical cross sections thus calculated are tabulated in comparison with the observed values in Table III for the $(n, 2n)$ reactions, and in Table IV for the (n, p) and (n, α) reactions respectively.

In the case of the $(n, 2n)$ reactions, it is found from Table III that the observed cross sections agree with the theoretical values within about factor 3, and that the formers are always less than the latters except for the case of copper. The ratio $\sigma_{exper.}/\sigma_{theor.}$ for Mo^{92} shows no distinctive anomalies in spite of its neutron magic number 50. The $(n, 2n)$ reactions for two silver isotopes, Ag^{107} and and Ag^{109}, are 458 mb and 604 mb respectively. This coincides with the fact that these threshold energies for the $(n, 2n)$ reactions are about 9.8 MeV for Ag^{107} and 9.1 MeV for Ag^{109}.

The results of the excitation measurement for the $Mo^{92}(n, 2n)Mo^{91}$ reaction are shown in Fig. 5 and also in Table V. The solid curve in Fig. 5 represents the relative excitation function calculated theoretically with the threshold energy of 12.48 MeV and a of 3.16 MeV^{-1} [10]. As far as the relative behavior is concerned, these results show a fairly good agreement with the theoretical curve.

Table V. Excitation data (Threshold Behavior) of $Mo^{92}(n, 2n)Mo^{91}$

Neutron energy (MeV)	Relative cross section (exper.)	Absolute cross section (exper.)	Absolute cross section (theor.)	$\frac{\sigma_{exper.}}{\sigma_{theor.}}$
		mb	mb	
14.80 ± 0.13	$1.00 \pm 3\%$	$180 \pm 17\%$	484	0.372
14.14 ± 0.18	$0.733 \pm 5\%$	$132 \pm 16\%$	308	0.429
13.76 ± 0.18	$0.556 \pm 6\%$	$100 \pm 18\%$	209	0.479
13.51 ± 0.11	$0.334 \pm 7\%$	$60.1 \pm 18\%$	149	0.403

As to the absolute values, however, the theoretical curve lies always above the experimental curve approximately by factor 2.4. These results were also observed in the cross section measurements.

It should be remarked that the threshold energy of the $(n, 2n)$ reaction for Mo^{92} is less than the corresponding (γ, n) threshold energy which was reported as 13.28 MeV by Hanson *et al.*[21]

Moreover, as stated in § 4, the shorter activity of the Mo^{91} isomer is not found for the neutron energy of 14 MeV, and Brolley has observed a weak 65.5 sec. activity by 18 MeV neutrons[10]. Therefore the threshold energy of the $(n, 2n)$ reaction for the 65.5 sec. isomer production seems to be larger than that for the 16 min. isomer, being inconsistent with King's comment[15].

In the cases of the (n, p) and (n, α) reactions, the even-odd effect was taken into account for the nuclear level density. If correction was made for this effect, the theoretical predictions agreed with the experimental cross sections within factor 2 except for the case of the $Al^{27}(n, \alpha)Na^{24}$ reaction as shown in Table IV.

The relative cross section of the reaction $Al^{27}(n, p)Mg^{27}$ to $Al^{27}(n, \alpha)Na^{24}$ was found 1:1.38 by the present experiment; while the theoretical value not corrected for the even-odd effect is 1:1.74, and the corrected value is 1:3.5. Thus in the $Al^{27}(n, \alpha)Na^{24}$ reaction, it appears that the experimental cross section rather agrees with the theoretical one not corrected for the odd-odd nucleus.

It is found from Table II that the gradient of the excitation curve for the $Cl^{37}(n, p)S^{37}$ reaction was $+6\% \cdot MeV^{-1}$. This value will not contradict the data of Cohen and White[22]. According to Cohen and White, the theoretical excitation curves based on both the statistical theory using (the extrapolation of) Gugelot's level densities[23] and the direct interaction described by Austern *et al.*[24] should have negative gradient in the energy range under consideration. Therefore the experimental results show a remarkable disagreement with the theoretical predictions as already pointed out by Cohen and White.

§ 6. Acknowledgements

The author desires to express his sincere thanks for the encouragements and many valuable discussions given by Dr. B. Arakatsu, the president of Kōnan University, and Profs. K. Kimura, M. Sonoda and S. Kawata. It is pleasure to acknowledge his indebtedness to his colleagues, Messrs. K. Yuasa, M. Sakisaka, K. Sugiyama, B. Saeki and Y. Oyama, who have been in cooperation during these experiments. Further he is greatly indebted to Dr. K. Hisano of Denkishikenjō and Mr. T. Oshida of Kōbe Kōgyō Corporation for their kindness to lend him the precious samples.

This work was partly supported by a grant-in-aid for scientific researches of the Ministry of Education.

Appendix

(1) Calculation of the reaction cross section

For cross section measurements, the irradiation by neutrons is made in the geometry shown in Fig. 6 (in the 90° direction).

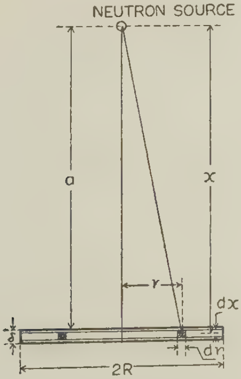

Fig. 6. Geometry of the irradiation by neutrons.

The number of the product nuclei generated by the neutrons in the "ring-element" of a sample of radius r and thickness dx can be written as follows:

$$\sigma\left\{\frac{n}{4\pi(r^2+x^2)}\right\}\cdot\{2\pi r\cdot dr\cdot dx\cdot m)dt\,,$$

where

σ = reaction cross section

m = number of the parent nuclei per unit volume (cm^{-3}) in the sample

n = total number of neutrons emitted from the Zr–T target per unit time (min^{-1})

dt = time of irradiation (min).

Hence, the number of the product nuclei in the sample disc of radius R is

$$dA=\sigma mndt\int_a^{a+\delta}dx\int_0^R\frac{r\cdot dr}{2(r^2+x^2)}$$
$$=\sigma mndt\cdot\frac{1}{4}\int_a^{a+\delta}\log\frac{R^2+x^2}{x^2}dx\,.$$

Immediately after the irradiations for a time interval T with constant intensity, the number of the existing active nuclei can be given by

$$A=\left[\frac{1}{4}\int_a^{a+\delta}\log\frac{R^2+x^2}{x^2}dx\right]$$
$$\times\int_0^T\sigma mn\exp\{-\lambda(T-t)\}dt$$
$$=\Omega'\sigma mn\frac{1-e^{-\lambda T}}{\lambda}\,,$$

where the abbreviation "Ω'" is used for the factor in the square bracket and λ is the decay constant for the beta-disintegration of the product nucleus. As mentioned in § 2 (A), it was assumed that the neutron intensity was constant for every one minute or 30 seconds interval during irradiations. Here let us consider the case of the "one minute-treatment". If the measurement of the activity of a sample is commenced t_0 minutes after the end of irradiation, the number of active nuclei existed in the sample at that time can be given by

$$A_0=\Omega'\sigma m\frac{1-e^{-\lambda}}{\lambda}\left[\sum_{i=1}^{T}n_i\exp\{-(T-i+t_0)\lambda\}\right],$$

where n_i is the total number of neutrons emitted from the target per minute in the i-th time interval.

The number n_i can be obtained from the net counts $n_{\alpha i}$ of α-particles per minute such that

$$n_i=n_{\alpha i}\times\frac{4\pi}{\omega}\,,$$

where ω is the solid angle which the α-detector subtends at the neutron source. Therefore

$$A_0=\Omega'\sigma m\cdot\frac{1-e^{-\lambda}}{\lambda}\cdot\frac{4\pi}{\omega}$$

$$\times\left[\sum_{i=1}^{T} n_{\alpha i}\exp\{-(T-i+t_0)\lambda\}\right].$$

As the β-activity is measured for ten minutes, the total number A_d of the nuclei which disintegrate by the beta-decay in that time interval is given by

$$A_d=\Omega'\cdot\sigma\cdot m\cdot(\lambda)\cdot\Sigma\cdot\frac{4\pi}{\omega}, \qquad (10)$$

where the abbreviations

$$\Sigma\equiv\left[\sum_{i=1}^{T} n_{\alpha i}\exp\{-(T-i+t_0)\lambda\}\right]$$

and

$$(\lambda)\equiv\frac{(1-e^{-\lambda})(1-e^{-10\lambda})}{\lambda}$$

are used.

On the other hand, by Eq. (1) the following relation holds between N_S and A_d:

$$N_S=\frac{f_S}{C_{G'}}\cdot A_d,$$

and accordingly, Eq. (10) now becomes

$$N_S=\frac{f_S\cdot\Omega'\cdot\sigma\cdot m\cdot(\lambda)\cdot\Sigma}{C_{G'}}\cdot\frac{4\pi}{\omega}.$$

If the beta-counts for the monitor irradiated in juxtaposition with the sample is designated by N_M, the apparent specific activity is proportional to $(N_S/N_M\cdot w)$ which is given by

$$\frac{N_S}{N_M\cdot w}=\frac{f_S\cdot\sigma\cdot m\cdot(\lambda)}{C_{G'}\cdot\rho}\cdot\frac{\Sigma}{N_M}\cdot\frac{4\pi}{\omega}\cdot\frac{\Omega'}{\delta}, \qquad (11)$$

where w and ρ are the thickness (in g/cm^2) and the density of the sample respectively.

Now, if w tends to zero, i.e., δ tends to zero, then $f_S\to 1$ and

$$\frac{\Omega'}{\delta}=\frac{1}{4\delta}\int_a^{a+\delta}\log\frac{R^2+x^2}{x^2}dx\xrightarrow[\delta\to 0]{}\frac{1}{4}\log\frac{R^2+a^2}{a^2}\equiv\Omega,$$

where it should be noted that (Σ/N_M) in Eq. (11) is constant irrespectively of the change of w.

From these relations the expression for the limiting value S of the apparent specific activity is given by

$$S\equiv\lim_{w\to 0}\frac{N_S}{N_M\cdot w}=\frac{\sigma\cdot(\lambda)\cdot\Omega}{C_{G'}}\cdot\frac{\Sigma}{N_M}\cdot\frac{4\pi}{\omega}\cdot\frac{m}{\rho}.$$

Then, if we use the relation $m/\rho=N_0\eta/M$, the reaction cross section can be written as

$$\sigma=\frac{M\cdot[N_M/\Sigma]\cdot S\cdot C_{G'}}{N_0\cdot\eta\cdot\Omega\cdot(\lambda)\cdot(4\pi/\omega)}.$$

Finally we obtain Eq. (2) by introducing the correction factor C_K concerning the branching ratio of the positive beta-decay to the orbital K-electron capture.

$$\sigma=\frac{M\cdot[N_M/\Sigma]\cdot S\cdot C_{G'}\cdot C_K}{N_0\cdot\eta\cdot\Omega\cdot(\lambda)\cdot(4\pi/\omega)}.$$

(2) Analysis of the pulse height distribution of the beta-rays measured by the 4π-proportional counter

Let us consider the typical pulse height distribution of β-rays by a proportional counter when a point source of β-rays is placed in the centre of the sample holder (see Fig. 2).

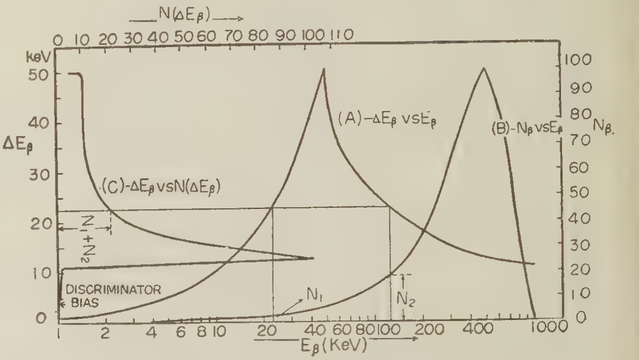

Fig. 7. Analysis of the pulse height distribution of the beta-rays measured by the 4π-proportional counter.

In Fig. 7, the curve A shows the energy loss in the counter gas ΔE_β plotted against the electron energy E_β on the logarithmic scale. The curve rises linearly to the maximum value determined by the dimension of the counter tube and then falls gradually towards the value corresponding to the minimum ionization. The range-energy relation for electrons used in this calculation was taken from the work by L. Katz and A. S. Penfold[25]. The curve B represents schematically an energy distribution of the beta-ray. The curve C was obtained from the curves A and B by the procedures indicated in Fig. 7. It shows the relation between ΔE_β and the number $N(\Delta E_\beta)$ of electrons which lose ΔE_β of their energies. The curve corresponds to the differential pulse height distribution to be expected for the β-rays shown by the curve B. The differential curve exhibits a peak at about $\Delta E_\beta=11$ keV corresponding to the neighbourhood of the minimum ionization.

Therefore the integral pulse height distribution curve appears to be nearly constant up to the bias-voltage corresponding to the peak point and then falls rapidly beyond this point. In the preliminary experiments, the integral pulse height distributions of the β-rays from La and K were observed and it was found that they were in good agreement with the above analysis.

Meson Showers by Heavy Primary Particles

By Senzo TOKUNAGA

Department of Physics, Saikyo University, Kyoto

(Received February, 7, 1957)

Meson showers by heavy primary particles which have energy of 500 BeV per nucleon were studied with nuclear emulsions. Dealing with the event, " the nuclear disintegration cascade by heavy primary particle ", it was possible to estimate the energy of the primary particle with much accuracy by two methods, one by usual median angle of shower particles and the other by the opening angle of the fragmentation products of heavy primary particle. The angular distribution of the shower particle was studied and compared with the theory of Fermi and that of Landau.

§ 1. Introduction

Studies on meson production by nucleon-nucleon or nucleon-nucleus collision with nuclear emulsions have been reported by many workers,1)-11) but studies on meson production by heavy primaries have been comparatively rare.12)-15) The former has given a good deal of knowledge, but there still remain some inconsistencies among their results,—for example, about the angular distribution of the produced mesons, the multiplicity of mesons, the inelasticity coefficient and so on. These discrepancies are considered to originate mainly in the attained statistical accuracy. For instance, when a few mesons are produced in a jet, it is very difficult to estimate the energy of the primary nucleon which caused the interaction with much accuracy.

When the interaction of a high energy heavy primary particle with a nucleus of emulsion is assumed to be the superposition of many simultaneous nucleon-nucleon collisions, or the collision of a certain number of nucleons among the incident heavy nucleus with the same number of those of the target nucleus in the emulsion, much information about nucleon-nucleon collision can be gained at one time, and it is possible to estimate the energy of the incident primary by the median angle method with more accuracy than in the case of simple nucleon-nucleon collision, owing to a greater number of mesons produced. Moreover, when the fragmentation products of heavy primary are accompanied in the interaction, it is also possible to estimate the energy of the primary particle by the opening angle of the fragmentation products, and the accuracy obtained by this method is better than the median angle method.

From these points of view we studied the meson production by heavy primaries. And the angular distribution of the produced meson was compared with the theory by Fermi16) and that by Landau.17) Having much to do with the mechanism of the meson production, the angular distribution of the produced meson is a very important problem.

§ 2. Experimental Procedure

§ *2.1 Emulsion Blocks and the Events Studied*

The stack we used consisted of 48 4-inch by 6-inch G5 600 microns pellicles and was flown with the emulsion surfaces vertical for 6 hours up to a maximum altitude of 33 km by a polyethylene balloon at Kobe in Japan in 1955.

In the stack were searched for events in which heavy primaries interacted with the nuclei of the emulsion causing meson showers. Fifteen examples of this kind have been found so far, but the events in which only a small number of mesons are produced were not suitable for our purpose, because it was not possible to estimate energies of the primary particles with sufficient accuracy by median angle method. Three events suitable for our analysis were selected among them and studied in detail. These were tabulated in Table I.

Table I. The events studied.

No. 1	$8+44_{\mathrm{Na}}$
No. 2	$19+9_{\mathrm{He}}$
No. 3	$17+120_{\mathrm{Li}}$

It is very remarkable that the events No. 1, 2 and 3 are nuclear disintegration cascade, which will be reported elsewhere.[18] As shown in Fig. 1, a heavy primary having charge Z 11, a Na nucleus, caused the event No. 1 at B, from which a He nucleus and a Li nucleus were emitted as a result of the fragmentation of the primary Na nucleus, and each caused the event No. 2 and No. 3 at C and D respectively.

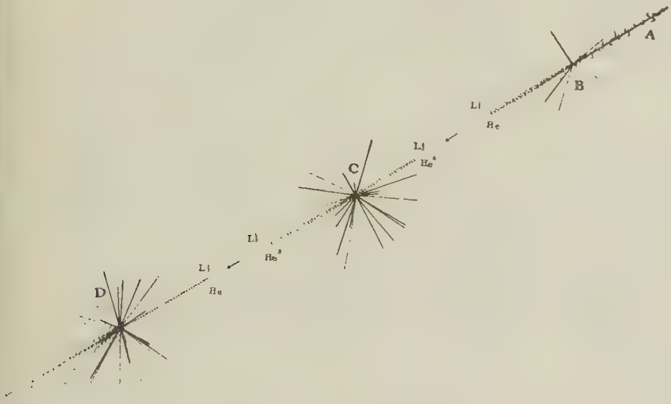

Fig. 1. Projection drawing of a nuclear disintegration cascade. A sodium nucleus producing a thin track at A continued to B, there causing a star $8+44_{\mathrm{Na}}$ (the event No. 1), from which a helium nucleus and a lithium nucleus were emitted, and each produced a star at C (the event No. 2) and D (the event No. 3) respectively.

§ 2.2 Determination of the Charge of the Heavy Primary Particle

The charge of the heavy primary particle was determined by δ-ray counting. The δ-rays with more than four grains were counted, and the charge of the primary was determined comparing with the result of Dainton et al.[19] When the number of charge is small as in the cases of a helium and a lithium nucleus, the gap-length method[20] was also used to get grain density of the track. The ratio of the charge of helium and lithium determined by two methods agreed so well as shown in Table II that it was possible to calibrate the relation between the number of δ-rays and the charge of particle.

Table II. The grain density and δ-ray density of the track of a helium and a lithium nucleus.

The grain density	
$g_{\mathrm{Li}}=144.0\pm6.1/100\,\mu$	$g^*_{\mathrm{Li}}=8.95\pm0.47$
$g_{\mathrm{He}}=61.2\pm2.6/100\,\mu$	$g^*_{\mathrm{He}}=3.80\pm0.20$
	$g^*_{\mathrm{Li}}/g^*_{\mathrm{He}}=2.35\pm0.14$
The δ-ray density	
$N_{\mathrm{Li}}=0.96\pm0.08/100\,\mu$	$N_{\mathrm{Li}}/N_{\mathrm{He}}=2.28\pm0.33$
$N_{\mathrm{He}}=0.42\pm0.05/100\,\mu$	

As the ratio of the square of the charge of lithium and of helium is 2.25, the results agree very well.

§ 2.3 Measurement of Angular Distribution of Shower Particles

In order to measure angles between the directions of secondary shower particles and primary particle, the primary track was aligned along the x-axis on a scattering microscope and y-coordinate of each secondary track was measured at several points on the track, and depth measurement of each track was also made. Making use of them the angles were calculated. By this method true angle between the primary particle and the secondary shower particle was possible to be measured with an error, the order of which is estimated to be 5×10^{-3} radians.

§ 2.4 Selection of Primarily Produced Mesons

Among the shower particles emitted in the interaction there would be included not only the primary produced mesons and protons which were constituents of the primary particle and had no concern with the interaction. In order to choose only the primarily produced mesons, the following two assumptions were made. Firstly, the number of protons which suffered no interaction was assumed to equal the difference between the charge of the incident nucleus and the sum of charge of multiply charged fragments. Secondly, the criterion by G. Bertolino,[8] which was used in his study of jet was adopted. The criterion is as follows: if the θ_n, the angle formed by the n-th track with the shower axis, is larger than twice of the θ_{n-2}, the angle formed by the $n-2$th track, the n-th track is not considered as the primarily produced meson. Taking the criterion into consideration, the results of the estimation of the energy of the primary particle of the event No. 1, 2 and 3 by median angle method agree very well.

§ 2.5 *Estimation of the Energy of the Primary Particle*

The estimation of the energy of the primary particle was made by kinematical method. We assume that the interaction of a heavy primary particle with a nucleus of emulsion is the superposition of simultaneous nucleon-nucleon collisions and that there exists the center of mass system for the interaction. By applying the Lorentz transformation assuming that the angular distribution of particles in the center of mass system is symmetric about a plane transverse to the direction of incident particle, we get

$$\tan\frac{\theta^*}{2}=\gamma_c\tan\theta \qquad (1)$$

$$\gamma=\frac{2}{\theta_F\theta_{1-F}} \qquad (2)$$

where θ^* and θ denote the angle of particle with the direction of motion of the incident particle in the c.m. system and laboratory system respectively, $\gamma_c=1/\sqrt{1-\beta_c^2}$, β_c, the velocity of the c.m. system, $\gamma=2\gamma_c^2-1$, energy per nucleon of the incident particle in the laboratory system, and the subscripts F and $1-F$ refer to the angles containing a fraction of the total number of produced mesons. The angle $\theta_{1/2}$ which has the greatest statistical accuracy was used in our analysis.

To check our assumptions concerning the angular distribution in the center of mass system, the integral angular distribution of the mesons in the laboratory system

$$F(\theta_F)=\frac{1}{N}\int_0^{\theta_F}N_\theta d\theta \qquad (3)$$

is plotted versus $\log\theta_F$, where N denotes the total number of particles, N_θ, the number of particles which is included within the angle θ with the direction of the incident particle, and θ_F, the angle containing a fraction of F of the total number of particles. The plots are shown in Fig. 2 and Fig. 3. It is seen that the plots are symmetric with respect to the reflection through the point $F=1/2$, $\log\theta_{1/2}$ as origin. The fact shows the consistency of our assumptions.

When some fragments are produced in the interaction, the estimation of the energy of the primary particle is also possible by measuring the opening angle of the fragmentation products. According to Kaplon et al. the root mean square angle which the shower particles of fragmentation products make with direction of the incident primary in the laboratory system is

$$<\theta^2>^{1/2}=0.06/E \qquad (4)$$

where E is the total energy per nucleon in BeV of the incident nucleus, and the largest observed angle of any particle in the laboratory system gives an upper limit for the energy of incident particle, which is given by:

$$E_{\max}\approx\frac{0.12}{\theta_{\max}} \qquad (5)$$

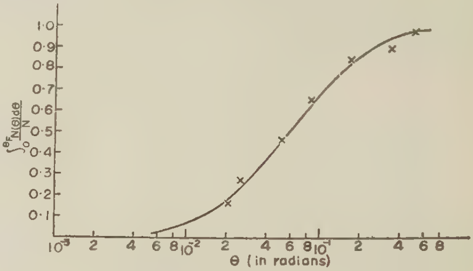

Fig. 2. Normalised integral angular distribution of mesons produced in the event No. 1 in the laboratory system.
Ordinate: Fraction of charged particles contained within the polar angle θ.
Abscissa: $\log\theta$.

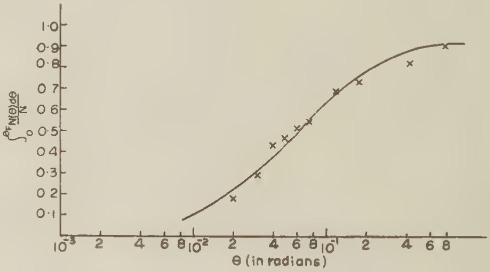

Fig. 3. Normalised integral angular distribution of mesons produced in the event No. 3 in the laboratory system.
Ordinate: Fraction of charged particles contained within the polar angle θ.
Abscissa: $\log\theta$.

The advantage of the method is that it gives results which have better accuracy than the median angle method. In the event No. 1 both methods were employed, and the values obtained agree very well with each other. Moreover, the energies obtained for the event No. 2 and No. 3 by the median angle of the shower particles also agree so well as shown in Table III, the value of the energy of the primary particle in the events No. 1, 2 and 3 seems to be certain. The fact that the results obtained by two methods agree shows our assumption to be correct.

Table III. Energy of the incident primary particles obtained by two methods.

	1. Energy obtained by the opening angle of the fragmentation products (BeV per nucleon)	2. Energy obtained by the median angle of shower particles (BeV per nucleon)
the event No. 1	336 (by eqn. (4)) 672 (by eqn. (5))	507
the event No. 2		507
the event No. 3		505

§ 3. The Angular Distribution of Mesons Produced in the Interaction by Heavy Primaries

Angular distributions in the center of mass system were shown in Fig. 4 and Fig. 5, in which the abscissa represents the ten parts that cover equal solid angle in the center of mass system, and I represents the forward direction and X the backward direction with respect to the direction of the incident particle. Among the particles which are emitted forwards there may be some protons which did not interact in the interaction as described in § 2.4. These protons being expected to be emitted making angles less than $\sim 10^{-4}$ radians with the incident particle, they always belong to the region I. We assumed the number of these protons to be equal to the difference in charge between that of the incident nucleus and the sum of charge of multiply charged fragments in the jet. In Fig. 4 and Fig. 5 the number of mesons is shown in full line, and the number of thin particles including protons is shown in dotted line.

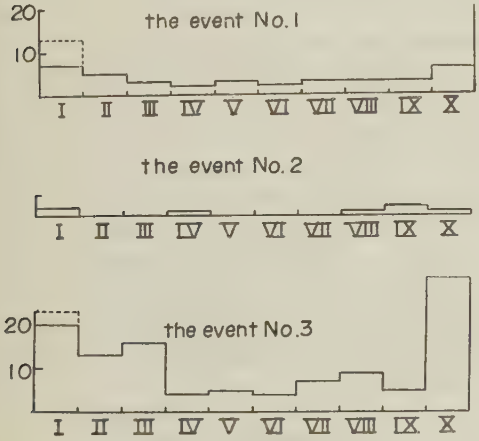

Fig. 4. The angular distribution of mesons produced in each event in c.m. system. The abscissa represent the ten parts which cover equal solid angle in c.m. system. *I* represents the forward direction and *X* the backward with respect to the incident particle.

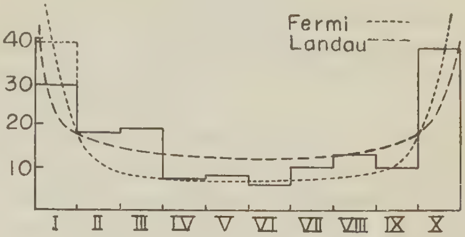

Fig. 5. The angular distribution of mesons produced in the event No. 1, 2 and 3. The dotted curve represents the theoretical angular distribution by Fermi, and the broken line by Landau.

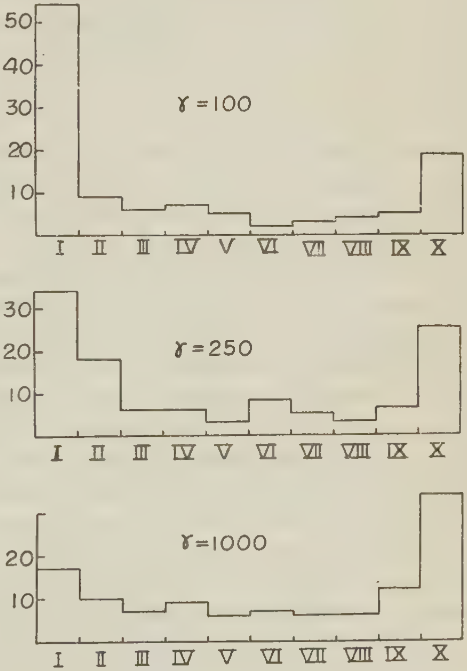

Fig. 6. The angular distribution of mesons produced in the event No. 3 in c.m. system for different γ.

From the results it is clearly seen that the angular distribution is not isotropic, and more mesons are emitted in the forward and backward direction than other directions.

The angular distribution was compared with the theory of Fermi and that of Landau. In Fig. 5 were shown the results of the calculation according to the theories, normalizing the total number of mesons with the experimental values. In the calculation with Fermi's theory the median impact parameter was taken. Though it is difficult to assert which theory is more fitted to the experimental results, it is seen that Landau's theory is rather fitted than Fermi's.

Though the angular distribution in the center of mass system varies with the values of γ, it would be recognized that, even if the value of γ changed more than a factor of two as shown in Fig. 6, more mesons are emitted in the forward and backward direction.

§ 4. Discussion

As our events are occuring by nucleus-nucleus collisions, it would not be right, strictly speaking, to look upon them as the superposition of nucleon-nucleon collisions, or the collisions of the same number of nucleons in the target nucleus with the same number of nucleons in the incident nucleus each other. It would be necessary to consider other mechanism concerning the events. However, the fact that the energy of the primary particle determined by the opening angle of the fragmentation products accords with the energy determined by the half-angle of the shower particles using the criterion of G. Bertolino shows that the events can be regarded approximately as the superposition of the simultaneous nucleon-nucleon collisions. Also, though the number of the grey and black prong is large in our events, their energies per nucleon of the primary particle are small comparing with the energy of the primary particle, so it would not be wrong to look upon them as the superposition of the nucleon-nucleon collisions. In the study of jet showers by nucleons, stars with black and grey prongs less than three are usually regarded as jets.

When we consider the events as the superposition of nucleon-nucleon collisions, a greater number of mesons being produced, it is a great advantage that much information can be obtained concerning the meson production by the incident nucleons having same energy at one time. It is also very favourable that the energy of the primary particle can be estimated by two methods, when the interaction is accompanying fragmentation products of heavy primary particle. In the events No. 1 the values of the energy per nucleon of the primary particle obtained by two methods agree well, and moreover, they are also in accord with those obtained for the events No. 2 and No. 3 by the median angle of shower particles. The fact shows that the estimation of the energy of the primary particle is reliable, and that the assumption of the superposition of nucleon-nucleon collisions is not wrong. As the method to determine the energy of the primary particle by the opening angle of the fragmentation products having comparatively a good accuracy, it is very profitable.

As stated in § 3, the angular distribution of the mesons is not isotropic, but more mesons are emitted in forward and backward directions, and the result favours Landau's theory. By G. Bertolino the angular distribution of mesons in the jet is isotropic.[8] It is inconsistent with our result. It seems that it is mainly due to the fact that owing to the many jets, each having different γ, his results are averaged over. In case of a small number of mesons being emitted in jet, the estimation of the energy of the primary particle by median angle method has much error. Collecting many jets for which the estimation of the energy is not possible with sufficient accuracy, it appeares that he obtained the isotropic angular distribution.

It is a characteristic of the present analysis that dealing with the event, "nuclear disintegration cascade by heavy primary particle," many nucleon-nucleon collisions, in which the incident particles have the same values of γ, are collected.

Acknowledgement

The author wishes to express his hearty gratitude to Prof. K. Kimura and Prof. O. Minakawa for their sustained interest and encouragement through the course of the work. Also, his sincere appreciation and thanks go to Dr. K. Nishikawa and Miss. T. Ishii for their cooperative efforts, and to the members of the Kansai Balloon Group for making possible the balloon flight.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 5, MAY, 1957

The Surface Potential of Selenium and its Relation to the Rectification and the Photovoltaic Effects

By Umejiro YOSHIDA and Akira SUZUKI

Faculty of Engineering Yokohama National University

(Received November 8, 1957)

The surface potential of selenium was measured by Kelvin's methods and was found to be influenced by the ambient. The characteristics of a rectifier obtained by making metal electrode contact with the selenium surface depend on the surface potential. The variation of the surface potential under illumination is of the same maginitude as the photoelectromotive force of the selenium cell. From these results, it is concluded that a blocking layer is formed on the selenium surface during the heat treatment.

§1. Introduction

The rectification properties of the selenium cell are known to come from a blocking layer localized in the interface between the selenium and the metal. Notwithstanding many studies about the selenium rectifier, there is no complete knowledge about the composition of the blocking layer. The polarization and the creep effect of the selenium rectifier may result from the unstable components of the blocking layer[1]. There is an opinion that cadmium selenide CdSe is the main component of the blocking layer, as it is detected in some selenium cell. By coating the selenium surface with a thin film of CdSe, its rectification ratio can be increased[2)].

It is known that the characteristics of selenium rectifiers are controlled in the early stage of treatments in the industrial manufacturing process. The surface state of selenium after heat treatment has important factors on its rectification action. After coating with the front electrode, its characteristics is improved under many processes such as electric aging; but its final characteristics is widely affected by the surface states at the time of coating with the front electrode. The blocking layer existing in finished selenium rectifiers may be formed by combination of the selenium surface and front electrode metal, in the course of manufacturing process and therefore its composition may be of complex nature.

This paper treats the characteristics of selenium cells immediately after heat treatment for finding the nature of blocking layer formation in the early stage of manufacturing process. The surface stages of selenium after heat treatment is measured by its surface potentials. There are some researches about the surface potential of germanium[3)], but none about that of selenium at present. The present work was undertaken to find the relation of the surface potential of the selenium after the heat treatment to its rectification and photovoltaic effect.

The surface potential of the selenium is found to change slowly for long time after the heat treatment. A rectifier is prepared by contacting a rod of wood metal with the selenium surface to find the relation between the rectification property and the surface potential. It is found that the surface potential and the rectification ratio is nearly of a constant value for a long time in the atmosphere if the selenium surface is coated with a thin film of synthetic resin. The variation of the surface potential under illumination is measured for a long time after the heat treatment and is found to be of a nearly constant value. A photovoltaic cell is obtained by contacting a transparent cadmium film with the selenium. The electromotive force induced under illumination is found to be nearly equal to the variation of the surface potential under same intensity of illumination.

§ 2. Experimental Arrangement

The surface potential of selenium is measured by Kelvin's method from the difference of work function between the reference electrode and selenium[4)]. Gold plate is used for the reference electrode as the work function of gold is not much influenced by the atmosphere. An electromotive force E is applied in such a way as to oppose the contact potential difference between the selenium and the gold plate. As shown in Fig. 1, the gold plate is separated at about 1 mm from the selenium surface and is made in vibration at about 200 c.p.s. by means of an electromagnet. When potential E is not equal to the surface potential, current proportional to the difference is induced in the resistance R in Fig. 1. The voltage across R is amplified and detected by a cathode ray oscillograph or a telephone receiver.

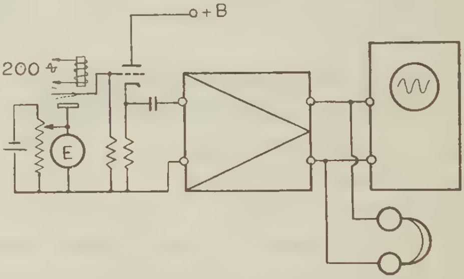

Fig. 1. Circuits of measurement apparatus.

When the electromotive force E is made equal to the contact potential difference, the output voltage of the amplifier becomes zero. The surface potential of selenium may be obtained from the value of E. For the measurement of the surface potential variation under illumination, this vibrating gold plate is replaced by a gold plate with a hole covered with fine mesh of gold wires, through which the selenium surface is irradiated with the light. In this experiment, a selenium plate of diameter 18 mm is used and the amplitude of vibration of the gold plate and mesh is controlled at about 0.1 mm. To measure the surface potential within the accuracy of 1 mv, the voltage gain of the amplifier is made larger than 120 d.b.

§ 3. The Surface Potential of Selenium after Heat Treatment

The selenium is melted evenly on an iron plate electroplated with nickel and is transformed into grey metallic stage by heat treatment at about 200°C. The surface potential of this surface is measured by the abovementioned Kelvin's method. The results of the measurement of the relation between the surface potential and the time after the heat treatment are shown in Fig. 2. As is seen from it, there is a rise and decay in the surface potential curve. For example, in the atmosphere of relative humidity 85%, the surface potential increases by about 0.16 V in 2 hours after the heat treatment and thereafter decreases gradually, as shown in the curve (1). In the atmosphere of lower relative humidity, the rise and decay of the surface potential becomes slower: the curve (2) and (3) show the surface potential of selenium exposed in the atmosphere of relative humidity 70% and 45%, respectively. When the surface of the selenium is oxidized by exposing in a stream of ozon, the surface potential increases by about 0.2 V from the initial value; and then decreases slowly in the same manner as the curve (1) or (2) according to the relative humidity of the atmosphere to which it is exposed. By exposing the surface in the saturated water vapour for a few seconds, its potential decreases suddenly by about 0.4 V. The surface potential decreases by about 0.4 V in the atmosphere of relative humidity 85% in 20 hours after the heat treatment. From these facts, it is seen that the surface potential increases by oxidization and decreases by absorption of moisture. As the surface of selenium is chemically active, it continues to oxidize with the oxygen in the atmosphere after the time of the heat treatment, and its surface potential increases. Then it absorbs water vapour from the atmosphere and the surface potential decreases depending on the relative humidity and hours exposed. The surface potential curve in Fig. 2 may be considered as coming from these oxidization and absorption of moisture. When the selenium surface is irradiated with light, its potential increases depending on the intensity of illumination. The amount of change in the surface potential is nearly independent of the time exposed in the atmosphere after the heat treatment. A plot of this variation of the surface potential against the intensity of illumination is shown in Fig. 3. The curve (1) shows results of measurements for the selenium surface immediately after heat treatment, curve (2) for that at 2 hours after heat treatment and curve (3) for that after a long time. It is evident that the linear relation does not hold between the variation of the surface potential and the intensity of illumination. The variation of the surface potential becomes about 0.2 V at high illumination. It is independent of the time exposed in the atmosphere.

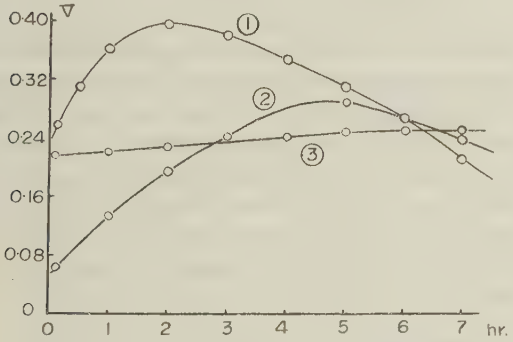

Fig. 2. Surface potential of Se after the heat treatment as a function of the time.

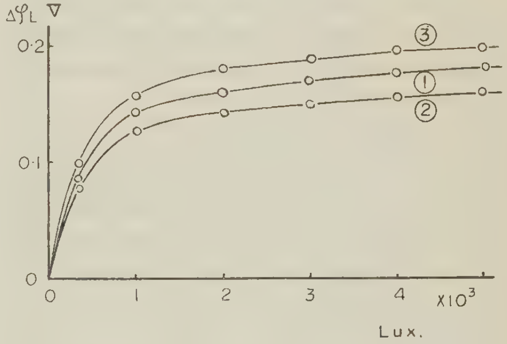

Fig. 3. Surface potential as a function.

§ 4. Rectification and the Surface Potential

The alloy of bismuth, cadmium and tin is used for the front electrode of a selenium rectifier as in the ordinary commercial type. The surface potential of this alloy is nearly of constant magnitude under exposure in the atmosphere. A rectifier is prepared by contacting a rod of alloy with the surface of selenium under a constant pressure to find the relation of the surface potential to the rectification. Fig. 4 shows the ratio of forward and backward current at 1 V. Corresponding to the increase in the surface potential in the atmosphere, the rectification ratio decreased slowly after heat treatment. It falls to the minimum value at the maximum surface potential. From this point, it becomes to be independent of the surface potential and the hours exposed in the atmosphere. From this curve it can be seen that the condition of the selenium surface after heat treatment has large effect on its rectification action. The electrostatic capacity of a rectifier prepared in the same manner is measured for finding the change occuring in the blocking layer. The electrostatic capacity is found to increase slowly after the time of contact, and in 5 hours it reaches the magnitude of 150–200% of that immediately after the contact. This may be due to the change of the surface potential in the interface.

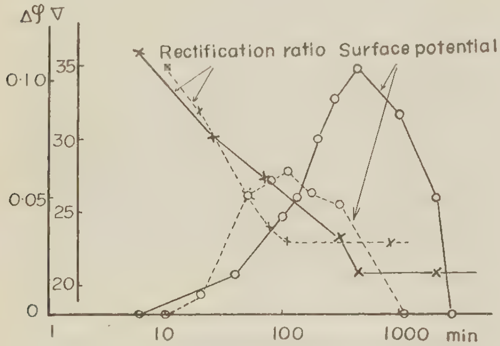

Fig. 4. Surface potential and rectification ratio.

In the process of industrial manufacture of rectifiers, the selenium surface is usually coated with a thin insulating film and the front electrode is placed on it. To find its effect on rectification action, the selenium surface is coated after heat treatment with a thin film of synthetic resin. Several synthetic resins different chemical composition are used for coating and the thickness of film is $10^{-6}\sim 10^{-5}$ cm. By coating with synthetic resin, the surface potential falls immediately after coating for all resins, and is nearly of constant magnitude for a long time, as shown in Fig. 5. From these curves, it can be seen that the insulating layer protects the selenium surface from the effect of the atmosphere. To find the effect of the insulating layer on the rectification action. A rectifier is obtained by contacting a rod of alloy with this surface under a constant pressure. In this rectifier there is no direct contact between the front electrode and the selenium surface, but for some synthetic resin its rectification ratio immediately after contact is larger than that of the direct contact type. Fig. 6, curve (1) shows the D.C. characteristics a rectified made on the free selenium surface, curve (2) and (3) that on the surface coated with insulating film of thickness about 5×10^{-6} cm. This shows that, also in the direct contact rectifier, the chemical combination between the metal and the selenium is no essential factor in the rectification action, at least in the earlier stage.

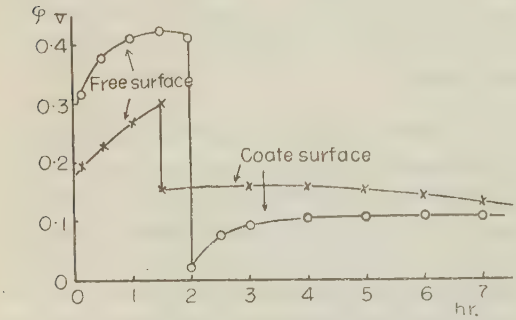

Fig. 5. Variation of surface potential after coating by synthetic resin as a function of the time.

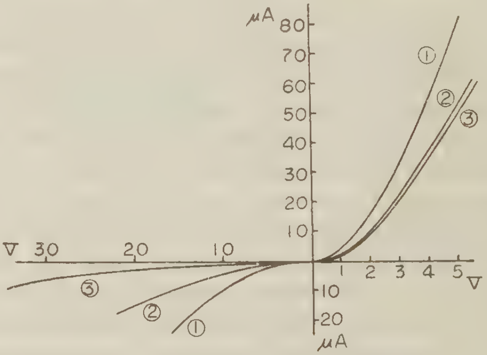

Fig. 6. D.C. characteristics of point contact rectifier.

§ 5. Photovoltaic Effect

By evaporating in vacuum or sputtering, a semitransparent cadmium film is obtained on a thin film made of a transparent synthetic resin. By contacting this film with the selenium surface a photovoltaic cell is prepared. A photoelectromotive force is induced between the film and the selenium by irradiating the surface with a light from a lamp through the synthetic resin. The current sensitivity of the cell is very low, but the voltage sensitivity is of the same magnitude at that of the commercial cell. The low current sensitivity may be explained by the small effective contact area between selenium and cadmium surfaces compared to the total surface of contact. The results of the measurement of the relation between the photoelectromotive force and the intensity of the illumination are shown in Fig. 7. Curve (1) shows the photoelectromotive force immediate after contact, and curve (2) that 2 hours after contact for the same cell; this may be considered to have occured by the change of surface states as in Fig. 3. This curve fits fairly well with the curve of the surface potential variation in Fig. 3. The photoelectromotive force is just of the same magnitude as the surface potential variation due to illumination at each intensity of illumination. A photovoltaic cell of the ordinary type is obtained by coating the surface of the selenium with a thin film of cadmium by sputtering in vacuum. The plot of the photoelectromotive force against the intensity of the illumination is shown in Fig. 8. Curves (1) and (2) show respectively the upper and lower limit of the range of sensitivity of these cells. For this type of cells, the photovoltaic current sensitivity is of the same magnitude as commercial cells, as the contact area between the front electrode and selenium is larger than that of the above-mentions contacting type; But there is no large difference in their voltage sensitivites between these photovoltaic cells.

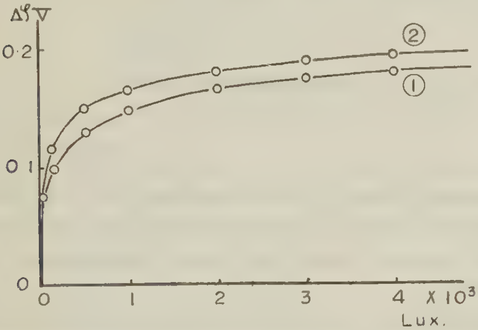

Fig. 7. Variation of surface potential under illumination for contact type cell.

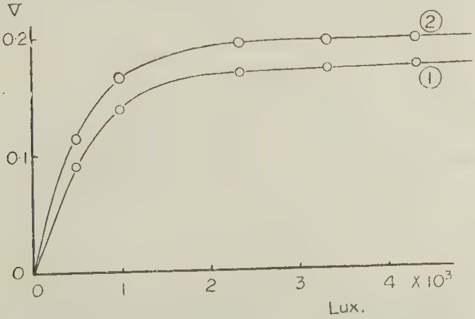

Fig. 8. Photovoltage of commercial type photovoltaic cell as a function of illumination.

§ 6. Conclusion and Acknowledgement

The surface of selenium is chemically active and its surface potential changes slowly under the effect of the ambient. The characteristic of the selenium rectifier made by contacting a rod of alloy on the surface is influenced by the surface condition. When the selenium surface coated with a thin insulating film is used, a rectifier of high rectification ratio is obtained. The surface potential of selenium under illumination varies in the same manner as the photoelectromotive force of selenium cells with the light intensity.

On the 180°-type Domain Wall of $BaTiO_3$ Crystal

By Wataru KINASE and Hidetosi TAKAHASI
Department of Physics, Faculty of Science,
University of Tokyo, Tokyo

(Received December 28, 1956)

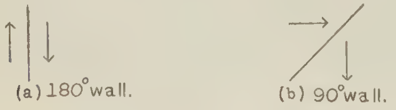
The energy of the 180°-type domain wall of $BaTiO_3$ crystal is obtained as 1.4 erg/cm^2 considering the dipole interaction and other interatomic energy of Born type.

The dipole interaction term has been obtained approximately from the difference of the energy of ferroelectric and antiferroelectric (stripes type) dipole configurations. The wall is found to be quite thin, that is, the change of polarization at the boundary is abrupt, in contrast with the ferromagnetic walls.

The structure of the 180° domains and their reversing process are also discussed.

§ 1. Introduction

Optical observations of single crystals of barium titanate have revealed a great deal about the domain structure of this crystal.[1)2)3)4)5)] In general, the domains are separated by two types of domain boundaries, that is, the 180°-wall and the 90°-wall which are boundaries between the two domains polarized respectively in antiparallel and perpendicular directions to each other (Fig. 1 (a) and (b)).



(a) 180°wall. (b) 90°wall.

Fig. 1.

The aim of our investigation is to find out the correct molecular model for the 180°-type domain boundary (or wall)*.

Treated in this paper are the atomic arrangement, the spontaneous deformation and polarization, the "thickness" and the energy of the 180°-type domain wall, considering the electrostatic dipole interaction and other interatomic forces of Born type.[6)] Of special interest is the fact that the dipole interaction energy at the boundary turns out to be nearly equal to that of the bulk crystal, resulting in an abrupt change of the dipole moments at the 180°-type boundary (Fig. 2) in contrast with the magnetic case, where more or less gradual change is found.

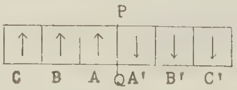


Fig. 2. Dipole arrangement near 180° boundary PQ.

We shall assume throughout this article that the dipole interaction is caused by the shift of Ti ions which are at the body-centres of the unit cells. The dipole moments by this shift will be shown by arrows as in Fig. 2.

§ 2. Ferro- and Antiferroelectric States

The calculation in the present paper makes use of the former results of the energy calculations for two periodic dipole configurations of $BaTiO_3$ crystal, that is, the ferroelectric configuration and one of the antiferroelectric configuration as shown in Figs. 3 and 4, respectively.

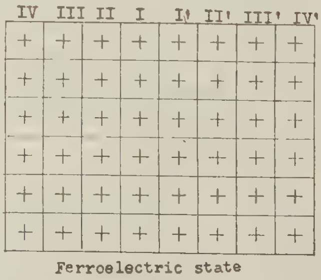

Fig. 3.

The energy and related quantities for these configurations have been calculated in a previous paper[8)] (Hereafter referred to as I) taking account of the electrostatic interaction among the sublattices.* There we obtained as the ratios γ and γ' of the electronic polarization of Ti ion (which is composed of the polarizations of the charge clouds of electrons) to the ionic polarization of Ti ion the values

---

* The two words "boundary" and "wall" will be used almost synonymously in this article.

0.1974 (eq. (15) in I) for the ferroelectric state and 0.1969 (eq. (19) in I) for the (stripes type) antiferroelectric state using the numerical values $c=64\times10^{-24}$c.c.$=(4\text{Å})^3$ for the volume of a unit cell and $4\pi\alpha_{\mathrm{Ti}}/c=0.0365$, $4\pi\alpha_{\mathrm{Ba}}/c=0.382$ and $4\pi\alpha_{\mathrm{O}}/c=0.470$ for the electronic polarizabilities of the ions[9], where the ionic polarization is defined as the sum of the moments of the dipoles contained in a unit volume[10], which correspond to the product of the effective charge ne and the shift from symmetrical position of Ti ion.** We can estimate the local fields acting on Ti ion caused by its own shift taking account of the above definition.

The local fields have been expressed in the preceding article[11]*** as

$$\gamma nex(1-8.17\Delta_a)/\alpha_{\mathrm{Ti}} \qquad (1)$$

for the ferroelectric state, where $\gamma=0.1974$, and

$$\gamma' nex(1-8.17\Delta_a)/\alpha_{\mathrm{Ti}} \qquad (2)$$

for the antiferroelectric state****, where $\gamma'=0.1969$, and x and Δ_a mean the shift of Ti ions and the fractional elongation of the lattice in the direction of the shift, that is, the lattice spacing is put as $4(1+\Delta_a)$ Å in this direction.

The potentials acting on Ti ion are obtained according to the usual definition of the "work" done to shift the Ti ion from the centre. Then multiplying eqs. (1) and (2) by a factor $-1/2$ and nex, we can get

$$\frac{-\gamma(ne)^2}{2\alpha_{\mathrm{Ti}}}\cdot(1-8.17\Delta_a)x^2 \qquad (3)$$

and

$$\frac{-\gamma(ne)^2}{2\alpha_{\mathrm{Ti}}}\cdot(1-8.17\Delta_a)x^2 \qquad (4)$$

as the potentials for the two states respectively.

§ 3. Local Fields at the Domain Wall

Figs. 5 (a) and (b) show schematically the dipole arrangement near a 180°-type domain boundary.

Let us consider the local field acting on Ti ion in the layer I and I' by the shift of Ti itself.

Here the method of the superposition of the local fields is useful for calculating the field in the domain boundary. For instance, the field acting on the point O by the ionic shift can be obtained if we know the field caused by the ionic shift of each layer in Fig. 6, which shows that the field in (a) is equal to the sum of those of (b), (c) and (d).

+	+	+	+	−	−	−	−

(b)

Fig. 5. Dipole arrangement near 180° wall.

Let us now consider the local field acting on Ti ion in the layer I in Fig. 5, where the ionic shift is $+x$ (upward arrows) and $-x$ (downward arrows) in the layer I, II, III,···· and I', II', III',····respectively.

For this purpose, we first consider Eqs. (1) and (2) which is for the cases of ferro- and antiferroelectric configurations shown in Figs. 3 and 4 respectively.

---

* Similar calculation was made independently by Y. Takagi.[7]

** ne means the "effective" charge of the Ti ion.

*** We refer to this paper as II.

**** Strictly speaking the two states have not the common factor $1-8.17\Delta_a$. However we neglect here this point, since the error is supposed to be small.

Now we shall put

$$ne(1-8.17\Delta_a)/\alpha_{\rm Ti}=k \qquad (5)$$

and apply the method of the superposition. Eqs. (1) and (2) are rewritten as

$$\begin{aligned} k\gamma x &= k\gamma_0 x+2\{k\gamma_1 x+k\gamma_2 x+k\gamma_3 x+\cdots\cdot\} \\ &= k\{\gamma_0+2(\gamma_1+\gamma_2+\gamma_3+\cdots\cdot)\}x \qquad (1)' \end{aligned}$$

and

$$\begin{aligned} k\gamma' x &= k\gamma_0+2\{k\gamma_1(-x)+k\gamma_2 x+k\gamma_2(-x)+\cdots\cdot\} \\ &= k\{\gamma_0+2(-\gamma_1+\gamma_2-\gamma_3+\cdots\cdot)\}x\,, \qquad (2)' \end{aligned}$$

where $\gamma_0, \gamma_1, \gamma_2, \gamma_3, \cdots\cdot$ are coefficients that characterize the effects of the shifts of the layers I, II (or I′), III (or II′), IV (or III′)···· in Figs. 3 and 4 on the layer I. The factor 2 before the parentheses in eqs. (1)′ and (2)′ means that the effects of the layers II and I′; III and II′; IV and III′; etc. are equivalent, and the alternate signs of $\gamma_0, -\gamma_1, \gamma_2, -\gamma_3, \cdots\cdot$ in eq. (2)′ correspond to the alternate directions of the shift in Fig. 4.

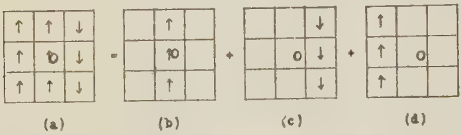

Fig. 6. Superposition of local fields caused by ionic shifts.

We get

$$\gamma=\gamma_0+2(\gamma_1+\gamma_2+\gamma_3+\cdots\cdot) \qquad (1)''$$

and

$$\gamma'=\gamma_0+2(-\gamma_1+\gamma_2-\gamma_3+\cdots\cdot)\,. \qquad (2)''$$

If we assume the relation

$$1:p=\gamma_0:\gamma_1=\gamma_1:\gamma_2=\gamma_2:\gamma_3=\cdots\cdot \qquad (6)$$

which certainly holds approximately, we obtain the relations

$$\gamma_0=\sqrt{\gamma\gamma'}\,, \qquad (7)$$

and

$$p=\frac{\sqrt{\gamma}-\sqrt{\gamma'}}{\sqrt{\gamma}+\sqrt{\gamma'}}\,. \qquad (8)$$

If we put $\gamma=0.1974$, $\gamma'=0.1969$ from eq. (1) and (2) we obtain

$$\gamma_0=0.19715 \qquad (9)$$

and

$$p=0.0006359=\frac{1}{1572.6} \qquad (10)$$

Here the smallness of p suggests that the local field acting on any Ti ion is mainly due to the shift of the ions within the same layer that contains the ion in question, the effect of the neighbouring layers being quite small. Our approximation may be inadequate in a general treatment of the local fields, but the error is considered to be small in cases where p is much smaller than unity.

The local field at the domain boundary can be found by using these values of γ_0 and p. The field in the layer I is

$$\begin{aligned} &k\gamma_0 x_1+k\gamma_1(x_2-x_1')+k\gamma_2(x_3-x_2') \\ &\quad +k\gamma_3(x_4-x_3')+\cdots\cdot \qquad (11) \end{aligned}$$

where

$$x_1, x_2, x_3, x_4, \cdots\cdot;\ x_1', x_2', x_3', x_4' \cdots\cdot$$

are the ionic shifts in the layers I, II, III, IV, ····; I′, II′, III′, IV′ ···· respectively. In a special case when the ionic shifts are all equal we can put the above x's as x. Then eq. (11) are rewritten simply as

$$k\gamma_0 x\,. \qquad (11)'$$

It may be admissible in a later treatment to take only the first term in eq. (11) into account and neglect the following term which are much smaller than $k\gamma_0 x_1$, because of the relation $\gamma_0 \gg \gamma_1 \cdots\cdot$ and $x_1 \gg x_2-x_1' \cdots\cdot$.

§4. The Lattice Spacings and the Ionic Shift at the Domain Boundary

We shall estimate here the lattice spacings in the domain wall.

The spontaneous deformation of the wall may be treated in a similar fashion as in II. The overlap, van der Waals' and Coulomb energy which were already discussed in the paper II are also available in the treatment of the domain wall. The dipole interaction may be taken from eq. (11), retaining only the first term, as already mentioned.

The potential acting on a Ti ion has been expressed as

$$(a'+a)x^2+bx^4 \qquad (12)$$

in the paper II, where $a'x^2$ is a negative term due to the dipole interaction and $|a'|>|a|$ in case of the "spontaneous" shift, while ax^2 and bx^4 are positive terms due to the van der Waals' and overlap interaction among the ions.[6)12)] The coefficients have been calculated in II for bulk crystals as

$$a'=\frac{-\gamma(ne)^2}{2\alpha_{\rm Ti}}\cdot(1-8.17\Delta_a)\,, \qquad (13)$$

$$a=10^5(5.1227-71.302\Delta_a+6.9541\Delta_{b1}+6.9541\Delta_{b2}+433.97\Delta_a{}^2-42.605\Delta_{b1}{}^2-42.605\Delta_{b2}{}^2) \tag{14}$$

and

$$b=10^{22}(1.8952-23.738\Delta_a-0.57603\Delta_{b1}-0.57603\Delta_{b2}+167.32\Delta_a{}^2+4.0873\Delta_{b1}{}^2+4.0873\Delta_{b2}{}^2)\ , \tag{15}$$

where γ, ne, α_{Ti} and Δ_a have the significance already mentioned, and Δ_{b1} and Δ_{b2} are the elongation of the cube edges relative to those of the standard cube in the two directions perpendicular to the ionic shift.

These coefficients must be somewhat modified in case of the domain boundary. Let us denote them by putting a bar on each symbol as $\bar{a}'$, $\bar{a}$ and $\bar{b}$. They are expressed as

$$\bar{a}'=\frac{-\gamma_0(ne)^2}{2\alpha_{\mathrm{Ti}}}\cdot(1-8.17\Delta_a)\ , \tag{13$'$}$$

$$\bar{a}=a+(6.8-47\Delta_{b2}) \tag{14$'$*}$$

and

$$\bar{b}=b+(-3+25\Delta_{b2})10^{16}\ . \tag{15$'$*}$$

Eq. (13)′ is obtained by putting γ_0 instead of γ in eq. (13). $\bar{a}$ is somewhat different from a, but the effect of this modification on the result is very small, the magnitude being expected to be about one-hundredth of the modification of a'. We also find that the difference between b and $\bar{b}$ is quite negligible. The above modification of a and b is due to van der Waals' and overlap interactions between Ti ions in the layers I and I′, and the interactions are so small as to leave a and b almost unchanged. Using the three coefficients $\bar{a}'$, $\bar{a}$ and $\bar{b}$ we can determine the lattice spacing and the ionic shift at the domain boundary by minimizing the energy for the domain boundary:

$$\bar{U}\doteq(\bar{a}'+\bar{a})x^2+\bar{b}x^4+\bar{U}_{\mathrm{overlap}}+\bar{U}_{\mathrm{Waals}}+\bar{U}_{\mathrm{Coulomb}} \tag{16}$$

as we have done in paper II for the bulk crystal.

The last three terms in eq. (16) represent the energy of the "unpolarized" tetragonal lattice, and do not contain x explicitly. Accordingly, by minimizing eq. (16) with respect to x, that is, by putting

$$0=\frac{\partial}{\partial x}\bar{U}, \tag{17}$$

we can obtain the spontaneous shift as

$$x=\pm\{(-\bar{a}'-\bar{a})/(2\bar{b})\}^{1/2}\ . \tag{18}$$

Substituting (18) into (16), the energy is rewritten as

$$\bar{U}=-(\bar{a}'+\bar{a})^2/(4\bar{b})+\bar{U}_{\mathrm{overlap}}+\bar{U}_{\mathrm{Waals}}+\bar{U}_{\mathrm{Coulomb}}\ , \tag{19}$$

the first term of `which corresponds to the "shift" energy.

It is reasonable to assume that the lattice spacings of the domain wall in the a and b_1 direction (that is, the direction parallel to the wall) are the same as in the bulk crystal, because the wall is clamped by the neighbouring lattices. Thus we have only to minimize the energy expression with respect to Δ_{b2} by solving the equation

$$0=\frac{\partial}{\partial\Delta_{b2}}\bar{U}\ . \tag{20}$$

We adopt here the values

$$\Delta_a=0.01951 \tag{21}$$

$$\Delta_{b1}=\Delta_{b2}=0.003723 \tag{22}$$

for Δ_a and Δ_{b1}, which has been obtained as the roots of the equations for the bulk crystal

$$0=\frac{\partial}{\partial\Delta_a}U\ , \qquad 0=\frac{\partial}{\partial\Delta_b} \tag{23 A, B}$$

in II, where U is the energy for the ferroelectric state of the bulk crystal. That is,

$$U=-(a+b)^2/(4b)+U_{\mathrm{overlap}}+U_{\mathrm{Waals}}+U_{\mathrm{Couloumb}}\ , \tag{24}$$

where we have assumed the effective charge of Ti ion to be 2.102* which corresponds to the value

$$\frac{\gamma(ne)^2}{2\alpha_{\mathrm{Ti}}}=5.4\times10^5 \tag{25}$$

in eq. (13) and to the total polarization 22 μ coul/cm² which may be compared with the observed value by W. J. Merz.[13]**

Putting these into eq. (20) we obtain

$$\Delta_{b2}=0.003745 \tag{26}$$

---

* In eq. (14)′ and (15)′ the factors 6.8 and −3 are due to the nearest neighbour Ti ion that is shifted in the antiparallel direction, while $-47\Delta_{b2}$ and $25\Delta_{b2}$ are due to the lattice deformation characteristic of the boundary.

* See Appendix A.

** The polarization reported is 15 μ (old) or 26 (new) μ coulomb/cm² at room temperature.

for the elongation of the spacing of lattice at the domain boundary and

$$x=\{(-a'-a)/(2b)\}^{1/2}=0.1402\ \text{Å} \tag{27}$$

for the shift of Ti ion in the adjacent layer. The above calculation leads therefore to the conclusion that the change of the lattice spacings and the ionic shift at the domain boundary are quite small, namely, 9×10^{-5} Å and -0.0007 Å which correspond to the relative differences 0.002 % and 0.5 % respectively.

Table I.

	Lattice spacings			Ionic shift
Bulk crystal	4(1+0.01951) Å	4(1+0.003723) Å	4(1+0.003723) Å	0.1409 Å
Domain boundary	〃	〃	4(1+0.003745) Å	0.1402 Å

We have hitherto considered only the shift of the Ti ions in the layers I and I′. Strictly speaking, we also had to take account of the modification of the shifts of the Ti ions in the layers II and II′, etc. These effects, however, are so small that they may be entirely neglected.

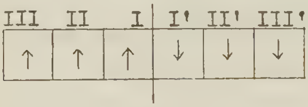

Fig. 7. Ionic shift at 180° wall.

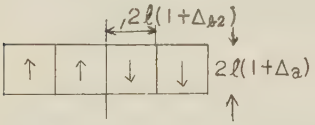

Fig. 8. Dipole moment by ionic shift.

§ 5. The Thickness and Energy of the 180°-Wall

We now calculate the ionic shifts in the layers near the domain boundary using the relation (11). The shift in the layers I, II, III etc. will be expressed as

$$x_1=(1-\delta_1)x_0\,,\quad x_2=(1-\delta_2)x_0\,,\quad x_3=(1-\delta_3)x_0\,,$$

etc. where x_0 is the shift in the normal ferroelectric state, $\delta_1=4.8\times10^{-3}$ from the last column in Table I. δ_2 is obtained as follows:

(i) For the uniformly polarized state the local field on the i-th layer is obtained as

$$k\gamma_0x_i+k\gamma_1(x_{i-1}+x_{i+1}) +k\gamma_2(x_{i-2}+x_{i+2})+\cdots \tag{28*}$$

from the eq. (11). If we retain only the first two terms and put

$$x=x_i=x_{i-1}=x_{i+1}=\cdots\,, \tag{29}$$

the eq. (28) is rewritten as

$$k\gamma_0x+2k\gamma_1x\,. \tag{30}$$

(ii) For the boundary layers I and I′ the ionic shift is $(1-\delta_1)x_0$.

The local field is obtained by putting

$$\left.\begin{aligned} &x_i=x\,,\qquad x_{i+1}=-x\\ \text{and}\qquad&\\ &x_{i-1}=\frac{x}{1-\delta_1}\,. \end{aligned}\right\} \tag{31}$$

Then eq. (28) is rewritten as

$$k\gamma_0x+k\gamma_1x\left(\frac{1}{1-\delta_1}-1\right)$$

$$\fallingdotseq k\gamma_0x+\delta_1k\gamma_1x\,.\ (\delta_1\ll1) \tag{32}$$

(iii) For the boundary layers II and II′ the ionic shift is $(1-\delta_2)x_0$. The local field is obtained by putting

$$\left.\begin{aligned} &x_1=x\,,\qquad x_{i+1}=x\cdot\frac{1-\delta_1}{1-\delta_2}\\ \text{and}\qquad&\\ &x_{i-1}=\frac{x}{1-\delta_2}\,. \end{aligned}\right\} \tag{33}$$

Then eq. (28) is rewritten as

$$k\gamma_0x+k\gamma_1x\left(\frac{1}{1-\delta_2}+\frac{1-\delta_1}{1-\delta_2}\right)$$

$$\fallingdotseq k\gamma_0x+(2-\delta_1)k\gamma_1x\,. \tag{34}$$

From eq. (30), (32) and (34) the difference of the local fields from the normal ferroelectric state are obtained as $(2-\delta_1)k\gamma_1x$ and $\delta_1k\gamma_1$ respectively for the layers I (or I′) and II (or II′). Taking account of the smallness of differences we can obtain the following relation of proportionality between the differences of the local fields and the ionic shifts from the normal ferroelectric state, that is,

---

* Eq. (28) is more general expression than eq. (11), since x_i means the ionic shift in an arbitrary layer.

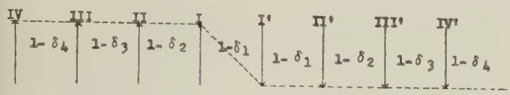
$$\frac{(2-\delta_1)k\gamma_1 x}{\delta_1}=\frac{\delta_1 k\gamma_1 x}{\delta_2}. \qquad (35)$$

By putting $\delta_1=4.8\times10^{-3}$ we obtain

$$\delta_2=\frac{\delta_1^2}{2-\delta_1}=1.2\times10^{-5}. \qquad (36)$$

In the same manner we can obtain

$$\delta_3=2.8\times10^{-8}, \quad \delta_4=6.6\times10^{-11}. \qquad (36)'$$



$$\delta_1=4.8\times10^{-3}, \qquad \delta_3=2.8\times10^{-8},$$
$$\delta_2=1.2\times10^{-5}, \qquad \delta_4=6.6\times10^{-11}.$$

Fig. 9. Relative ionic shift near 180° wall to the shift of uniformly polarized crystal.

Considering the smallness of δ's obtained above we may say that the wall thickness is practically "zero".*

From the above estimation we may regard the 180°-type domain wall will be very thin accompanied by a remarkable change of the dipole orientation there, which is in contrast with the magnetic domain wall whose thickness is estimated to be hundreds of lattices and where the gradual change of spin orientation is expected.[14)]

Of course our discussion is valid at room temperature, and more thorough consideration may be necessary in the transition temperature where the domains disappear.

The energy of the domain wall can be obtained from eq. (19) and (24). The difference between $\overline{U}$ and U means the energy required to form a domain boundary layer, that is, the wall energy, and is given by

$$\overline{U}-U=U_{\text{shift}}+U_{\text{lattice}}, \qquad (37)$$

where

$$U_{\text{shift}}=\{-(\overline{a}'+\overline{a})^2/(4\overline{b})\}-\{-(a'+a)^2/(4b)\}, \qquad (38)$$

$$U_{\text{lattice}}=\{\overline{U}_{\text{overlap}}+\overline{U}_{\text{Waals}}+\overline{U}_{\text{Coulomb}}\} -\{U_{\text{overlap}}+U_{\text{Waals}}+U_{\text{Coulomb}}\}. \qquad (39)$$

Here U_{shift} and U_{lattice} mean respectively the contributions of the shift and the lattice deformation to this difference. Taking eq. (14), (15), (14)′, (15)′, (21), (22), (26) and also Table I into account, we obtain

$$U_{\text{shift}}=1.179\times10^{-15}\,\text{erg}, \qquad (40)$$
$$U_{\text{lattice}}=-0.0336\times10^{-15}\,\text{erg}, \qquad (41)$$
$$\overline{U}-U=1.145\times10^{-15}\,\text{erg}. \qquad (42)$$

These energy expressions are concerned with the unit cells in the layer I or I′ in Fig. 9, so we must multiply them by a factor two. Then the wall energy per unit area (cm²) is obtained as

$$(\overline{U}-U)\times2\times\frac{1}{4l^2(1+\Delta_a)(1+\Delta_{b1})}$$
$$=1.40\,\text{erg/cm}^2, \qquad (43)$$

where $l=2$ Å and the fraction means the number of the unit lattice per cm².

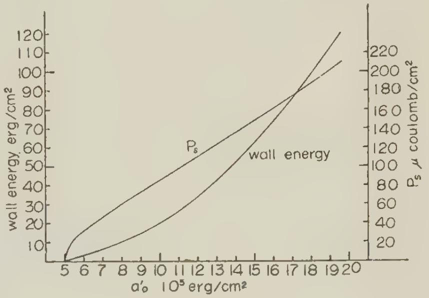


Fig. 10 (a). Wall energy and spontaneous polarization, which are calculated taking dipole interaction coefficient a_0' as a parameter.

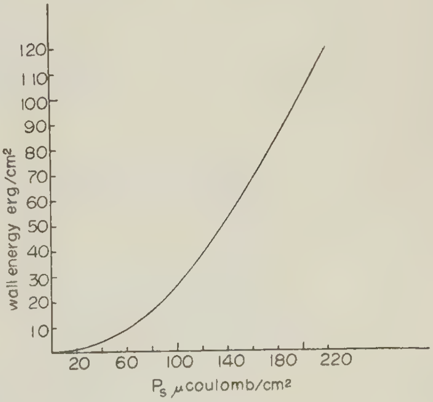

Fig. 10 (b). Wall energy vs. spontaneous polarization.

The calculated wall energy and polarization vs. the dipole interaction (the effective charge) are shown in Fig. 10 and Table II. The dependency of wall energy to polarization can be roughly obtained as $U=0.0032\,P_s^{1.96}$ from the figure and Table II.

---

* In the definition of the wall thickness we have adopted here the definition of a unit cell with a Ti ion at its centre. If, on the other hand, we define a unit cell so that a Ba ion is at its centre, the thickness would be "one layer".

Table II.

§ 6. Estimation of the Domain Width

Above results will now be used to determine the width of the domain of 180°-type from the condition of the counterbalance of the wall energy and the electrostatic energy caused by the free poles at the crystal surface, in the same manner as Kittel[14] did for magnetic domains.*

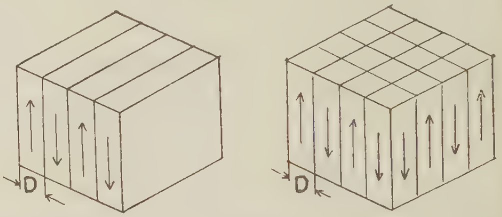
It is true that there is a difference between the magnetic and electric case, because of the existence of the neutralizing charges in the electric poles, so that in the equilibrium state the eletrostatic energy disappears and cannot be the cause of domain structure. However we must take account of the fact that the domain structures may be determined just at the instant of change to ferroelectric state, that is, before the neutralizing charges have enough time to wander on to the free poles.

Kittel's results, applied to the electrostatic energy, for three different configurations A, B and C in Fig. 11 are**

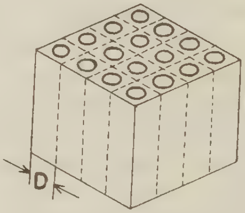
$$U_{\text{electric}}=\begin{cases}0.8525\ (\eta P_s)^2D\,, & (A)\\ 0.53\ \ (\eta P_s)^2D\,, & (B)\\ 0.374\ (\eta P_s)^2D\,, & (C)\end{cases}\qquad (44)$$

where D means the domain width, and P_s means the spontaneous polarization. The factor $(0\leqq\eta\leqq1)$ before P_s in (44) has been added in order to take account of the effect of partial neutralization of surface charges that may occur during the phase change.

If we assume the crystal shape as rectangular parallelepiped whose three edges are d_1, d_2 and d_3 respectively as in Fig. 12, the electrostatic energy at the surface and the domain wall energy is expressed as



Stripes domain (A) Checker-board domain (B)



Cylindrical domain (C)

Fig. 11. Three domain configurations.

$$U_{\text{total}}=U_{\text{electric}}+U_{\text{wall}}$$
$$=\xi_i(\eta P_s)^2\cdot\frac{d_1}{N}\cdot d_1d_3+\zeta_iNd_2d_3\,,\qquad (i=1,2,3)\qquad (45)$$

where

$$\xi_1=0.8525,\quad \xi_2=0.53,\quad \xi_3=0.374$$

and

$$\zeta_1=1.40,\quad \zeta_2=2\times1.40,\quad \zeta_3=(2\pi)^{1/2}\times1.40\qquad (46)$$

according to Kittel. $i=1,2,3$ correspond respectively to the three domain configurations shown in Fig. 11.

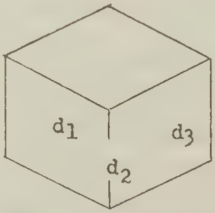


Fig. 12. Rectangular parallelepiped of the crystal.

---

* The discussion for KH_2PO_4 crystal was done by W. Känzing and R. Sommerhalder.[15]

** Recently the 180° domains were observed using the etching method by D.S.Campbell[16], J.A. Hooton and W.J.Merz[17]. Some of their etch patterns are circles, and some look more complicated in shape.

N is the number of domain stripes as seen on the $d_1\,d_2$ plane. So d_1/N in eq. (45) means the domain width D in cases (A) and (B), and the distance between the centres of the neighbouring cylinders in case (C), where the radius of the circle should be $D/(2\pi)^{1/2}$ so that total cross-section of the cylinders is half the area $d_1\,d_3$.

By solving the equation

$$0=\frac{\partial}{\partial N}(U_{\text{electric}}+U_{\text{wall}}) \qquad (47)$$

which is the condition of the minimum energy, we obtain the domain width

$$D=\frac{d_1}{N}=(1.40d_2\zeta_i/\xi_i)^{1/2}\cdot\frac{1}{\eta P_s}\quad (i=1,2,3)\,. \qquad (47)'$$

Table III shows some numerical results.

Table III. Domain Width (Unit in 10^{-4} cm).

	$\eta=1$			$\eta=0.5$			$\eta=0.1$		
	$d_2=1$ cm	$d_2=0.5$	$d_2=0.1$	$d_2=1$	$d_2=0.5$	$d_2=0.1$	$d_2=1$	$d_2=0.5$	$d_2=0.1$
(A) stripes	0.19	0.14	0.061	0.39	0.27	0.122	1.9	1.36	0.61
(B) checkerboard	0.35	0.24	0.109	0.69	0.49	0.22	3.5	2.4	1.09
(C) cylinder	0.46	0.33	0.146	0.92	0.65	0.29	4.6	3.3	1.46
(diameter)	0.37	0.26	0.116	0.74	0.52	0.23	3.7	2.6	1.16

The result is in the same order of magnitude with the observed domains, which are about 10^{-4} cm wide.[16)17)] Eq. (47)′ shows that the neutralizing charge has the effect of making the domain width larger. Since the actual shapes of the domains are generally more complicated, our result may give only a rough estimate of the domain size.

§ 7. Discussion

Comparison with Merz's theory

The wall energy 1.40 erg/cm² obtained by us differs substantially from the value 7 erg/cm² by W. J. Merz.[13)] The origin of this discrepancy lies mainly in the difference of the models of both theories, for we have started from the model of the wall accompanied by an abrupt change of the dipole direction, while Merz has simply brought the model for the Bloch wall of ferromagnetics, where a gradual change of the spin direction is effected by *rotation*, into dielectric case. In case of the 180° wall of $BaTiO_3$ the rotation of dipoles without change of magnitude is highly improbable because of the great anisotropy within the wall due to the clamping effect of spontaneous deformation of the bulk crystal, so that the analogy to the Bloch wall is not justified.

In order to make this comparison more directly, we can put the wall energy in the form

$$E_{\text{wall}}=AN+\frac{B}{N}$$

as Merz did (eq. (10) in his article).[13)] Merz regarded the first term as anisotropy energy and the second term as the dipole interaction energy. However this interpretation will be entirely inadequate, if we assume that the *magnitude* and sign of polarization changes without rotation.

We divide the dipole interaction energy in $BaTiO_3$ in two parts, that is, the interaction in the direction parallel and perpendicular to the polarization, which are the order of 10^{-14} erg and 10^{-15} erg per unit cell respectively from the calculation in § 5. It must be the latter one rather than total dipole interaction energy as Merz assumed, that mainly contributes to the wall energy and plays a role similar to the exchange energy in Bloch wall thickness, while the other term (proportional to N) tending to decrease the wall thickness is mainly the parallel part of the dipole interation rather than the anisotropy energy.

By putting proper values for A and B (5.88×10^{-14} erg and 2.36×10^{-15} erg respectively)*, we again have $N=0.2$ which is equal to saying that the thickness is "zero".

The lattice spacing within the 180° wall is almost equal to the bulk system as shown in

---

* The value of B is equal to $2U_{\text{shift}}$ in (40) (that is, for both sides of the boundary), while the value of A corresponds to $(a'+a)^2/(4b)$ in (38).

Table I. However this may not be necessary the case in the 90° wall, where the rotation of the dipoles occurs accompanied by the lattice deformation due to the tetragonality of the lattice. This tetragonality is about 1 %,[18][19] so the deformation energy may take some part in the 90° wall, adding to the dipole interaction energy. Anyhow the 90° wall is expected to be thicker, and its energy larger than 180° wall. The quantitative estimation of the energy and thickness of the 90° wall seems to be more complicated than the 180° wall.

Origin of domain formation

The domain width obtained from the consideration of electrostatic depolarizing field has been found to be in fair agreement with observation. However, our treatment applies only to the virgin state of a free crystal (without electrode) cooled from above the Curie temperature. The domains observed at room temperature in crystals in the way of its polarization reversal cannot be determined by equilibrium considerations. These are determined rather by the wedge shaped domain nuclei formed at the surfaces. Tentative explanation of the origin of these nuclei will be given later.

The origin of the 90° domains is more obvious. Since the 90° rotation of polarization is accompanied by a large deformation, a mechanically clamped crystal must be split into domains in order to relax its elastic stress. A quantitative discussion of the domain width would require, however, a knowledge about the energy of the 90° walls as well as a precise mathematical treatment of the elastic energy of multi-domain configurations.

Polarization reversal

Let us now discuss the field strength required to move the wall sideways. First we will estimate the field strength required to cause a simultaneous reversal of the polarization of a whole domain. The reversing field strength corresponds to the steepest gradient of the double minimum potential acting on Ti ion, that is, the gradient at the inflection-point P and P' in Fig. 13.

This is obtained from the equation

$$\frac{\partial^2}{\partial x^2}\{(a'+a)x^2+bx^4\}=0 \tag{48}$$

and is given by

$$x=\{(-a'-a)/(6b)\}^{1/2}\,. \tag{49}$$

The gradient of the potential curve at P is

$$\frac{\partial U}{\partial x}=\frac{4}{3}(-a'-a)\{(-a'-a)/(6b)\}^{1/2}\,. \tag{50}$$

The expression (50) represents the force which is required to act on each Ti ion in order to cause the reversal, and is related to the local field E_{local} at the Ti position by

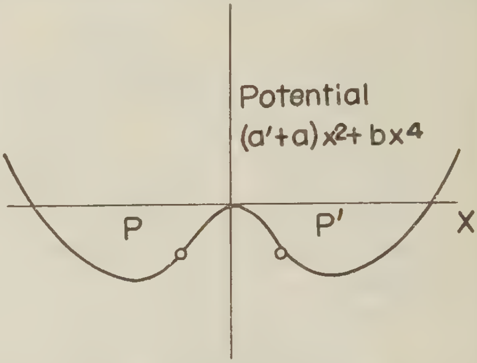

Fig. 13. Double minimum well of potential acting on Ti ion.

$$\frac{\partial U}{\partial x}=E_{\text{local}}\cdot ne\,, \tag{51}$$

where ne is the effective charge. E_{local} is equal to 3.246 E where E is the applied field strength (See Appendix B).[10][20]*

Taking as the numerical value $n=2.102$**, we obtain the field strength E required to reverse the polarization as

$$1.96\times10^4 \text{ e.s.u.}$$

or

$$5.88\times10^6 \text{ volt/cm.} \tag{52}$$

This value seems to be too large to have any correspondence with experimental data.

Then let us calculate the minimum field strength required to move a 180° wall. The mechanism of the movement of a 180° wall may be explained as follows.

When we apply the electric field which is strong enough, the reversing of the polarization at the boundary layer which is polarized in the opposite direction to the applied field will take place at first. In the reversing process the polarization of the boundary layer will decrease in magnitude and tend to zero at last, and then the layer will be polarized in the same direction of the applied field and complete the reversing. The change of the polarization of other layers will give little effect to the reversing, for the sideway interaction of the dipoles is much smaller than that of the dipoles in the same layer as discussed in the preceding sections. So we treat here the reversing of the boundary independently of other layers, considering only the potential acting on Ti ions at the boundary layer.

---

* These values are calculated for the cubic crystal (4Å). Strictly speaking, we must calculate for the more accurate lattice considering the lattice deformation. Moreover the electrostriction due to the applied field must be taken into account for the more precise estimation.

** This value 2.102 was used in the preceding sections when we discussed the wall energy.

The potential at the boundary is expressed as

$$(\overline{a}'+\overline{a})x^2+\overline{b}x^4 \text{ instead of } (a'+a)x^2+bx^4$$

in the bulk crystal as already mentioned, so we can obtain the field to move the wall in the same way as above, the result being

$$1.93\times10^4 \text{ e.s.u.}$$

or

$$5.79\times10^6 \text{ volt/cm .} \tag{53}$$

Note that there is no substantial difference between (52) and (53), that is, to move a 180° wall is no easier than to reverse the polarization of a whole domain, in sharp contrast with the ferromagnetic case. This difference is the result of the difference of the wall thickness.*

Actually the reversal of the polarization takes place at a very low field of the order of hundreds of volts per cm. And so we shall have to assume a certain mechanism that enable the motion of the wall in a substantially lower field. Although we are not going to give a complete discussion of the possible mechanism, we shall suggest a few of them. Namely

1. The domain wall may not be parallel to (001) axis. That is, microscopically, there may be many steps in the wall²³⁾. These steps may be able to move within the wall by a much lower external field, and may effectively shift the wall in the direction perpendicular to it. This mechanism may be responsible for the growth of wedge-shaped domains, which have been observed by Merz¹³⁾ and Little²¹⁾.

2. While usually these steps may disappear at the crystal boundary after it has travelled across the wall surface, there may by some steps which originate at the screw dislocations running perpendicular to the wall. These steps are permanently connected to the dislocation, and will move around the dislocation making spirals, but never disappear at the crystal boundary, causing effectively a parallel shift of the domain walls.*

3. Our results apply only to the inner part of the crystal. The situation would be quite different at the surfaces, especially at those perpendicular to the polarization, where the internal field is caused only by an array of semi-infinite dipole chains. In other words, the large spontaneous polarization gives rise to a large surface charge, which produces a strong depolarizing field. It is true that, in experimental conditions, these surfaces are always covered by conducting electrodes, and the depolarizing charges are completely canceled by the induced charge in the electrode, and therefore the surfaces are not all too different from the bulk. However, it is also probable that there are many pinholes and also small local gaps in the electrode, where the compensating charge are not effective. Since a slight decrease of the internal field is sufficient to make the crystal non-ferroelectric, these defects in the electrode will cause small non-ferroelectric specks on the crystal surface. The dipoles in the neighbourhood of these specks will have a gradual change as shown schematically in Fig. 14. Since a small field will be sufficient to reverse the polarization in these transition regions, they will act as the nuclei of the new domains. Eventually, these surface charges would have been neutralized by external charges.** In this case, the polarization in these parts will not be reversed by a reversed field, and will form small wedge-shaped domains around it.

---

* The polarization reversal taking into account of the shape of the hysteresis loop has been discussed by R. Landauer, D. R. Young and M. E. Drougard.²²⁾

* Refer to the article "T. Nakamura, Jour. Phys. Soc. Japan, 9 (1954) 425 about this mechanism.

** W. Känzig has assumed that these exist a surface layer which traps electrons as in the case of usual semiconductors. See Phys. Rev. 98 (1955) 549.

These will also act as nuclei when the field is again reversed.

4. Another possible cause of domain nuclei, which can be effective on the surface as well as within the crystal, is the edge dislocation. Since the 180° reversal of the polarization does not cause mechanical strain, a homogeneous stress in the crystal cannot have any effect on the 180° wall. However, inhomogeneous stress of the type found around an edge type dislocation will definitely favour the domains of one polarization against the domains of opposite polarization, and "trap" a small wedge domain polarized in that direction when the external field is in the opposite direction. These small trapped domains will also act as the nuclei when the field is again reversed. It is possible that the observed fine domain structure of real crystals is caused mainly by these inhomogeneous stresses rather than by the electrostatic energy of free poles.

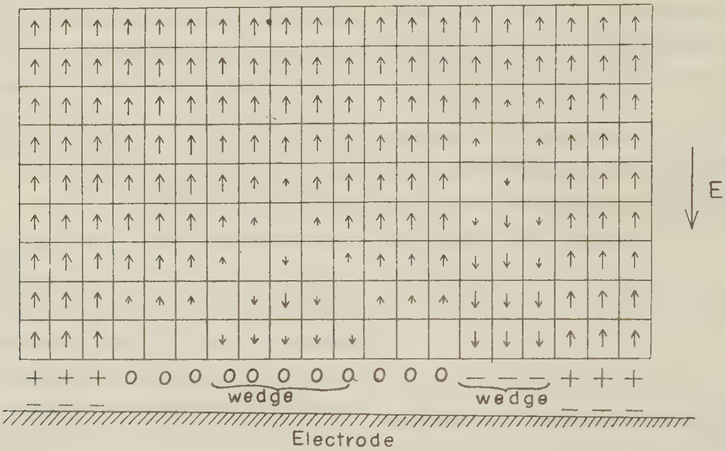

Fig. 14. The state of polarization at the surface, which is speculated tentatively. An external field E was applied downward just now, and the growth of wedge-type domains is shown. Electrodes are attached at the surfaces (In the figure only lower surface is found.), and generally neutralizing charges are induced at the Electrodes. + and − indicate the signs of charges, and O means that there exist no charges. Two types of the wedge-type domains are shown in the figure, one is polarized spontaneously at the surface and the other is not. Shorter arrows correspond to weaker polarizations, and the polarization has just induced at the surface of the wedge-type domain in the left side. The surface region indicated by − or O corresponds to the "speck" in the article, while that indicated by + is the normal region of the surface.

A crystal may contain edge dislocations of one sign in excess of ones of opposite sign. In such a case the crystal would have a tendency to polarize in one direction and will reveal asymmetrical hysteresis loops. This will explain the asymmetry of the hysteresis loops found in the crystal plates forming butterfly pairs.[24)]

5. Thermal motion of ions will cause the wall displacement by any mechanism discussed above in a still lower field. This would result in a "creep", that is, a gradual displacement of walls at a definite rate that depends on the applied field.[13)]

Summarizing our article, the 180° wall of $BaTiO_3$ is considered to be quite thin at room temperature, and its energy is estimated to be 1.4 erg/cm^2. The formation of the 180° domains can be explained by considering the electrostatic energy of the free poles, resulting in the domain width of the order of 10^{-4} cm for the possible domain configurations and the crystal sizes. The reversing process cannot be explained by the abrupt reversing, and some mechanisms for the nucleation and the growth of the reversed domains are suggested.

This work was supported by the Grant for Scientific Researches from Education Ministry.

Appendix A

Our previous article on spontaneous deformation of $BaTiO_3$ (J. P. S. J. 10 (1955) 942) has been found to contain some numerical mistakes and will be corrected as follows:—

The equations (20 A, B, C, D, E), which represent the relation between ionic and electronic polarizations taking account of the lattice deformation, should be read.

$$u=0.1974(1-8.17\Delta_a)u_0\,,$$
$$v=-0.0630(1-39.9\Delta_a)u_0\,,$$
$$w=1.9090(1-4.80\Delta_a)u_0\,,$$
$$x_1=0.1014(1-3.32\Delta_a)u_0\,,\quad (20\ A, B, C, D, E)$$
$$x_2=0.1014(1-3.32\Delta_a)u_0\,.$$

The changes are made for the coefficients of Δ_a.

Corresponding corrections should be made for Table I and Table II.

The corrected version is as follows:

Table I. Standard cube is (4 Å)^3.

Appendix B

The local fields caused by the applied external field has been calculated by the method of J. C. Slater[10] and T. Oguchi.[20]

The local fields acting on ions are obtained by solving the following equations.

Field on Ti$=(c/\alpha_{\mathrm{Ti}})u$

$$=E+\frac{1}{\varepsilon_0}\left\{\frac{1}{3}u+\frac{1}{3}v+\left(q+\frac{1}{3}\right)w+\left(-q+\frac{2}{3}\right)x\right\}, \tag{A}$$

Field on Ba$=(c/\alpha_{\mathrm{Ba}})v$

$$=E+\frac{1}{\varepsilon_0}\left\{\frac{1}{3}u+\frac{1}{3}v+\left(-p+\frac{1}{3}\right)w+\left(p+\frac{2}{3}\right)x\right\}, \tag{B}$$

Field on Oa$=(c/\alpha_{\mathrm{O}})w$

$$=E+\frac{1}{\varepsilon_0}\left\{\left(q+\frac{1}{3}\right)u+\left(-p+\frac{1}{3}\right)v+\frac{1}{3}w+\left(p+\frac{2}{3}\right)x\right\}, \tag{C}$$

Field on Ob$=(c/\alpha_{\mathrm{O}})x$

$$=E+\frac{1}{\varepsilon_0}\left\{\left(-\frac{1}{2}q+\frac{1}{3}\right)u+\left(\frac{1}{2}p+\frac{1}{3}\right)v+\left(\frac{1}{2}p+\frac{1}{2}\right)w+\left(-p+\frac{2}{3}\right)x\right\}, \tag{D}$$

where c is the volume of a unit cell 64×10^{-24} C.C.,

α's the polarizabilities of Ti, Ba and Oxygen ions respectively ($\alpha_{\mathrm{Ti}}=2.34\times10^{-24}\varepsilon_0$ C.C., $\alpha_{\mathrm{Ba}}=24.42\times10^{-24}\varepsilon_0$ C.C. and $\alpha_{\mathrm{O}}=30.0\times10^{-24}\varepsilon_0$ C.C. in M.K.S. system), and u, v, w and x the polarization due to Ti, Ba, Oa and Ob ions respectively.

Solving these equations we get

$$u=0.1185\varepsilon_0 E, \tag{E}$$

$$v=0.9197\varepsilon_0 E, \tag{F}$$

$$w=1.4305\varepsilon_0 E, \tag{G}$$

$$x=1.1585\varepsilon_0 E. \tag{H}$$

By putting these values into (A), (B), (C) and (D), we obtain the local fields

$$(\text{Field on Ti})=3.246E, \qquad (\mathrm{J})$$

$$(\text{Field on Ba})=2.408E, \qquad (\mathrm{J})$$

$$(\text{Field on Oa})=3.044E, \qquad (\mathrm{K})$$

$$(\text{Field on Ob})=2.465E. \qquad (\mathrm{L})$$

After Effect of the Domain Motion in Rochelle Salt Crystal

By Terutaro NAKAMURA
Department of Physics, Faculty of Science,
University of Tokyo

(Received February 8, 1957)

After effect of the domain motion in rochelle salt crystal was observed for several hours. Quasi-static f–E hysteresis loop was obtained, where f is the fraction of the domain saturated in one direction to the total volume of the crystal. Comparing this with P–E hysteresis loop at 50 cps, differences are remarkable. A.c. hysteresis loop has shallow sloping sides and high coercivity, while quasi-static f–E hysteresis loop is almost square and shows much lower coercivity. f is time dependent and can be expressed in the formula:

$$f(t)=1-e^{-\alpha t}$$

where time constant $1/\alpha$ is about one hour for critical field about 60 v/cm, in the sample of thickness 0.6 mm at 10°C.

§ 1. Introduction

Recently the domain structure of rochelle salt crystal has been investigated in detail by several authors[1),2),3),4)].

It was reported by Mitsui and Furuichi[1)] that the domain motion showed after effect when an electric field of a square wave was applied, the frequency of which was 22 cps. It was also shown by Marutake[2)] that the polarization of the crystal was reversed, unlike ferromagnetics, not only by the sidewise motion of domain walls, but also by the nucleation of antiparallel domains, and that the motion of the domains were accompanied with a marked after effect, when one cycle was completed in 30∼90 min. Any closer study on the after effect of the domain motion in rochelle salt crystal, however, has not yet been made.

On the other hand, it has been known that polarization of rochelle salt crystal, if measured electrostatically, (not optically), also shows a marked after effect[5)]. This phenomenon was subsequently studied in detail by Takahasi and Hara[6)], and recently by Marutake[7)]. Electrical measurements of the after effect for an extremely long time, however, were impossible, since experiments were limited by such characteristics as resistivity of insulators. Change of polarization due to the domain motion was able to be measured by an optical method for a considerably long period of time.

The present article reports some measurements on the long time after effect of the domain motion in rochelle salt crystal by the optical method.

§ 2. Experimental

A-plate rochelle salt crystals of the size 0.6 mm × 20 mm × 10 mm, cut out from large crystals, were employed in experiments. The domain structure were observed by means of a polarization microscope through a hole of about 1 mm in diameter in silver foil electrodes attached to the crystals. The foiled crystal was placed between metal electrodes, as shown in Fig. 1. Measurements were made at room temperature.

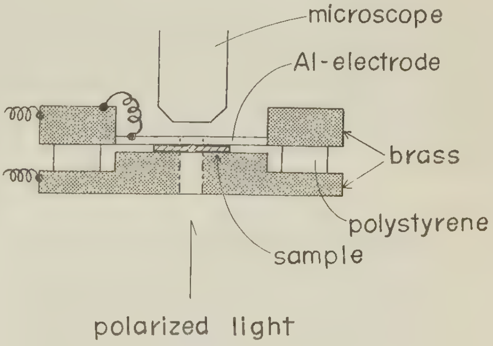

Fig. 1. Device for holding a sample under a microscope.

The schematic diagram in Fig. 2 shows the arrangement for the experimental observations. When Sw.1 moves from a to b, and then from b to c, and so on, the field applied to the crystal changes stepwise. The polarity of the field was controlled by Sw.2.

After a certain electric field had been attained, the domain structure was observed for a long time, taking photographs at successive intervals. Suppose a fraction f of the total volume of a crystal is saturated in one direction, then a fraction $(1-f)$ is saturated in the opposite direction. Then the net polarization P is expressed in terms of f and P_s:

$$P=fP_s-(1-f)P_s=(2f-1)P_s$$

where P_s denotes spontaneous polarization of the crystal. f or $(1-f)$ was obtained from the photograph, by cutting out the regions which point in one direction separating from those which point in the opposite direction, and by comparing the weight of those two by the use of a chemical balance.

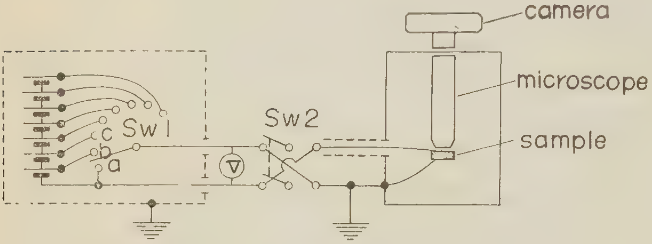

Fig. 2. Experimenatl arrangement for the observation of quasi-static domain motion.

For fields lower than 40 v/cm, no domain motion was observable. In Fig. 3 f was plotted as a function of electric field E, observations being made for a long time until no detectable change in the domain pattern was observed. From A to B or from C to D about 10 hours were taken. A group of photographs taken in the course from A to B are shown in plates (1)∼(6).

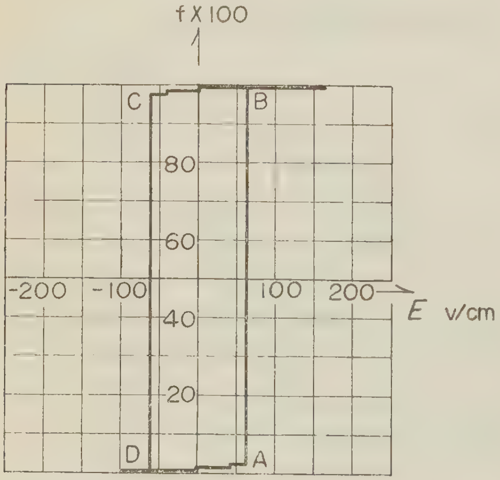

Fig. 3. Quasi-static f-E hysteresis loop for a 0.6 mm thick sample at 10°C.

It must be noted here that the quasi-static $f-E$ hysteresis loop is almost square. Coercive field seems to be somewhat different for different samples, being about 62.5 v/cm in Fig. 3. The actual critical value, however, will be lower than this value, because foil electrodes have holes, through which the domain structure is observed.

Figs. 5 contain hysteresis loops obtained at 50 cps by the usual Sawyer and Tower method, in the same scale of abscissa as $f-E$ hysteresis loops. There is no evidence that states of saturation attained in a.c. hysteresis loop actually correspond to states $f=0, 1$.

Comparing the quasi-static $f-E$ loop with the usual $P-E$ loop at 50 cps, differences prove to be remarkable. First, in the case of an electric field of 50 cps, a field lower than about 150 v/cm* gives almost linear $P-E$ curve, scarcely giving hysteresis loop as shown in Fig. 5(f), while electrostatic fields higher than about 60 v/cm give saturated hysteresis loop. Secondly, an a.c. field higher than about 150 v/cm* and lower than about 400 v/cm* gives hysteresis loop with shallow sloping sides and high coercivity, having the shape of parallelogram with rounded vertices, as shown in Fig. 5(e). Thirdly, a.c. fields higher than

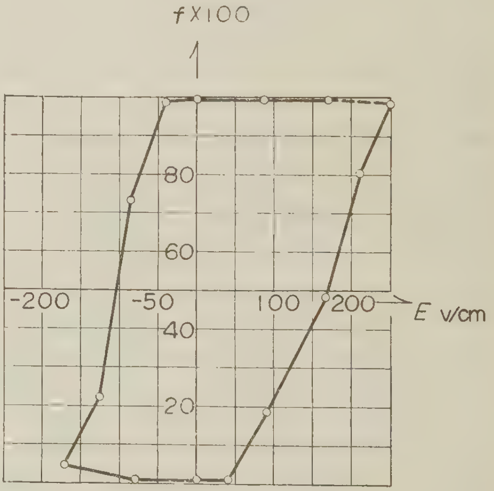

Fig. 4. f-E hysteresis loop for 0.6 mm thick sample at 10°C. One cycle was completed in 1h 27m.

---

* given by peak values.

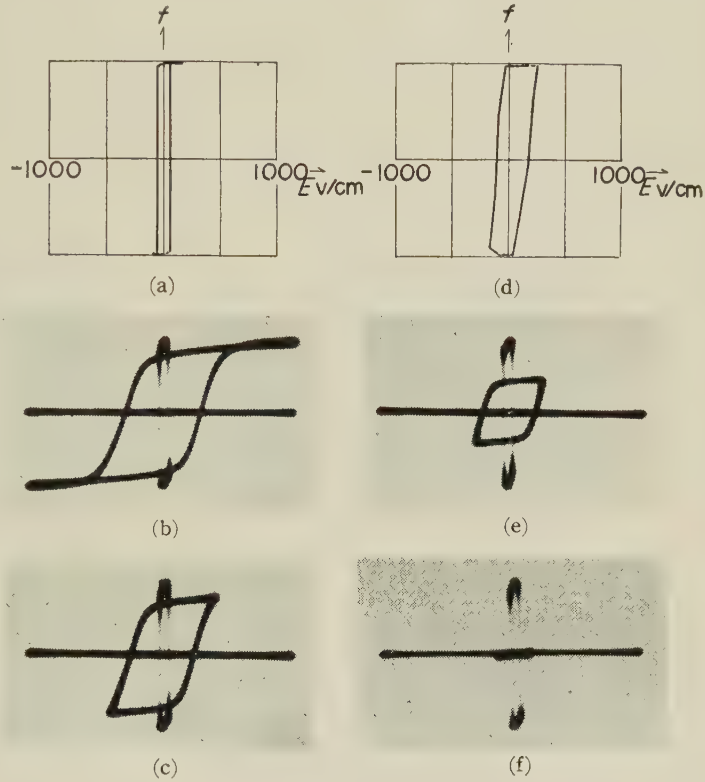
about 400 v/cm* give saturated hysteresis loops, and complete saturation is attained at about 1000 v/cm* as shown in Figs. 5(b) and (c), while static fields higher than about 60 v/cm cause the saturation. The saturated hysteresis loop obtained by a.c. field also has shallow sloping sides and much higher coercivity than the quasi-static $f-E$ hysteresis loop.

Fig. 4 shows similar hysteresis loop as Fig. 3, but one cycle was completed in 1 h 27 m. Coercive field is larger than Fig. 3, the curve has rather shallow sloping sides. This curve is essentially consistent with Marutake's results²⁾, except that there is a little difference in the shape of the loop in the part near zero field. This difference may be due to the hystory of samples, but remains not fully explained.

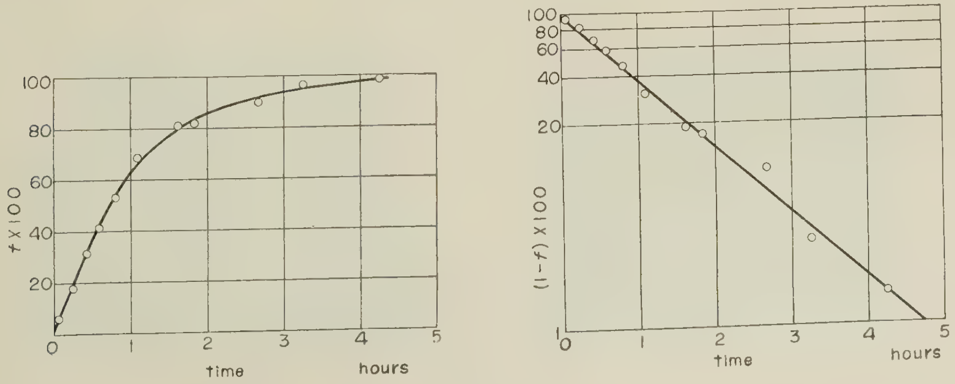
Plates (1)~(6) clearly reveal that the motion of domains is very slow when the critical field is applied. In Fig. 6(a) f is plotted as a function of time in the course from A to B in Fig. 3. Fig. 6(b), logarithmic representation of Fig. 6(a), shows that $f(t)$ is fairly expressed in the form:

$$f(t)=1-e^{-\alpha t}$$

where α denotes a constant which generally depends on the field applied to the crystal.



Figs. 5. P–E hysteresis loops obtained by Sawyer and Tower method at 50 cps, compared with f–E hysteresis loops, abscissa being presented in the same scale. At 10°C, the thickness of the sample 0.6 mm.
(a) Quasi-static f–E hysteresis loop, (b) 1200 v/cm a.c., (c) 440 v/cm a.c., (d) f–E hysteresis loop, one cycle completed in 1h27m, (e) 300 v/cm a.c., (f) 130 v/cm a.c. Voltage of 50 cps is given by the peak value.



(a) (b)

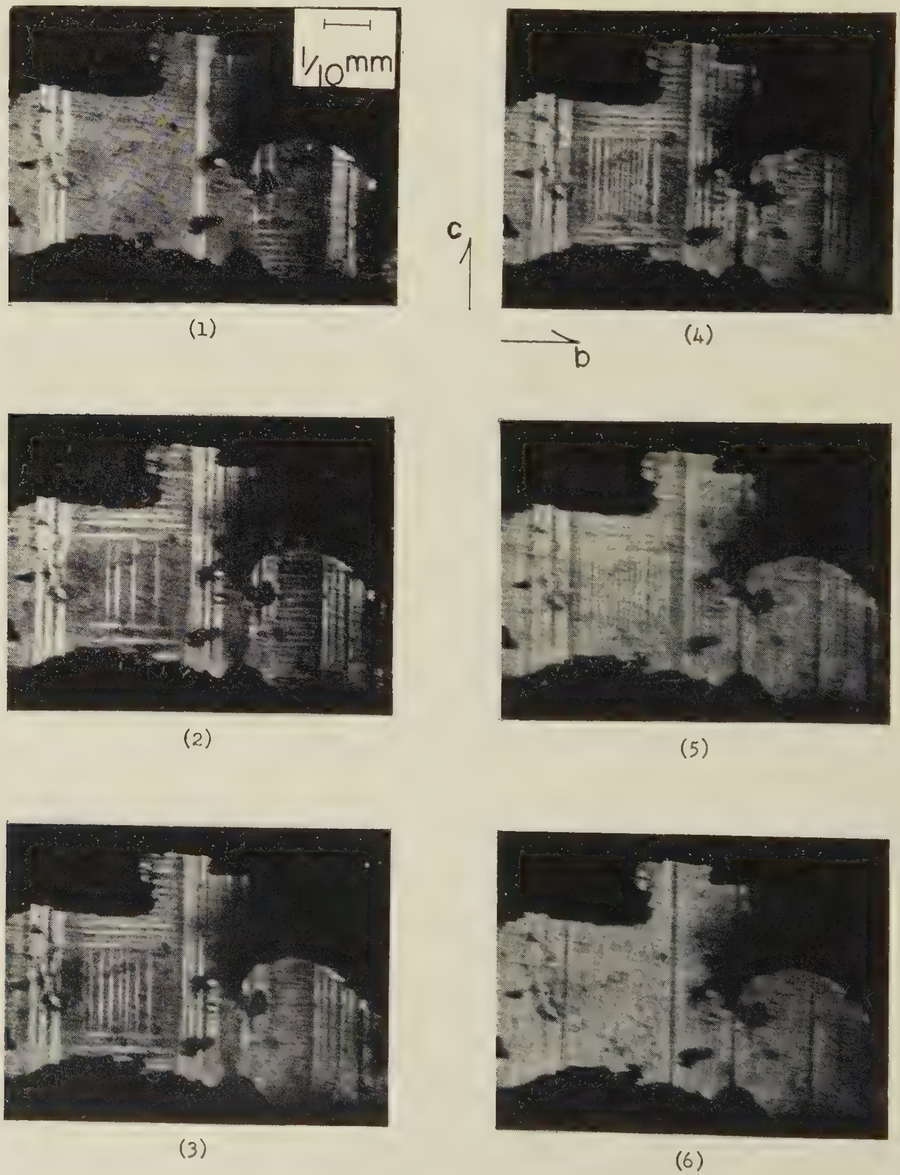
Figs. 6. Time dependence of f, from A to B in Fig. 3.
(a) f as a function of time.
(b) $\log(1-f)$ as a function of time.

From Fig. 6(b) time constant $1/\alpha$ is obtained to be approximately 62 min for the sample of thickness 0.6 mm, at 10°C.

§ 3. Discussions

If an external field, which saturated a ferroelectric specimen, is reduced and reversed, domains of reverse polarization are nucleated in several regions of specimen and the irreversible domain motions begin. E_{ni} will be defined as the critical field strength for domain creation for i-th nucleus. It will be defined as positive if it is oriented in the direction of the polarization within the new domain. The polarization of the rochelle salt crystal is reversed by the irreversible motion of 180° domain walls, as well as nucleation of the domains[2]. E_{wi} will be defined as the critical field strength for irreversible motion of the walls which enclose the i-th necleus domain of reverse polarization.

Our experiments showed that



(1) (4)
(2) (5)
(3) (6)

Plates (1)~(6)
Relaxation phenomenon of the domain motion, in the course from A to B in Fig. 3.
(1) 15 min (2) 35 min (3) 48 min (4) 1h5m (5) 1h50m
(6) 3h15m after applying the field.

for $E<E_0$, f is effectively zero,

for $E\geqq E_0$, $f(t)=1-e^{-\alpha(E)t}$,

where $1/\alpha=62$ min for $E_0=62.5$ v/cm, in the sample of thickness 0.6 mm, at 10°C, and that E_{ni} and E_{wi} will be:

$$E_{ni}\approx E_{wi}\approx E_0\,.$$

The existence of the critical field E_0 causes an almost square hysteresis loop as shown in Fig. 3.

This implies that the after effect is remarkable and time constant is of the order of one hour. It is clear that the large difference between $P-E$ hysteresis loops at 50 cps and the quasi-static $f-E$ loop is due to the marked after effect. Hence, after effect of the domain motion must be taken into account, in discussing about the shape of the hysteresis loops, coercive field, and the energy dissipation which corresponds to hysteresis loop.

It will be interesting to note here that the photographs shown in Plates (1)∼(6) clearly indicate a process of polarization reversal, within a square area that is bounded by *b*-axis domains and *c*-axis domains. A few nuclei, which were formed in the first place, cannot broaden beyond a certain domain width. Instead of the growth of the first domains, many new domains are created. This phenomenon may be understood in a following way. Displacement (v, w), which is given by the expression:

$$y_{zs}=\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}$$

must be continuous on the domain boundary, where y_{zs} denotes spontaneous strain[8]. If the first nuclei broaden more and more, this boundary condition becomes unsatisfied, and hence, new domains must be created at the expense of domain wall energy and elastic energy.

Our experiments showed that for the sample of thickness 0.6 mm fields lower than 40 v/cm do not give rise to any detectable domain motion, and that the domain motion due to the critical field is accompanied with a marked relaxation phenomenon. These two facts seem to indicate that for a small field of a few v/cm and of frequency higher than or of the order of 50 cps domain motion must not occur for crystals of the thickness 0.6 mm. In measuring initial permittivity, accordingly, the domain must not contribute to the change of polarization. This view is also supported by following considerations:

(1) The motion of wedge-shaped domains due to weak fields are not detectable[2].

(2) Suppose that a crystal of size a cm × b cm × c cm is composed of domains of width h cm as shown in Fig. 7, polarization change due to sidewise motion of domain walls will be:

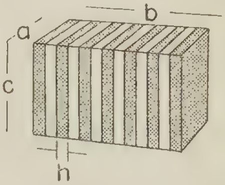


Fig. 7. A crystal composed of laminated domains perpendicular to *b*-axis.

$$\delta P=2P_s\delta x ac\left(\frac{b}{h}-1\right)\frac{1}{abc}\approx 2P_s\delta x\,\frac{1}{h}$$

where δx denotes average sidewise displacement of domain walls. If δx is proportional to field E, permittivity due to sidewise motion of the domain wall must be inversely proportional to h. It can be, therefore, said that the permittivity due to the sidewise motion of domain walls depends on h, hence on the domain structure of the crystals. Most careful measurements by Kawai[9] indicated that initial permittivity does not depend on the method of the preparation of the crystal, hence on h, or on the domain structure of the crystal.

(3) Measurements of dielectric after effect at low field by Marutake also gave a support of this view[7].

Thus it may be inferred that the initial permittivity appears to be independent of the domain motion, although the latter largely affects the shape of hysteresis loop.

Coercive field seems to be largely dependent upon the thickness of the specimen, i.e., the coercive field decreases with increasing thickness, but no detailed studies on this phenomenon were made.

The author's thanks are due to Prof. H. Takahasi for his helpful discussions, and also to Dr. M. Marutake for supplying samples of rochelle salt crystals. Progress of this study was facilitated by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

Study of Metallic Carbides by Electron Diffraction
Part I. Formation and Decomposition of Nickel Carbide

By Sigemaro NAGAKURA

Tokyo Institute of Technology, Oh-okayama, Meguro, Tokyo

(Received February 5, 1957)

Thin nickel films formed by evaporation were carburized in CO gas stream at temperatures from 250°C to 500°C and were studied by electron diffraction. Only Ni_3C was found to be formed. This has c.p.h. arrangement of nickel atoms with lattice constants $a_h=2.628$ Å and $c_h=4.306$ Å, but showed super-lattice reflections due to a hexagonal lattice of $a=\sqrt{3}a_h$ and $c=3c_h$, which is considered to be caused by a regular arrangement of carbon atoms.

The carbide was formed below 450°C in CO gas with slow rate and decomposed rapidly above 430°C in vacuum. The rate of the carbide formation was highest at about 350°C, although it depended very much on the texture of nickel films. Hydrogen atmosphere did not alter essentially the stability of the carbide.

It was found that nickel carbide is formed from metallic nickel with an epitaxial relation $(00.1)_{Ni_3C}//(111)_{Ni}$ and $[10.0]_{Ni_3C}//[10\bar{1}]_{Ni}$ (Ni_3C: c.p.h. indices) at the nucleation stage.

A mechanism of the lattice transformation from metallic nickel to the carbide was suggested. This mechanism explains the epitaxy and its destruction in the growth stage of the carbide crystal.

§ 1. Introduction

Carbides of transition elements, iron, cobalt and nickel are important substances in metallurgy and are considered to play an important rôle in Fischer-Tropsch synthesis. They are known to be interstitial compounds, but their structures have not yet been fully established. The present author has studied these carbides by the electron diffraction method and some results of metallurgical interest have already been published[1]. Fuller description will be reported in this series of papers, of which the first two papers (Part I and II) are concerned with nickel carbide.

The existence of nickel carbide was found by Bahr and Bahr[2]. They carburized fine nickel powder in CO gas at temperatures between 250° and 300°C and found a weight increase corresponding to formation of the carbide of a form of Ni_3C. Jacobson and Westgren[3] studied Ni_3C by the X-ray powder method and concluded that it has a hexagonal lattice having

$$a_h=2.649\text{ Å},\quad c_h=4.338\text{ Å}\quad\text{and}\quad c_h/a_h=1.636$$

with nickel atoms located at the close packed hexagonal positions (1/3, 2/3, 1/4) and (2/3, 1/3, 3/4) as shown in Fig. 1. Although positions of carbon atoms were difficult to be determined by the X-ray diffraction method, they proposed by a geometrical consideration that the carbon atoms should be distributed over the octahedral interstices (0, 0, 0) and (0, 0, 1/2).

The preparation of X-ray specimens requires very long time on account of slow rate of carbide formation. For example, Bahr and Bahr spent more than a hundred hours in carburizing fine nickel powder prepared by reducing nickel oxide with hydrogen. Jacobson and Westgren failed in producing the carbide by direct addition of carbon to molten nickel; they obtained it only from fine nickel powder carburized in CO gas for a week. On the other hand, since a very small amount of substance is sufficient to give rise to fairly strong electron diffraction patterns, carbide samples for electron diffraction studies can be more easily prepared by carburizing evaporated thin metal films. Even single-crystalline samples of carbides can be prepared by this method4). Furthermore, since the scattering power of carbon atom relative to that of nickel atom is more than twice larger for electrons than for X-rays, the electron diffraction is more favourable to study the structure of carbides than by the X-ray method.

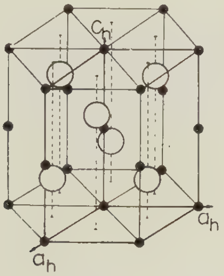

Fig. 1. The structure of Ni_3C. Large circles represent nickel atoms and small black circles represent octahedral interstices, possible positions for carbon atoms. (after Jacobson & Westgren)

In the present paper (Part I), the formation and the decomposition of the carbide Ni_3C and hydrogenation of carbidic carbon are described. Detailed structure analysis of the carbide, especially the determination of positions of carbon atoms will be reported in the next paper (Part II).

§ 2. Experimental Method

In the present experiment nickel carbide was produced by carburizing nickel films of thickness 200~300 Å in CO gas. The nickel films were prepared by evaporating commercial electrolytic nickel in vacuum. Hereafter, films without preferred orientation and films with single-crystalline orientation will be designated as 'P.C.' and 'S.C.' films, respectively. The former were prepared by evaporating nickel on cleavage faces of rock-salt kept at room temperature and the latter, on the faces kept at 450°~500°C. A transmission electron diffraction pattern of a P.C. film is reproduced in Photo. 1. The mean particle size of nickel in the film was estimated to be less than 50 Å from the half-breadth of Debye rings. Photo. 2 reproduces a diffraction pattern of a S.C. film taken with an incidence of electrons perpendicular to the film. It reveals that crystallites grow on the substrate with a preferred orientation $(001)_{Ni}//(001)_{NaCl}$ and $[100]_{Ni}//[100]_{NaCl}$.

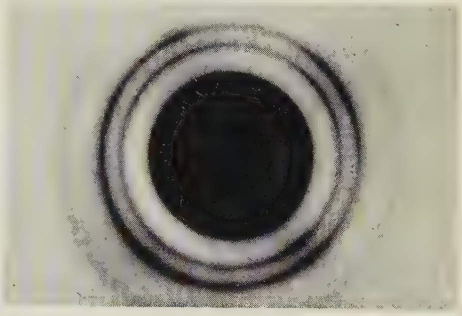

Photo. 1. Diffraction pattern of P.C. film of nickel evaporated on cleavage face of rock-salt kept at room temperature.

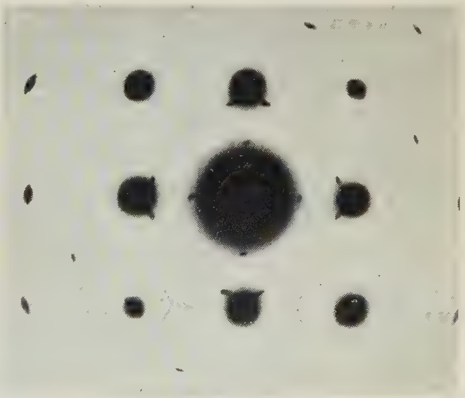

Photo. 2. Diffraction pattern of S.C. film of nickel evaporated on cleavage face of rock-salt kept at 450°C. Incident electrons are perpendicular to the film surface.

The apparatus used for cementation is shown in Fig. 2. CO_2 gas from the vessel A is reduced to CO through the converter furnace B which is filled with charcoal particles heated at 950°～1100°. CO gas, after purified through the stage C, is led to the reaction furnace D where nickel films are to be carburized. The purifying stage C consists of a series of cooled active carbon (-12°C), soda-lime and metallic sodium. The charcoal particles in the converter furnace were heated beforehand at 700°～800°C for 6～8 hrs. to eliminate impurities.

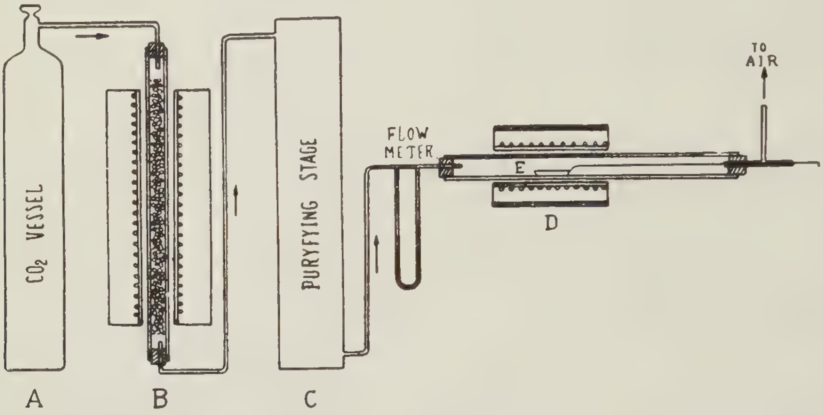

Fig. 2. Schematic diagram of apparatus used for cementation. A: CO_2 vessel, B: converter furnace (filled with charcoal particles) for producing CO gas, C: gas-purifying stage consisting of a series of cooled active carbon, soda-lime, calcium chloride and metallic sodium, D: reaction furnace, in which specimen films are carburized, E: porcelain boat, on which specimen films are put.

The procedure of cementation was as follows: Nickel films not detached from the substrates or transfered on nickel gauzes of about 150 meshes were put on the porcelain boat E and the boat was inserted into the quartz reaction tube kept at a desired temperature in a flow of CO gas. The heating temperature and the heating period were from 250° to 500°C and from 4 to 40 hrs., respectively. Rate of flow in the reaction tube was kept at about 100 cc per min.; the temperature fluctuation was kept within ±10°C. After the treatment, the boat was drawn out to a cold part and cooled down in the flow of CO gas as fast as possible by pouring water around the tube.

The study of thermal decomposition of nickel carbide in vacuum was carried out in two ways: (i) Carbide films were heated in a vacuum furnace for certain periods and examined by electron diffraction. (ii) The carbide films were heated in an electron diffraction camera and changes of the diffraction pattern were continuously observed. In both the methods the vacuum was of the order of 1×10^{-5} mmHg.

The study of decomposition of the nickel carbide due to hydrogen treatment was carried out with the same apparatus as used for the cementation (Fig. 2) by replacing CO gas with hydrogen gas. Hydrogen gas was produced by electrolysis of water and purified by red-heated copper and through the same purifying stage as used for the purification of CO gas.

An electron diffraction camera of the standard type of specimen-plate distance 250 mm having single focussing lens was used with an accelerating voltage 40 kV. Sometimes, however, a high resolution diffraction camera* with two focussing lenses and a specimen-plate distance 380 mm was also utilized with an accelerating voltage 50 kV. For high temperature examination, a high temperature specimen holder** attached to the high resolution camera was utilized. The temperature of specimen was measured by a thermo-couple placed as near as possible to the specimen film. In order to check possible differences between temperatures of the specimen film and the thermo-couple, the change of electron diffraction pattern due to melting was observed for evaporated tin films about 200 Å in thickness. It was found that the melting occurred when the thermo-couple indicated a temperature 220°C, which is 12°C lower than the known melting point of tin, 232°C. However, in view of Takagi's result⁶⁾ that the melting point of an evaporated thin metal film is always lower than that of bulk metal by an amount of this order, the accuracy of the thermo-couple indication may be a few degrees.

* Hillier type diffraction camera set in Miyake-Honjo Laboratory.

** Designed and constructed by G. Honjo and N. Kitamura. Its construction is a modification of the low temperature specimen holder reported by them[5].

§ 3. Formation of Nickel Carbide

1. Electron Diffraction Pattern of Ni_3C

In Photo. 3(a) and (b) electron diffraction patterns from P.C. films carburized at 350°C for 5 hrs. and 10 hrs. are reproduced. The latter is the pattern due to nickel carbide, while the former is composed of rings due to the carbide and residual nickel***. In Table I, observed spacings and visual intensities of the carbide rings are tabulated and compared with the X-ray data of Ni_3C given by Jacobson and Westgren.

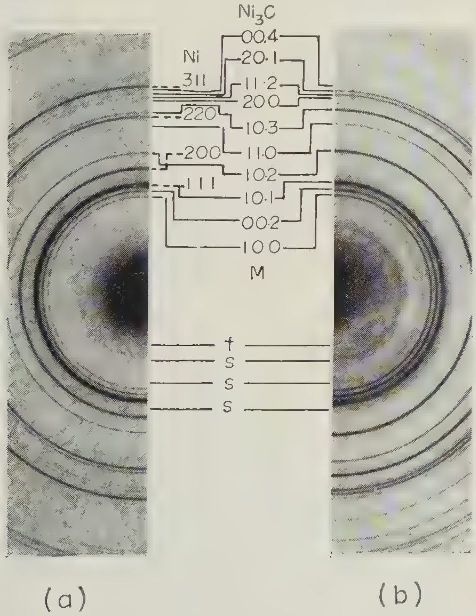

Photo. 3. Diffraction pattern of carburized P.C. films.
(a) Partly carburized at 350°C for 5 hrs.
(b) Completely carburized at 350°C for 10 hrs.
Indices of reflections are indicated. Classification of reflections such as *M*, *f* and *s*: see text.

The observed rings are classified into three groups '*M*' (main), '*f*' (forbidden) and '*s*' (super-lattice) reflections, as indicated in Photo. 3 and in Table I. The *M* reflections are strong and sharp, corresponding to a mean particle size 290 Å, and are well interpreted by the close packed hexagonal structure of Ni_3C proposed by Jacobson and Westgren. Their spacings correspond to the lattice constants (at 25°C)

$$a_h=2.628\ \text{Å},\quad c_h=4.306\ \text{Å}\quad \text{and}\ c_h/a_h=1.638,$$

which are smaller than Jacobson and Westgren's values only slightly (0.79% for a_h and 0.78% for c_h). The relative intensities of the rings agree in general with the X-ray data.

The "extra" rings *f* and *s*, which were not observed by Jacobson and Westgren, were found to coexist always with the *M* reflections in the electron diffraction patterns of the carburized nickel films. Moreover, the rings *M*, *f*, and *s* disappeared simultaneously when the carbide is decomposed (see Photo, 7). The *f* reflections are sharp but weak, and are indexed by the same unit cell for the *M* reflections, though they are forbidden reflections for the close packed hexagonal structure. The *s* reflections, which are weak and diffuse, can not be indexed by this unit cell. They, together with *M* and *f* reflections, can be indexed by the following hexagonal cell:

$$a=\sqrt{3}\,a_h=4.553\ \text{Å}\quad \text{and}\ c=3c_h=12.92\ \text{Å}\ .$$

The new hexagonal lattice is a super-lattice of the Jacobson and Westgren's as shown in Fig. 3. The indices of reflections corresponding to this unit cell and calculated spacings are tabulated in Table I. In Part II, where a detailed analysis of the observed intensity is given, it will be concluded that the above diffraction pattern is appropriate for Ni_3C having the crystal structure as depicted in Fig. 3. Here, large circles represent nickel atoms arranged in the close packed hexagonal positions and small circles represent carbon atoms located regularly in the positions of one-third of

---

*** Lattice constant of the residual nickel is 3.521 Å, which coincides very well with the known value of nickel $a_{Ni}=3.517$ Å.

the octahedral interstices of nickel atoms. The structure is in accordance with that of Jacobson and Westgren so far as the nickel positions are concerned. In what follows, therefore, Jacobson and Westgren's unit cell will be utilized for the sake of convenience.

In Photo. 4, a diffraction pattern from a S. C. film carburized for 20 hrs. at 350°C is reproduced. A schematic diagram of the pattern is illustrated in Fig. 4. Besides spots due to metallic nickel having the same arrangement as observed in Photo. 2, there appears an array of slightly arced and elongated spots which are situated with a definite geometrical relation with respect to the nickel spots. The former spots are due to Ni_3C. The pattern reveals that the nickel carbide Ni_3C is produced from nickel metal with the orientational relation

$$(00.1)_{Ni_3C}//(111)_{Ni} \quad \text{and} \quad [10.0]_{Ni_3C}//[10\bar{1}]_{Ni}\,.$$

This means that the closest packed atomic planes and atomic rows of the both crystals are parallel to each other.

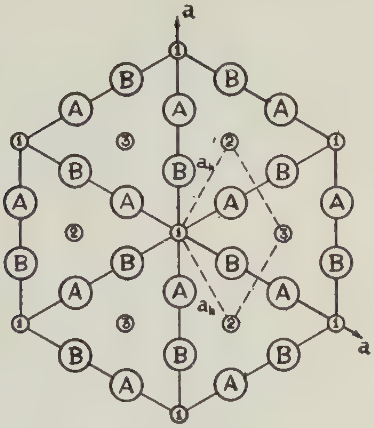

Fig. 3. Structure of Ni_3C. The figure shows projection of atomic arrangement on basal plane. Large circles represent nickel atoms (A and B) and small circles, carbon atoms (C_1, C_2, C_3). Unit cell is indicated by heavy lines and Jacobson and Westgren's unit cell, by dotted lines. Relation of lattice constants between the two lattice is $a=\sqrt{3}a_h$ and $c=3c_h$. Height of atoms: A(1/12, 5/12, 9/12); B(3/12, 7/12, 11/12); C_1(2/12, 8/12); C_2(4/12, 10/12); C_3(0/12, 6/12). A and B atoms form the close packed hexagonal arrangement and C atoms occupy one-third of the octahedral interstices regularly. The structure can be represented by the following stacking order $A(C_1)B(C_2)A(C_3)B(C_1)A(C_2)B(C_3)A\ldots$

It should be mentioned here that, in the whole course of the present study, Ni_3C is the only product formed by the cementation of nickel films, and the existence of any other carbide such as Ni_3C_x suggested by Bahr and Bahr was not recognized. It must be also added that the f reflections did not appear in the diffraction patterns when crystal size of Ni_3C was estimated to be smaller than about 100 Å. This seems to show the fact that f reflections are caused by multiple reflections of electrons, the effect which is considered to be remarkable when the crystal is large enough.

2. Progress of Carburization

The temperature range of carbide formation was determined by carburizing many P.C. films for 4～6 hrs. at various temperatures from 250°C to 500°C with an interval of 50°C. Below 450°C, the carbide was formed, though nickel rings of appreciable intensity always remain as already shown in Photo. 3(a). At 500°C, on the other hand, only amorphous

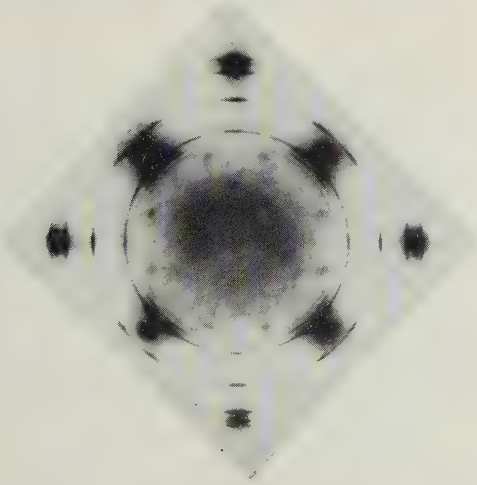

Photo. 4. Diffraction pattern of Ni_3C formed from S.C. film by the cementation at 350°C for 20 hrs. Note the epitaxial relation between Ni_3C reflections and nickel reflections. (cf. Fig. 4)

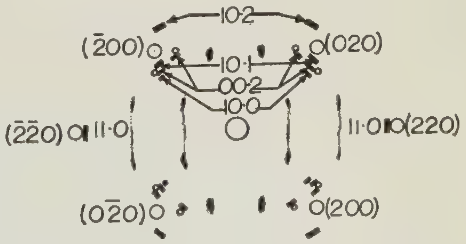

Fig. 4. Key diagram of Photo. 4. Large and small plain circles represent ($kh0$) main spots and (111) twin spots due to nickel, respectively. Short rods and elongated bars are M and s reflections due to Ni_3C, respectively. (Equivalent two orientations of Ni_3C relative to nickel are found in Photo. 4. But in this figure the spots due to one of them are shown.)

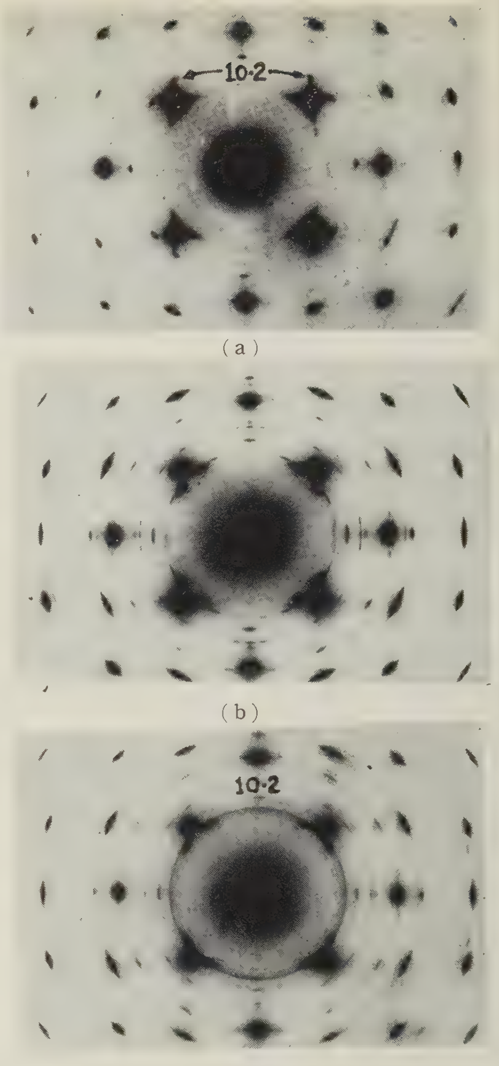
carbon was deposited on nickel films without the carbide formation. The electron diffraction patterns obtained in this case are similar to Photo. 7(d). From the intensities of the carbide rings, it was found that the maximum rate of the carbide formation is attained at about 350°C. Above 400°C and below 300°C, the rate was slower.

By prolonged treatments carried out at about 350°C for 10~20 hrs., some specimens were carburized completely and gave the diffraction patterns as already shown in Photo. 3(b). The completely carburized films, however, were not always obtained, though it was not so difficult to obtain partly carburized films: Of about 80 nickel films carburized for 20~40 hrs. at about 350°C, only 10 films gave diffraction patterns composed of the carbide rings alone, and patterns from the other films contained more or less nickel rings besides carbide rings. It is notable that the residual nickel does not grow up over 100 Å even after such prolonged heating. The degree of carburization was different from film to film, even when the films were treated under the same condition. It was observed that the carburization was delayed when the starting P.C. films were prepared on substrates kept at somewhat elevated temperatures ($\gtrsim$200°C), where they gave sharper diffraction rings corresponding to the particle size about 100 Å. However, any systematic difference could not be recognized between the films transfered on meshes and those not detached from the substrates.

The carburization was in general more difficult for S.C. films. For instance, while fairly strong carbide reflections were almost always obtained from P.C. films by 10 hrs. treatment, this was not always the case for the S.C. films.

Examination of degrees of carburization in the course of the cementation showed that a small amount of the carbide was formed initially but the carburization did not always proceed with a prolonged cementation.

The experiments on S.C. films revealed the following characteristic relation between the degree of orientation of the carbide crystals and the degree of carburization: In the initial stage of the carbide formation, the orientation is in general fairly good, but it is destroyed by further progress of the carburization. This can be seen from Photo. 5(a), (b) and (c), which are the diffraction patterns obtained



(a)

(b)

(c)

Photo. 5. Diffraction patterns of carburized S.C. films illustrating change of degree of orientation of Ni_3C with progress of carburization.

(a) Good orientation corresponding to the nucleation stage of the carbide crystal. Typical Ni_3C spots (10.2) are indicated by arrows. cf. Fig. 4. (carburized at 350°C for 10 hrs.)

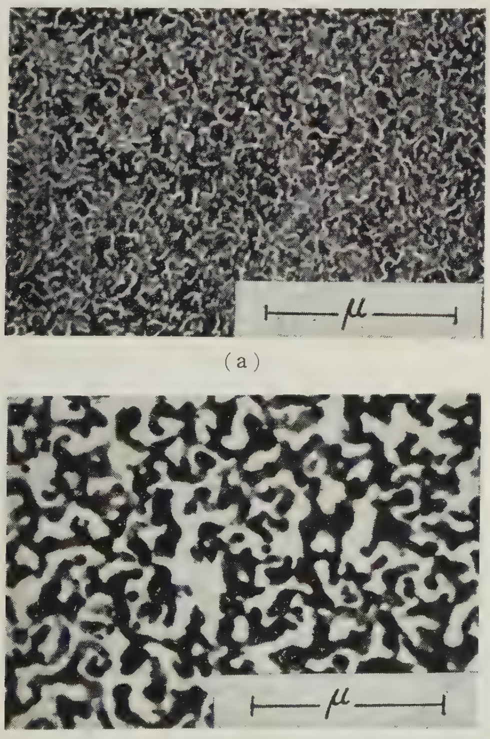
(b) Partly destroyed orientation corresponding to development of crystal growth. (carburized at 380°C for 14.5 hrs.)

(c) Completely* destroyed orientation corresponding to growth stage of the carbide crystal. (carburized at 350°C for 20 hrs.) *For example, $(10.2)_{Ni_3C}$ reflections have turned into a continuous ring. Note the fact that the degree of the orientation of nickel is not changed by the progress of the carburization.

from S.C. films subjected to the cementation for 10 hrs. at 350°C, for 14.5 hrs. at 380°C and for 20 hrs. at 350°C, respectively. In Photo. 5(a), the carbide spots, which are weak and diffuse corresponding to the nucleation stage, are manifesting a good orientation of crystallites. The crystal size estimated is about 50 Å. In Photo. 5(c), the carbide reflections appear in a form of sharp Debye rings. This shows that the particles have grown larger than 200 ~300 Å and, at the same time, that the orientation has been completely destroyed. Photo. 5(b) corresponds to an intermediate stage of the above two cases. In these patterns it is seen that the degrees of the orientation of metallic nickel are not appreciablly changed by the treatment.

3. Electron Microscopic Observation

Electron microscopic observations were performed on some of nickel and carburized films. Photo. 6(a) and (b) reproduce electron micrographs of a S.C. film and a partly carburized S.C. film at 350°C for 26 hrs., respectively. It can be seen that a considerable aggregation of crystallites takes place during the cementation. The formed carbide crystallites have no characteristic shape. This coincides with the fact that the diffraction patterns do not show any fine structure such as due to the effect of refraction and shape transform.



(a)

(b)

Photo. 6. Electron micrographs of (a) S.C. film prepared on cleavage face of rock-salt kept at 480°C and (b) S.C. film party carburized at 350°C for 26 hrs. Considerable aggregation of crystallites is observed to be caused by the prolonged treatment.

§ 4. Decomposition of Nickel Carbide

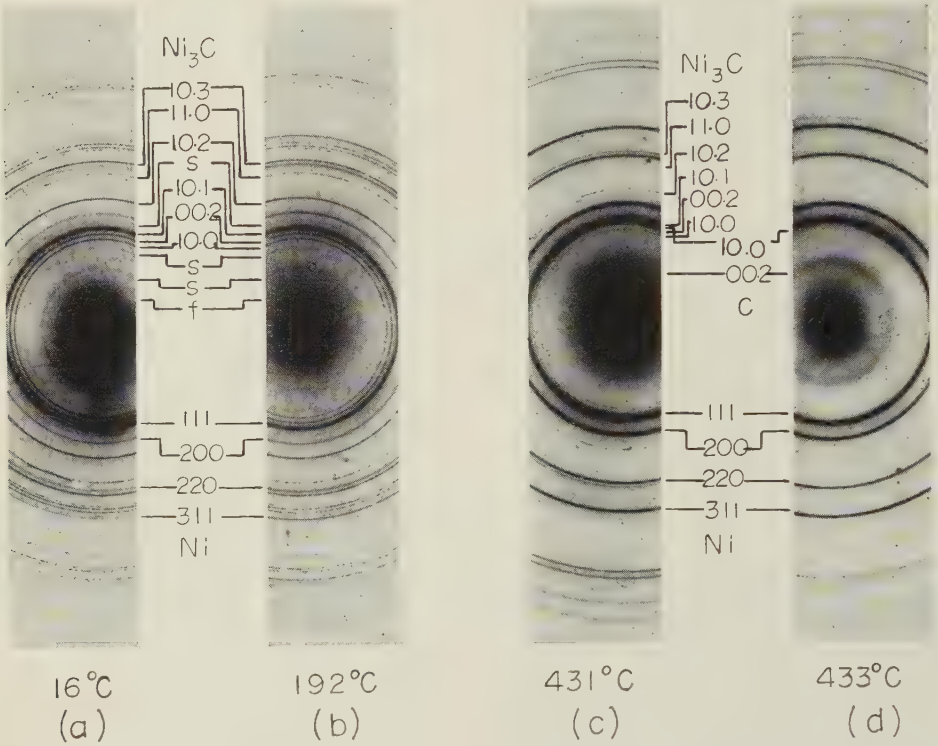
Bahr and Bahr reported that, when the carbide was heated in nitrogen at 380°~420°C, it decomposed to nickel and carbon, and that, when heated in hydrogen at 180°C, the carbidic carbon was completely hydrogenated to methane, leaving only metallic nickel.

In the present experiment, it was found that nickel carbide films kept in a desiccator over a year showed no appreciable change in electron diffraction pattern, indicating that the carbide is stable at room temperature. In order to investigate the stability of the carbide at elevated temperatures, the carbide films were heated in vacuum and in hydrogen stream.

1. Thermal Decomposition of the Carbide

When completely carburized P.C. films were kept at 300°C for 21 hrs., the diffraction pattern still consisted almost solely of the carbide rings, though a trace of nickel rings appeared. At 400°C, heating for 30 min. produced also no remarkable change but after 2~4 hrs. heating the carbide decomposed completely; the films gave patterns as shown in Photo. 7(d). At 500°C the decomposition occurred more rapidly than at 400°C.

Study of continuous change of the diffraction pattern of the carbide during heating was performed on partly carburized films having no preferred orientation using a high temperature electron diffraction camera. The rate of temperature rise was 2°~4°C per min.. Photo. 7(a)~(d) reproduce a series of photographic records. No difference is recognized between the patterns of Photo. 7(a) and (b) which were taken at 16°C and 192°C, respectively. Similar pattern persisted until 431°C, but at this temperature a considerable change took place. In Photo. 7(c) taken just after the change, the carbide rings weaken, while the nickel rings become stronger and diffuse carbon rings appear, showing that the decomposion of the carbide has been started. In Photo. 7(d) at 433°C, taken 2 min. after Photo. 7(c), any carbide rings are not found, showing that the decomposition has been completed. The disappearance of the carbide rings at this temperature proceeded very rapidly and completed within a few seconds.



16°C (a)

192°C (b)

431°C (c)

433°C (d)

Photo. 7. A series of diffraction patterns at various temperatures taken by the high temperature electron diffraction camera. Between the pattern (a) at 16°C and (b) at 192°C, no appreciable change is observed. The pattern (c) at 431°C shows that the thermal decomposition of Ni_3C has started and the pattern (d) at 433°C, that the decomposition has completed. Note the fact that the *f* and *s* reflections disappear simultaneously together with *M* reflections.

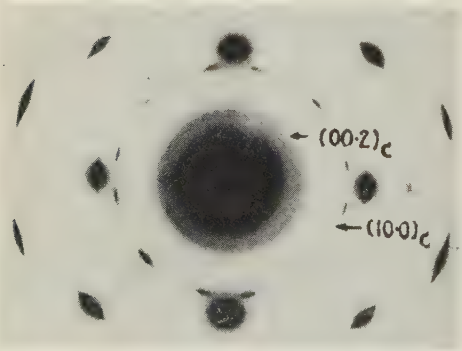


Photo. 8. Diffraction pattern after heating at 500°C for 10 min. of the carburized S.C. film of Photo. 4. Diffuse rings are due to amorphous carbon. Note the well-defined nickel spots showing the same disposition as Photo. 2.

From the half-breadth of the rings, it can be seen that the carbide particles of about 300 Å decompose to metallic nickel, particle size of which being less than 100 Å.

It was observed that films giving the patterns as reproduced in Photo. 4 changed by decomposition to films giving a pattern as reproduced in Photo. 8. This pattern is composed of diffuse rings due to amorphous carbon and regular array of the diffraction spots due to nickel, being arranged in the same disposition as in Photo. 2. From this observation it is seen that, when the carbide of single-crystalline orientation is decomposed, the produced metallic nickel restores its original orientation.

2. Hydrogen Treatment of the Carbide

Completely carburized films without preferred orientation were heated in hydrogen gas stream. At 300°C, after treatment for 18 hrs., the film produced weak nickel rings but their intensities did not change appreciably even after 26 hrs., showing that hydrogenation of the carbidic carbon takes place only very slowly at this temperature. At 400°C, for one specimen treated for 20 hrs., carbide rings were weakened and nickel rings became stronger without producing carbon rings. But for another specimen treated for 3 hrs., the carbide rings disappeared and nickel and diffuse carbon rings appeared. At 500°C, the films produced nickel and diffuse carbon rings after 3 hrs. treatment.

These results show that reaction of methane formation, $Ni_3C+2H_2=3Ni+CH_4$, may take place actually as reported by Bahr and Bahr, but its rate is very slow. The carbon deposition above 400°C indicates, however, that at higher temperatures the simple thermal decomposition predomiates over the hydrogenation of the carbidic carbon.

§ 5. Thermal Expansion of Nickel Carbide

From high temperature electron diffraction patterns at various temperatures such as reproduced in Photo. 7(a)∼(c), thermal expansion coefficients of nickel carbide were determined by taking reference to the lattice constant and the thermal expansion coefficient of metallic nickel as follows:

$$a_{\mathrm{Ni}}=3.5168\ \text{Å} \quad (\text{at } 25°\mathrm{C})$$

$$\alpha_{\mathrm{Ni}}=13.3\times10^{-6}/°\mathrm{C}\ .$$

The lattice constant of the carbide a_h was determined at various temperatures from (10.0), (20.0) and (11.0) rings and c_h, from (00.2) and (00.4) rings. The results are plotted in Fig. 5 against temperature t°C. They give the following relations for the thermal expansion of the carbide (using the least square method),

$$a_h=2.628(1+\alpha_\perp t)\ , \qquad \alpha_\perp=10\times10^{-6}/°\mathrm{C}\ ,$$

$$c_h=4.304(1+\alpha_\parallel t)\ , \qquad \alpha_\parallel=16\times10^{-6}/°\mathrm{C}$$

and

$$c_h/a_h=1.638\{1+(\alpha_\parallel-\alpha_\perp)t\}\ ,$$

$$\alpha_\parallel-\alpha_\perp=6\times10^{-6}/°\mathrm{C}\ .$$

This result shows a little anisotropy in the thermal expansion. Mean expansion coefficient $\bar{\alpha}$ was calculated from the above values using the relation

$$\bar{\alpha}=\overline{\alpha_\parallel\cos^2\theta}+\overline{\alpha_\perp\sin^2\theta}\ ,$$

where θ is the angle between c_h axis and the direction for which α is averaged. It gives

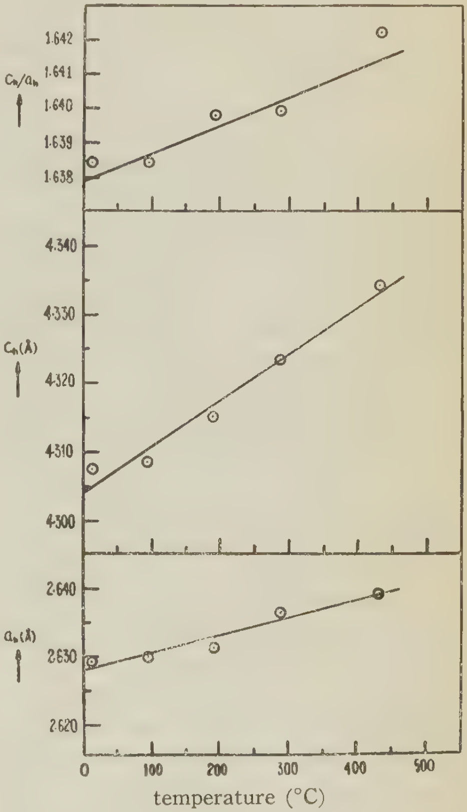

Fig. 5. Thermal change of lattice constants and axial ratio of Ni_3C.

$$\bar{\alpha}=12\times10^{-6}/°\mathrm{C}\ ,$$

which is sensibly close to α_{Ni}.

§ 6. Discussion

1. Formation and Decomposition of Nickel Carbide

The reaction of carbide formation

$$M+2CO=MC+CO_2$$

(M: metallic element, MC: its carbide) is considered to proceed by following processes: First, (1) CO molecules are adsorbed on the surface of specimen, and subsequently, (2) the molecules are decomposed and generate active carbon atoms, then (3) these carbon atoms diffuse into solid, and finally, (4) combine with metal atoms to form a carbide. The process

(4) is divided further into two processes: nucleation and growth.

As in the cases of many other solid reactions, the rate of carbide formation is considered to be determined mainly by the process (3). The diffusion process is accelerated by increasing temperature, so that the rate of the carbide formation increases with temperature rise. This may be the case below 350°C. At higher temperatures, however, the increasing rate of the diffusion is surmounted by increasing rate of the decomposition (§4.1), resulting in the maximum rate of the carbide formation at about 350°C (§3.2).

The diffusion process should be highly dependent on lattice imperfections such as vacancies, dislocations and grain boundaries. These imperfections may trap carbon atoms to form nuclei of the carbide crystals[7], and also may accelerate the diffusion of carbon atoms. In the films prepared on the substrates kept at elevated temperatures, the lattice imperfections must be much fewer than in the films prepared on the substrates kept at room temperature, since the former films are tempered by the heating during preparation[8]. Such a difference may be the main reason for the difference of the rate of carbide formation for P.C. and S.C. films (§3.2).

It was observed that the carbide was formed comparatively easily at the initial stage of the cementation but prolonged cementation did not always increase the amount of the carbide (§3.2). This may be partly due to the fact that the texture of the films is gradually improved during heating. Also the rate of diffusion of carbon atoms through the carbide crystal is considered to be slower than through nickel metal: The formation of the carbide layer on the surface prevents further progress of the carbide formation.

The thermal decomposition of the carbide and the hydrogenation of the carbidic carbon are considered to proceed as follows: The carbidic carbon atoms are driven out onto the crystal surface and, when the samples are heated in vacuum, the carbon atoms combine with one another on the surface to form amorphous carbon, while, when heated in hydrogen atmosphere, the atoms react with hydrogen on the surface to produce hydrocarbon such as methane which escapes out from the surface. So that the existence of hydrogen does not affect substantially the rate of the decomposition (§4.2).

2. Nucleation and Growth of Nickel Carbide

It was mentioned in §3.1 that the nuclei of carbide crystal are formed with a particular epitaxial relation to metallic nickel, $(111)_{\mathrm{Ni}}//(00.1)_{\mathrm{Ni_3C}}$ and $[10\bar{1}]_{\mathrm{Ni}}//[10.0]_{\mathrm{Ni_3C}}$, and in §4.1 that, when they decompose, produced metallic nickel restores the original orientation.

As well known, the face centred cubic lattice of metallic nickel is characterized by a stacking order ABCABC··· of the closest packed atomic planes, and the close packed hexagonal lattice of nickel atoms in $\mathrm{Ni_3C}$, by a stacking order ABAB···. Therefore, the nucleation of nickel carbide is considered to be a lattice transformation from the ABC··· stacking to the ABAB··· stacking and its decomposition is the reversed process.

Here, we suppose a lattice transformation by the following scheme:

$$\begin{array}{ccccccc}
\mathrm{A} & \to & \mathrm{C} & \to & \mathrm{B} & \to & \mathrm{A} \\
\mathrm{B} & \to & \mathrm{A} & \to & \mathrm{C} & \to & \mathrm{B} \\
\mathrm{C} & & \mathrm{C} & \to & \mathrm{B} & \to & \mathrm{A} \\
\mathrm{A} & & \mathrm{A} & \to & \mathrm{C} & \to & \mathrm{B} \\
\mathrm{B} & & \mathrm{B} & & \mathrm{B} & \to & \mathrm{A} \\
\mathrm{C} & & \mathrm{C} & & \mathrm{C} & \to & \mathrm{B} \\
\vdots & & \vdots & & \vdots & & \vdots
\end{array}$$

Namely, every two layer of nickel metal in the left hand side of the scheme slips by one step to produce the carbide lattice in the right hand side of the scheme. Each slip can be produced, as well known, by a half dislocation moving on the slip plane $\{111\}_{\mathrm{Ni}}$ or $\{00.1\}_{\mathrm{Ni_3C}}$ along the direction $\langle 112\rangle_{\mathrm{Ni}}$ or $\langle 21.0\rangle_{\mathrm{Ni_3C}}$. When the face centred cubic lattice and the close packed hexagonal lattice are transformed into each other by this mechanism, it is evident that they have the epitaxial relation as mentioned above. Therefore, it is very conceivable that the formation and the decomposition processes of nuclei of nickel carbide take place by the mechanism proposed above. The interplaner and interatomic distances of the closest packed atomic planes and atomic rows, which are kept parallel in the transformation, are tabulated in Table II. The fact that these values are very close, also favours the proposed mechanism.

Table II. Interatomic and interplaner distances of metallic nickel and nickel carbide.

	Ni	Ni_3C	Vernier period
Interatomic distance along the most densly packed atomic row (Å)	⟨110⟩ 2.488 $(=a_{Ni}/\sqrt{2})$	⟨10.0⟩ 2.628 $(=a_h)$	19 $(=a_h/(a_h-a_{Ni}/\sqrt{2}))$
Interplaner distance between the most densly packed atomic planes (Å)	{111} 2.030 $(=a_{Ni}/\sqrt{3})$	{00.1} 2.152 $(=c_h/2)$	18 $(=(c_h/2)/(c_h/2-a_{Ni}/\sqrt{3}))$

The mechanism of transformation by a series of microscopic slips is quite similar to that of martensitic transformation of cobalt from the face centred cubic to the close packed hexagonal structure[9]. In this case driving force is supplied by internal stress due to cooling. In the transformation of the carbide nucleation the driving force is considered to be supplied by internal stress produced by diffusing-in carbon atoms.

Differing from the case of cobalt metal, however, there exists a definite, though small, misfitness between the carbide and the nickel lattice. The vernier period[10] between them are tabulated in Table II. It means that 19 nickel atoms on the closest packed plane of the carbide crystal must face to 20 atoms on that of the nickel crystal and 18 layers of the closest packed plane of the carbide must join to 19 layers of the nickel. This relation is illustrated in Fig. 6, where atomic arrangement of nickel atoms (plain circles) on $(1\bar{1}0)_{Ni}$ plane of the matrix (left-lower region) and that on $(1\bar{2}.0)_{Ni_3C}$ plane of the epitaxially formed carbide crystal (right-upper region) are shown. Thus, on the boundary face between the two crystals there must exist one dislocation per one vernier period.

When the carbide crystal grows up, such dislocations are accumulated on the interface of the two crystals. They have the same sign and arranged on the same slip plane, so that they repel one another. As a result, the destruction of the epitaxial relation may take place as observed in the growth stage of the carbide crystal (§ 3.2). In fact the destruction of epitaxy was observed to occur when the crystal size of the carbide becomes larger than about 100 Å, which is a few multiples of the vernier period mentioned above.

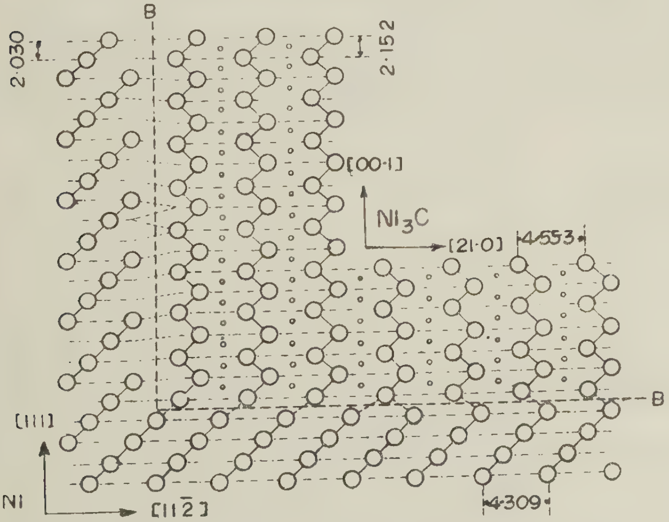

Fig. 6. Atomic arrangement of Ni_3C crystal (right-upper region) formed from nickel crystal (left-lower region). This figure shows the atomic arrangement on $(1\bar{2}.0)_{Ni_3C}$ and $(1\bar{1}0)_{Ni}$ planes, where large circles represent nickel atoms and small circles represent possible positions for carbon atoms. Interface of the two crystals are indicated by broken line *BB*, the nearest neighbour atoms are linked by full lines and the closest packed atomic planes are represented by chain lines. Dislocations are produced at the crystal boundary.

It has been reported many observations on the epitaxial growth of metallic films deposited on single crystal surfaces[11]. In these cases, the epitaxy is well preserved upto a crystal size of several hundred Ångströms even when the misfitness between the depositing crystals and the substrate crystals is much larger than the present case. In fact, the orientation of S.C. film of Photo. 2 was preserved in its own growth upto, at least, 400 Å, in spite of the very small vernier period of about 5. In the case of surface deposition, nuclei of deposited crystals, whose orientation is determined by the substrate, can grow up by themselves in free space incoherently with the substrates[12]. The nickel carbide, however, must grow up, not in free space but in the matrix of nickel, so that its growth produces necessarily dislocations at the interface. This results in the destruction of epitaxy when the carbide grows up more than a few multiple of the vernier period.

In the carburized P.C. films the carbide crystal grows upto about 300 Å in spite of the fact that residual nickel does not grow upto more than 100 Å. Therefore, in the process of the carbide formation, a considerable recrystallization must take place. On the contrary, in the decomposition process, such a large carbide crystal decomposed into several smaller crystals of metallic nickel (~100 Å) and no recrystallization of them was observed.

Studies on the Radial Distribution Analysis in Diffraction Methods

I. Errors due to the Approximation of Integration by Summation*

By Tadashi INO

The Institute of Polytechnics, Osaka City University, Osaka

(Received February 8, 1957)

In the calculation of a radial distribution function

$$rD(r)=(1/2\pi^2)\int_0^\infty sI(s)\sin sr\,ds$$

we usually approximate the integral by such a sum as

$$rD_\Sigma(r)=(\Delta s/2\pi^2)\sum_{n=1}^\infty n\Delta s\cdot I(n\Delta s)\cdot\sin(n\Delta sr)\,.$$

In this paper the mathematical property of $rD_\Sigma(r)$ is derived and the error due to the approximation is proved to be expressed as

$$rD_\Sigma(r)-rD(r)=\sum_{\substack{m=-1\\ \neq 0}}^{\infty}{}'\,(r+2m\pi/\Delta s)D(r+2m\pi/\Delta s)\,.$$

Furthermore, the formula for the estimation of the error is derived. It turned out that in order to obtain a high accuracy from the approximation we must make the spacing Δs less than π/R_0, where R_0 is the distance beyond which $rD(r)$ is regarded practically zero.

§ 1. Introduction

In order to analyze the diffraction data of gaseous, liquid, and amorphous substances we generally use two methods; the "*correlation*" and the "*radial distribution*" methods. The former is an empirical "*trial* and *error*" method, consisting in the theoretical calculations of scattering intensities for various models and the comparison of these values with the observed data. The latter consists in Fourier inversion of diffraction data which requires essentially the accurate intensity data and laborious numerical calculations, while it can offer the structural information straightforward. Recent advances in the experimental techniques of diffraction method and the availability of punched card methods[1] for the calculation have made it more practicable to carry out this method and made the results obtained more reliable and accurate. In this series of papers, problems concerning the radial distribution analysis will be discussed.

The intensity function $I(s)$ sensitive to the structure of the substance is connected with the radial distribution function $D(r)$[2] by the following relation,

$$sI(s)=4\pi\int_0^\infty rD(r)\sin sr dr \qquad (1)$$

where $s=(4\pi/\lambda)\sin\theta/2$, θ=scattering angle, and λ=wave length. The Fourier transform of eq. (1) becomes

$$rD(r)=(1/2\pi^2)\int_0^\infty sI(s)\sin srds \qquad (2)$$

In numerical calculation of eq. (2) we usually approximate the integral by the sum over evenly spaced s values as follows.

$$rD_\Sigma(r)=(\Delta s/2\pi^2)\sum_{n=1}^\infty n\Delta s\cdot I(n\Delta s)\cdot\sin(n\Delta sr)$$

The aim of the present paper is to make clear the nature of the error introduced by this approximation.

§ 2. Derivation of Formula

In practice, $I(s)$ cannot be obtained in the whole range of s, but is limited in a certain range of $0\leqslant s\leqslant s_{\max}$ and we are forced to treat the integrals of the type

$$(1/2\pi^2)\int_0^{s_{\max}} sI(s)\sin srds \qquad (3)$$

or

$$(1/2\pi^2)\int_0^{s_{\max}} sI(s)\exp(-a^2s^2)\sin srds\,, \qquad (4)$$

instead of the integral (2). To treat the errors introduced in the calculations of these integrals by approximation generally, we introduce a modification function $M(s)$*, a modified intensity function $\boldsymbol{I}(s)$, a modified radial distribution function $\boldsymbol{D}(r)$, and its approximation function $\boldsymbol{D}_{\Sigma}(r)$ given by following eqs.

---

* Read at the Meeting of Physical Society of Japan, Tokyo, April, 1955.

$$\boldsymbol{I}(s)=M(s)I(s) \tag{5}$$

$$r\boldsymbol{D}(r)=(1/2\pi^2)\int_0^{\infty} s\boldsymbol{I}(s)\sin srds \tag{6}$$

$$r\boldsymbol{D}_{\Sigma}(r)=(\Delta s/2\pi^2)\sum_{n=1}^{\infty} n\Delta s\cdot\boldsymbol{I}(n\Delta s)\cdot\sin(n\Delta s\cdot r) \tag{7}$$

With the use of the property of odd function of $r\boldsymbol{D}(r)$ and the Fourier inversion of eq. (6) as

$$s\boldsymbol{I}(s)=4\pi\int_0^{\infty} t\boldsymbol{D}(t)\sin stdt$$

eq. (7) can be transformed:

$$\begin{aligned} r\boldsymbol{D}_{\Sigma}(r)&=(\Delta s/\pi)\lim_{N\to\infty}\int_{-\infty}^{\infty} t\boldsymbol{D}(t)\sum_{n=1}^{N}\cos\{n\Delta s(t-r)\}dt \\ &=(\Delta s/\pi)\lim_{N\to\infty}\int_{-\infty}^{\infty} t\boldsymbol{D}(t)\frac{\sin\{(2N+1)\Delta s(t-r)/2\}}{2\sin\{\Delta s(t-r)/2\}}dt \end{aligned}$$

Since the sine part of the integrand has a period of $2\pi/\Delta s$, the integral can be conveniently transformed into an infinite series:

$$r\boldsymbol{D}_{\Sigma}(r)=(1/\pi)\lim_{M\to\infty}\sum_{m=-\infty}^{\infty}\int_{-\pi/2}^{\pi/2}\left(r+\frac{2m\pi}{\Delta s}+\frac{2x}{\Delta s}\right)\boldsymbol{D}\left(r+\frac{2m\pi}{\Delta s}+\frac{2x}{\Delta s}\right)\frac{\sin Mx}{\sin x}dx$$

where

$$t=r+\frac{2m\pi}{\Delta s}+\frac{2x}{\Delta s} \quad \text{and} \quad M=2N+1\,.$$

Suppose

$$\sum_{m=-\infty}^{\infty}\left(t+\frac{2m\pi}{\Delta s}\right)\boldsymbol{D}\left(t+\frac{2m\pi}{\Delta s}\right)$$

converges, a further transformation can be carried out by the theorem of Dirichlet's integral:

$$r\boldsymbol{D}_{\Sigma}(r)=\sum_{m=-\infty}^{\infty}(r+2m\pi/\Delta s)\boldsymbol{D}(r+2m\pi/\Delta s) \tag{8}$$

or

$$r\boldsymbol{D}_{\Sigma}(r)-r\boldsymbol{D}(r)=\sum_{\substack{m=-\infty\\ \neq 0}}^{\infty}{}'(r+2m\pi/\Delta s)\boldsymbol{D}(r+2m\pi/\Delta s)\,. \tag{9}$$

§ 3. Properties of the Approximation Function

a) According to eq. (7) or eq. (8) it is evident that $r\boldsymbol{D}_{\Sigma}(r)$ is periodic with a period $2\pi/\Delta s$ and is zero at the points

$$r=m\pi/\Delta s\,, \qquad m\text{: integer}\,.$$

Since eq. (7) is a sine series, it is antisymmetric about the zero points as illustrated in Fig. 1.

b) According to eq. (9) the error due to this approximation is expressed by:

$$\sum_{\substack{m=-\infty\\ \neq 0}}^{\infty}{}'(r+2m\pi/\Delta s)\boldsymbol{D}(r+2m\pi/\Delta s)\,.$$

Consequently if $r\boldsymbol{D}(r)$ is zero outside the range $(-\pi/\Delta s, \pi/\Delta s)$, all the values of $(r+2m\pi/\Delta s)\times\boldsymbol{D}(r+2m\pi/\Delta s)$ $(m\neq 0)$ are zero inside the range $(-\pi/\Delta s, \pi/\Delta s)$. Therefore $r\boldsymbol{D}_{\Sigma}(r)$ is identical with $r\boldsymbol{D}(r)$ inside the same range. On the contrary, if $r\boldsymbol{D}(r)$ is different from zero somewhere outside the range $(-\pi/\Delta s, \pi/\Delta s)$, it is not the case. These features are shown in Fig. 2 and Fig. 3 respectively. In Fig. 3 the value of $r\boldsymbol{D}_{\Sigma}(r)$ at a position, say Q_0, is quite different from the value of $r\boldsymbol{D}(r)$ at the same position Q_0, since the value of $r\boldsymbol{D}(r)$ is not zero at such positions as $Q_1, Q_{-1}, \cdots$ separated mutually by a distance $2\pi/\Delta s$. But in Fig. 2 the value of $r\boldsymbol{D}(r)$ is zero at those position, hence $r\boldsymbol{D}_{\Sigma}(r)$ is equal to $r\boldsymbol{D}(r)$.

$$\begin{aligned} M(s)&=1 && 0\leqslant s\leqslant s_{\max} \\ &=0 && s_{\max}<s \end{aligned}$$

In the case of (4):

$$\begin{aligned} M(s)&=\exp(-a^2s^2) && 0\leqslant s\leqslant s_{\max} \\ &=0 && s_{\max}<s \end{aligned}$$

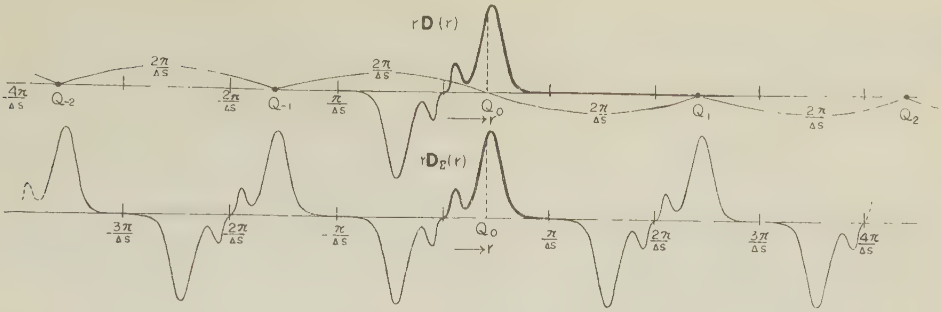

Fig. 2. non-zero range of $rD(r) \leq \pi/\Delta s$

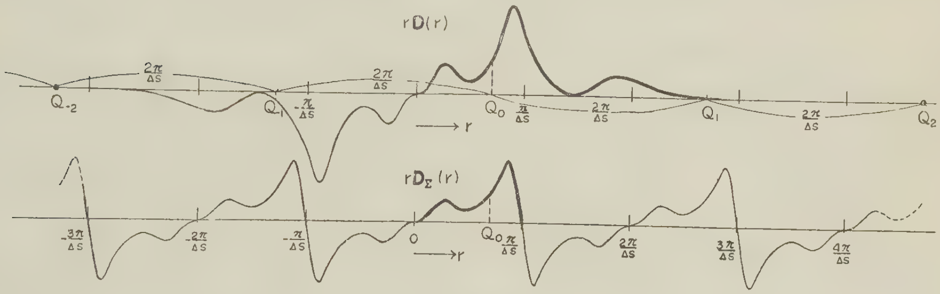

Fig. 3. none-zero range of $rD(r) > \pi/\Delta s$

§ 4. Estimation of Error

Since the approximation is considered as a modified trapezoidal law of numerical, integration, the error can be estimated by usual way as follows:

$$2\pi^2 r(D_\Sigma(r)-D(r))$$
$$=(\Delta s/2)(sI(s))_{s_{\max}} \sin(s_{\max} r)$$
$$+(s_{\max}/12)\Delta s^2 (sI(s)\sin sr)''_{s=\sigma}$$

or

$$2\pi^2 r(D_\Sigma(r)-D(r)) \sim (\Delta s/2)(sI(s))_{s_{\max}} \sin(s_{\max} r)$$
$$+(\Delta s^2/12)\{(sI(s)\sin sr)'_{s_{\max}}-(sI(s)\sin sr)'_0\}$$
$$-(\Delta s^4/720)\{(sI(s)\sin sr)'''_{s_{\max}}-(sI(s)\sin sr)'''_0\}$$
$$\cdots\cdots\cdots\cdots$$

where σ is a certain value in the range $(0, s_{\max})$.

However, eq. (8) being applied, a more convenient formula will be obtained. Since

$$2\pi^2 \rho D(\rho)=\int_0^{s_{\max}} sI(s)\sin s\rho\, ds$$

and $sI(s)$ is an odd function, then an asymptotic formula can be derived by repeated partial integration:

$$2\pi^2 \rho D(\rho) \sim -(sI(s))_{s_{\max}} \frac{\cos s_{\max}\rho}{\rho}$$
$$+(sI(s))'_{s_{\max}} \frac{\sin s_{\max}\rho}{\rho^2}$$
$$+(sI(s))''_{s_{\max}} \frac{\cos s_{\max}\rho}{\rho^3}$$
$$-(sI(s))'''_{s_{\max}} \frac{\sin s_{\max}\rho}{\rho^4}$$
$$\cdots\cdots\cdots \qquad (10)$$

Eq. (10) can be used successfully for the estimation of $\left(r+\frac{2m\pi}{\Delta s}\right)D\left(r+\frac{2m\pi}{\Delta s}\right)$ $(m \neq 0)$, if $L=2\pi/\Delta s$ is sufficiently large and $|r| \leqslant L/2$. Then according to eq. (9), the error can be expressed:

$$2\pi^2 r(D_\Sigma(r)-D(r)) \sim$$
$$-(sI(s))_{s_{\max}} \cos s_{\max} r \sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (r+mL)^{-1}$$
$$+(sI(s))'_{s_{\max}} \sin s_{\max} r \sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (r+mL)^{-2}$$
$$+(sI(s))''_{s_{\max}} \cos s_{\max} r \sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (r+mL)^{-3}$$
$$-(sI(s))'''_{s_{\max}} \sin s_{\max} r \sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (r+mL)^{-4}$$
$$\cdots\cdots\cdots \qquad |r| \leq L/2$$

With the help of the following relations;

$$e_1(z)=\sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (z+m\pi)^{-1}=\cot z-1/z$$

$$
\begin{aligned}
e_{n+1}(z) &= \sum_{\substack{m=-\infty \\ \neq 0}}^{\infty}{}' (z+m\pi)^{-(n+1)} \\
&= \frac{(-1)^n}{n!} \frac{d^n}{dz^n} (\cot z - 1/z) ,
\end{aligned}
$$

the error can be transformed:

$$
\begin{aligned}
& 2\pi^2 r (D_\Sigma(r) - D(r)) \sim \\
& \quad -(sI(s))_{s_{\max}} (\Delta s/2) e_1(\Delta sr/2) \cos s_{\max} r \\
& \quad +(sI(s))'_{s_{\max}} (\Delta s/2)^2 e_2(\Delta sr/2) \sin s_{\max} r \\
& \quad +(sI(s))''_{s_{\max}} (\Delta s/2)^3 e_3(\Delta sr/2) \cos s_{\max} r \\
& \quad -(sI(s))'''_{s_{\max}} (\Delta s/2)^4 e_4(\Delta sr/2) \sin s_{\max} r \\
& \quad \cdots\cdots\cdots \qquad |r| \leqslant \pi/\Delta s \qquad (11)
\end{aligned}
$$

Hence the error can be estimated by a small number of terms in eq. (11), provided that Δs is sufficiently small. These terms are determined by the magnitude of Δs and values of $sI(s)$ and its derivatives simply *at* $s=s_{\max}$. This is characteristic of eq. (11), because the other equations mentioned before contain the additional terms determined by the derivatives of $sI(s)$ *at* $s=0$ or $s=\sigma$.

Since $z \cot z = 1 - \sum_{n=1}^{\infty} 2^{2n} B_n z^{2n}/(2n)!$ where $\pi > |z|$ (B_n: Bernoullian number), $e_n(z)$ is a monotonic functions of z in the same range and the first four functions are illustrated in Fig. 4. Therefore, the error is approximately expressed as a ripple consisting of $\sin s_{\max} r$ and $\cos s_{\max} r$ terms.

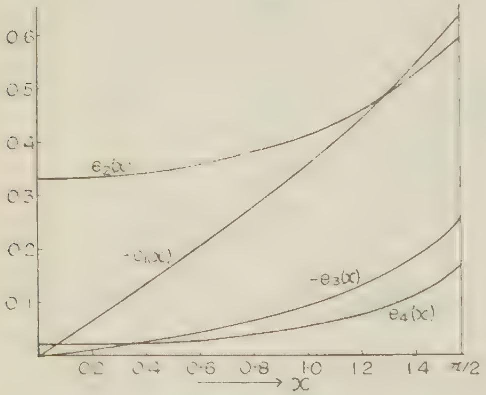

Fig. 4.

§ 5. Discussion

According to the mathematical properties of $rD_\Sigma(r)$, we can deduce facts to be noted in practical calculation of radial distribution function.

As mentioned before, the function obtained by this approximation has a periodicity which is not dependent upon the structure but only upon the magnitude of Δs. Then the functional behaviour outside the range $(-\pi/\Delta s, \pi/\Delta s)$ is simply the repetition of that in side the range $(-\pi/\Delta s, \pi/\Delta s)$. Therefore the function by no means gives the information of the structure outside the range $(-\pi/\Delta s, \pi/\Delta s)$. Consequently if we desire to obtain the information as far as $r=R'$ the spacing Δs must be taken as follows,

$$\Delta s < \pi/R' .$$

This condition however is not always a sufficient but a necessary one, as discussed in the following.

The error due to the approximation can be estimated according to eq. (11) if the values of the derivatives of $sI(s)$ at $s=s_{\max}$ can be determined. But according to eq. (8) one can derive a rule concerning the accuracy of the approximation: when $rD(r)$ may be regarded practically zero beyond R_0 (which may be called the *non-zero range*), a high accuracy can be expected from the computation where such a spacing given by

$$\Delta s \leq \pi/R_0$$

is used.

Since the integral given by (3) has extraneous ripples due to the termination effect[3], its non-zero range R_0 is much larger than that of $rD(r)$. Therefore the error is large, unless Δs is taken very small. On the other hand the convergence factor, for example, $\exp(-a^2s^2)$ improves the accuracy of the evaluation of radial distribution function, since it attenuates the amplitudes of the extraneous ripples and generally the coefficients of terms in eq. (11). Consequently the error due to the approximation of (4) is smaller than that of (3) if the same spacing is taken. In the radial distribution method the integral (4) is more advantageous than the integral (3) from the viewpoint of the accuracy of the approximation.

Since the integral given by (4) can be expressed as the convolution[4] of $rD(r)$ and $\exp(-r^2/4a^2)$, the non-zero range of the $rD(r)$ may be nearly equal to that of $rD(r)$. Therefore the suitable spacing Δs for a satisfactory approximation can be determined, when the non-zero range of $rD(r)$ can be estimated. From this discussion one can easily infer the following empirical rule to be reasonable:

taking a spacing $\Delta s=\pi/10$ and using the factor $\exp(-a^2s^2)$ (with 'a^2' chosen so that $\exp(-a^2s^2_{\max})=0.1$), one can obtain fully satisfactory results even for $r=7A$ in the electron diffraction study of gas1). Morito and Kuchitsu5) showed that the spacing $\Delta s=\pi/10$ gives sufficiently accurate result as well as the spacing $\Delta s=\pi/50$ in the electron diffraction study of acethyl chloride. This fact is in agreement with our result.

In the cases of liquid and amorphous substances the non-zero range of $rD(r)$ is as large as the size of the specimen. Hence the suitable spacing Δs for a satisfactory approximation must be taken very small and the calculation is too laborious to perform. On the other hand $r(D(r)-D_0)$ has a much smaller non-zero range than $rD(r)$ where D_0 is the volume average of $D(r)$6). Hence from the standpoint of the accuracy of the evaluation it is highly necessary that we should treat the intensity corresponding to $r(D(r)-D_0)$ instead of $rD(r)$ in these cases*. This requirement is satisfied by the usual procedure in the radial distribution analysis of liquid and amorphous substances6).

R. E. Franklin7) discussed briefly the problem on the spacing of summation in the study of the diffuse X-ray diagrams of carbon. Her result is also consistent with our conclusion.

§ 6. Acknowledgement

The author wishes to express his sincere thanks to Prof. J. Kakinoki and Mr. K. Katada for their kind advices and Prof. R. Uyeda for his valuable discussions. The author is also indebted to the Ministry of Education for the research grant.

Radiative Collisions between Molecular and Electron Beams

II. Angular Momentum Distribution of OH* Radicals Splitting from H_2O_2 Molecules

By Tadao HORIE, Takayuki NAGURA and Masamoto OTSUKA

Faculty of Science, Osaka University

(Received December 6, 1956)

A molecular spectroscopic study of the radiative collision of electrons with H_2O_2 molecules leads to a pronounced abnormal rotation of the OH* radical split by electron impact from H_2O_2. A homogeneous electron beam is fired at right angles across a localized jet of H_2O_2 vapor in a vacuum chamber maintained at a pressure of about 1×10^{-4} mmHg. The angular momentum distribution curve obtained shows a single maximum which is located near the rotational quantum number of 20, and the rotational temperature corresponds to 20,100°K, being remarkably higher than the initial gas temperature. In comparison with the double maxima found for H_2O, there are two differences, namely—the absence of the first maximum and the shift of the second maximum towards higher rotational quantum numbers.

§ 1. Introduction

The earliest study of the abnormal rotation of the hydroxyl radical splitting away from H_2O_2 was reported in 1936 by A. A. Frost and O. Oldenberg[1]. They observed the OH absorption by the hydroxyl radicals left unrecombined immediately after interrupting an electrical discharge of brief duration through H_2O_2 vapor. After that in 1951, P. J. Dyne and D. W. G. Style[2] made a study of the OH emission from the OH* radicals present in a fluorescence cell through which a steady flow of hydrogen peroxide vapor at a few tenths of 1 mmHg was maintained. These observations seem to be in agreement with each other with respect to the qualitative property of the rotational intensity distribution. According to a comparison of the OH bands obtained in their experiments with H_2O_2 with that frequently observed in electrical discharges through H_2O, the band-tail representing the highest rotation is more intense in the former, while the band-head is much more intense in the latter.

As for H_2O, however, the OH (0, 0) band emitted from an electrical discharge through its vapour is widely variable in respect of the rotational intensity distribution depending upon the condition under which water molecules are excited. For instance, it has been proved by H. P. Broida and W. R. Kane[3] that the relative intensity of the first maximum to the second of the R_2 branch undergoes a remarkable change with varying discharge pressure even in one and the same tube of an electrodeless ring discharge. In order to avoid such a danger of fluctuation, the most fundamental collisions of electrons with water molecules have been taken up in Part I.[4] In such a simplified collision process, the rotational intensity distribution of the Q_1 branch exhibits double maxima almost independently of the energy of impinging electrons in the wide range from 20 to 1,000 volts, the second (abnormal) maximum near the tail being at all energies predominant over the first (thermal) maximum near the head.

As an origin of the double maxima, a tentative mechanism has been proposed in Part I[4] on the basis of a localized electron pair bond theory of the H_2O molecule. Briefly summarized, when either one of the hydrogen atoms within a water molecule flies off nearly in the direction along the line of centers of the two hydrogen atoms, the remaining hydrogen atom must, for the law of angular momentum conservation, start an abnormal rotation about the oxygen atom, the second maximum being caused by such a swarm of hydroxyl radicals. Alternatively, when a hydrogen atom flies off in the direction along the O–H bond concerned, the H atom left behind does show merely a thermal rotation, the first maximum resulting from such a swarm of hydroxyl radicals. In order to examine such a proposal, it may be desirable to compare the angular momentum distribution of the OH* radicals splitting away from H_2O_2 molecules excited by electron impact with that found for H_2O.

§ 2. Experimental

In order to realize the simplest condition of collision of electrons with molecules, a nearly homogeneous electron beam is fired at right angles to a beam of molecules in a vacuum of about 1×10^{-4} mmHg as depicted in Fig. 1. The OH* radicals appearing at the intersection of two beams—an electron beam ejected from an especially designed electron gun and a beam of H_2O or H_2O_2 molecules—emit a crowd of rotational lines of the (0, 0) band near λ 3,064, the intensity distribution among them giving full information about the angular momentum distribution under investigation.

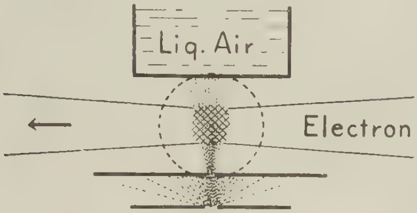

Fig. 1. The intersection of the two beams; the dotted circle means a quartz window.

Looking into the collision chamber through a quartz window, a reddish glow is visible around the intersection of an electron beam with a beam of water molecules. Its shape is more or less varied depending upon the strength of the focusing magnetic field of the electron gun, the width of the image slit, the intensity of the electron beam, the pressure of the collision chamber, and other experimental conditions, as shown in Fig. 2. The whole apparatus used is largely the same as described in detail in Part I.[4]

The preparation of the sample of H_2O_2 was made in two steps as follows. Firstly, the commercial 30% solution was concentrated after the recipe given by G. Brauer.[5] A glass flask, provided with a fine glass capillary to secure regular boiling and prevent superheating, containing 180 cc of the dilute solution was immersed in a water bath kept at 45–50°C. The side tube of the flask was connected with a pumping system via a spiral condenser and a receiving flask of about 150 cc. After a vacuum distillation for 3.5 hours at a pressure between 16 and 22 mmHg, the volume of the content was reduced down to about 45 cc, the residue being found to be about 90% H_2O_2 in weight. Secondly, the flask containing the residue was taken off and attached to another high vacuum system. Before the H_2O_2 vapour was used in the collision experiment, a vacuum distillation of long duration at much lower pressures was preceded to make the residue as free as possible of air and water dissolved into it.

Since H_2O_2 decomposes when in contact with stopcock grease, metals and harsh surfaces of ground glass, precautions were taken against the H_2O_2 vapour to contact with anything but smooth surfaces of clean glass walls both in the preparation procedure and in the collision experiment. From the reservoir of H_2O_2 to the image slit, all parts were made of glass. Without any stopcock, the pressure of the

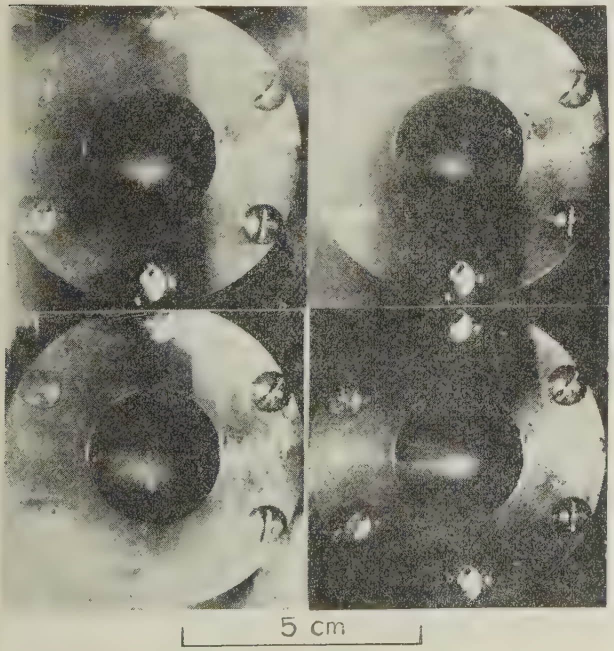

Fig. 2. Owing to the Balmer lines, a reddish glow is visible in various shapes under somewhat different conditions of operation at the intersection between an electron beam and a localized jet of water vapor.

H_2O_2 vapour was controlled only by cooling or heating the reservoir. The two metallic slits used in the preceding experiment with H_2O were also replaced with ones of glass as follows. After one end of a glass tube was closed in a blow-pipe flame, the thickness of the glass wall at the closed end was adjusted by blowing into the tube so as to become moderately thin. A slit was bored at the central portion of the closed end by a grinding device and sharp edges caused by grinding were all rounded off by a dilute solution of hydrogen fluoride.

§ 3. Result

The result of photographic photometry measurements for the rotational lines emitted from the OH* radicals splitting away from H_2O_2 molecules bombarded by electrons is compared in Fig. 3 with that observed in the experiment with H_2O. Both of them were obtained at sufficiently higher energies of impinging electrons ranging from 500 to 700 volts so that the ambiguity due to the possibility of what is called electron exchange collision might be set aside from the subject.

In general, $I(K')$, the intensity of the rotational line corresponding to the rotational quantum number K', is related to $N(K')$, the number of the excited radicals per unit volume at the rotational state with K', as follows:

$$N(K')=CI(K')(2K'+1)/i(K', K''),$$

where $i(K', K'')$ is the intensity factor. In the Q_1 branch considered, $C(2K'+1)/i(K', K'')$ varies quite gradually as a function of K' alone, the fluctuation of which does not exceed 1.3% of its magnitude in the range of K' from 3 to 30. These figures, therefore, may be able to be regarded as the distributions of number of radicals against rotational quantum number without any serious alteration, merely except for the range of K' less than 3.

Now in the case of H_2O_2, the distribution curve has a single maximum near the rotational quantum number K' of 20. The effective rotational temperature corresponds to 20,100K°, which is remarkably higher than the initial gas temperature. On the contrary, in the case of H_2O, in addition to the thermal maximum near K' of 5, the abnormal maximum is located near K' of 17 and the rotational temperature corresponds to about 14,000°K. On comparison of these figures it is seen that the thermal maximum found for H_2O is entirely absent for H_2O_2 and moreover the abnormal maximum is found at a higher rotational quantum number for H_2O_2 than it is for H_2O.

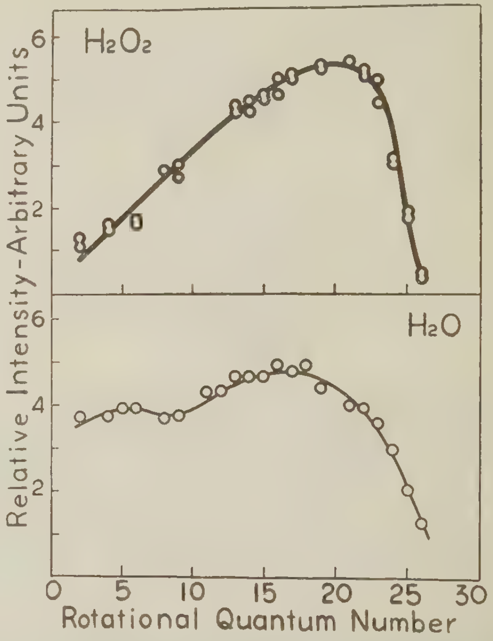

Fig. 3. Rotational intensity distributions of the Q_1 branch in the OH (0, 0) band excited in the radiative collision of elections with H_2O_2 and H_2O molecules.

In order to show the absence of the thermal maximum in the case of H_2O_2, the first fourteen members of the Q_1 branch in the OH (0, 0) band excited in several kinds of collision processes are compared with one another in Fig. 4, in which (a) was taken by the hydrogen canal ray impact experiment with water molecules,[7] (b) by the radiative collision of electrons with hydrogen peroxide molecules and (c) by the radiative collision of electrons with water molecules. These intensity dis tributions are undoubtedly quite different from one another, and it may be recognized that the $Q_1(2)$, $Q_1(4)$ and $Q_1(6)$ lines, for example, are very much fainter especially in the electron-impact excitation of H_2O_2, (b). On the other hand, the higher members, for example, the $Q_1(13)$ and $Q_1(14)$ lines in (b) and (c) are comparable with each other, while in (a) they fade out in rapid succession in

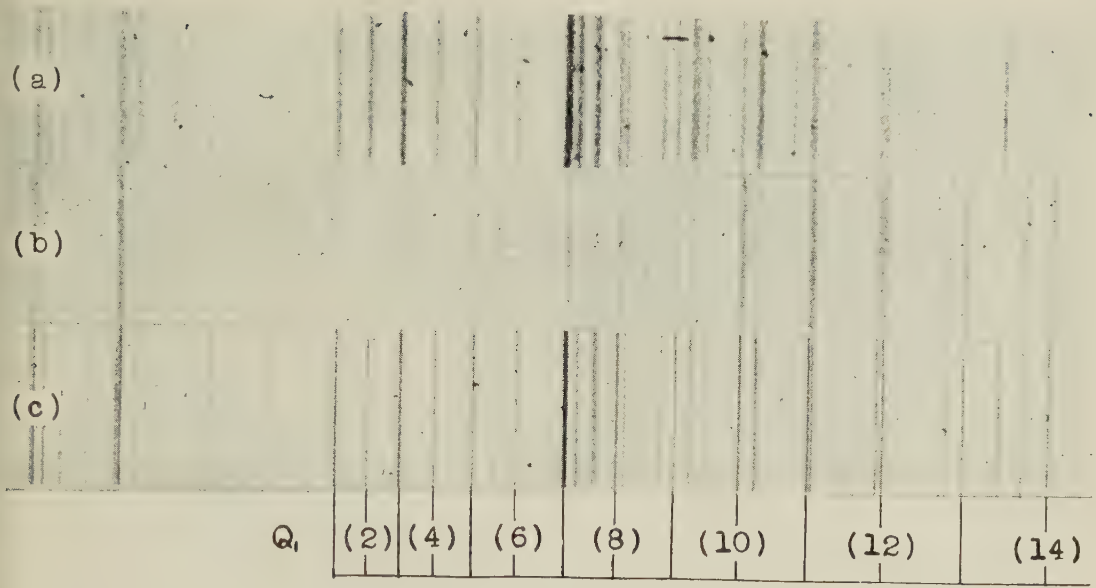

Fig. 4. The OH (0, 0) band; (a) hydrogen canal-ray-impact excitation of H_2O, (b) electron-impact excitation of H_2O_2, and (c) electron-impact excitation of H_2O.

contrast with the growing-up as seen in (b). It is also obviously doubtless that the gas temperature is not the main reason for such variations, because the parent molecules were certainly in all cases at room temperature.

§ 4. Discussion

As regards the molecular structure of the H_2O_2 molecule, three models have so far been suggested as depicted in Fig. 5.[6] Since in 1934 W. G. Penny and G. B. B. M. Sutherland[8] indicated theoretically that the nonplanar structure (c) was most probable, a number of works, as reviewed by J. T. Massey and D. R. Bianco,[9] tended to confirm their conclusion from both theoretical and experimental points of view. Especially the recent investigations by J. T. Massey *et al.*[9][10] with the microwave spectra and by P. A. Giguère *et al.*[11][12] with the infrared absorption spectra, all of them having been carried out in the *vapour* state, provided further strong confirmations for the nonplanar structure.

As is well known, H_2O_2 can be composed by various procedures of preparation, some of them being based on the association reaction of H atoms with O_2[13], and others on the recombination reaction of OH radicals liberated in electrical discharges through H_2O.[16] It was in 1932 that K. H. Geib and P. Harteck[13] proposed the existence of the isomer with the structure (b) in discussing about their experimental study of the former method. Since then the existence of such an isomer has long been the point in dispute for 20 odd years. Meanwhile, the recent work performed by P. A. Giguère and E. A. Secco[14] with the infrared absorption spectra in the *solid* state of hydrogen and deuterium peroxides produced in an electrodeless ring discharge revealed a new indication in favour of the existence of the isomer, $\begin{matrix}H\\H\end{matrix}\!>O^{+}-O^{-}$.

As far as the gaseous state is concerned, however, all the recent evidences cited above would allow us to set aside the model (b) from the question. And in fact, this model does not account for the absence of the first maximum, because it involves within itself a triangular configuration of HOH. Judging from this structure, whether it may be planar or pyramidal as suggested by A. D. Walsh,[15] the OH* radical must be produced as, for example,

$$\text{(A)}\quad H_2O_2 + e \rightarrow OH^* + \begin{cases} H + O + e \\ H^* + O + e \\ H^+ + O + 2e\,. \end{cases}$$

Accordingly, two different possibilities may exist for the direction of the recoiling hydrogen atom or proton, as has been indicated in the case of H_2O, namely—the direction along the line of centers of the two hydrogen atoms and that along either one of the O–H bonds respectively. If a recoiling hydrogen atom, whether it may be normal, excited, or ionized, were projected in the direction extending the O–H bond concerned, the OH* radical left behind would thermally rotate for the law of angular momentum conservation, such a swarm of OH* radicals leading to the thermal maximum. But, in point of fact, the experimental result does not give any evidence of the thermal maximum, as shown in Figs. 3 and 4.

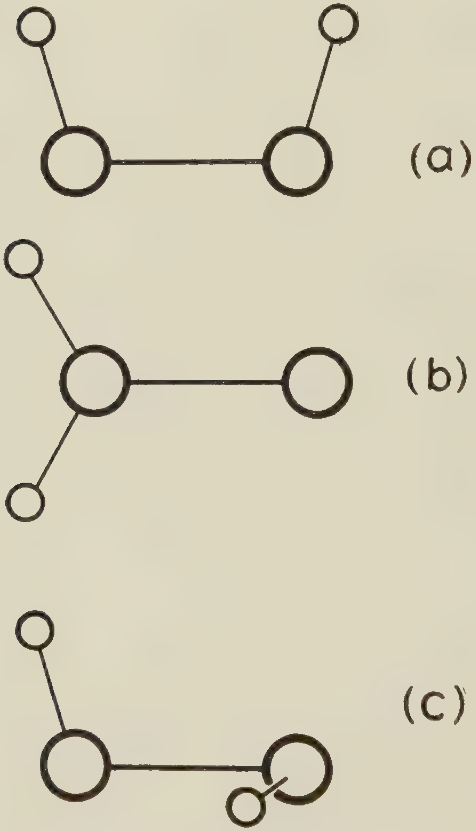

Fig. 5. Suggested models of H_2O_2; (c) is non-planar.

Such being the case, the absence of the first maximum must be attributed to the structures shown by the models (a) and (c). Owing to hindered rotation,[9)10)] the two OH bars within the H_2O_2 molecule in the ground state may take various orientations with respect to each other about the axis of the O–O bond; then the molecule may transitorily take various shapes, including the *cis* (a), the *trans* and the nonplanar (c) structures. In the case of such a structure, when excited by electron impact, the H_2O_2 molecule would be expected to split more probably into two hydroxyl radicals rather than into pieces as shown in (A). These considerations are in good agreement with the fact that the hydrogen Balmer series is very much weaker in the radiative collision of electrons with H_2O_2 than with H_2O as shown in Fig. 6. The faint traces of the Balmer lines in (b) may be due in part to a small quantity of H_2O impurities contained in the H_2O_2 molecular beam and in part to small probabilities for decompositions into pieces of the H_2O_2 molecule.

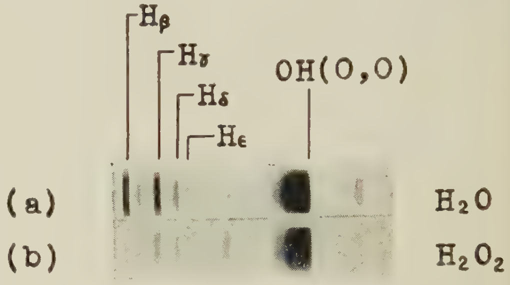

Fig. 6. Relative intensities of the hydrogen Balmer series to the OH (0, 0) band in the radiative collision of electrons with (a) H_2O and (b) H_2O_2 molecules.

Accordingly, the essential features in the angular momentum distribution curve observed in the experiment with H_2O_2, namely—the absence of the first (thermal) maximum and the shift of the second (abnormal) maximum towards higher rotational quantum numbers—may be attributable chiefly to the mechanism of the simultaneous excitation and dissociation by electron impact of H_2O_2 different from that of H_2O as follows:

$$\text{(B)}\qquad H_2O_2 + e \rightarrow OH^* + \begin{cases} OH + e \\ OH^* + e \\ OH^+ + 2e\,, \end{cases}$$

and

$$\text{(C)}\qquad H_2O + e \rightarrow OH^* + \begin{cases} H + e \\ H^* + e \\ H^+ + 2e\,. \end{cases}$$

The excitation by radiation of diatomic molecules is strictly governed by the Franck-Condon principle. If the relative positions of the potential-energy curves for a diatomic molecule in its lowest state and in an excited state were assumed as shown in Fig. 7, (a) or (b), excitation results in a molecule which at once dissociates into atoms. At that time, the relative kinetic energy of the two atoms with which they fly apart is given by the vertical distance of the horizontal line *AB* from the asymptote of the upper potential-energy curve.

Although the dissociation by electron impact of the HO–OH molecule may be in actuality a complex phenomenon, the qualitative feature of the process may likewise be understood. Now the two-dimensional potential-energy curves of the diatomic molecule must be replaced by polydimensional surfaces, but the Franck-Condon principle is still admittedly applicable to the process of excitation by electron. The potential energy above the asymptotic plane of the point on an upper potential-energy surface reached after the quantum jump must now be converted not only into the translational energies but also into the rotational energies of the fragment radicals. Accordingly, the surplus energy corresponding to *E* indicated in Fig. 7 must at all times be partly expended in enhancing the rotational energy of the H atom circling the O in the OH* radical splitting away from the H_2O_2 molecule excited by electron impact, thus the absence of the thermal maximum being brought about. It may be of interest to study the over-all distribution curve in more detail from a theoretical point of view.

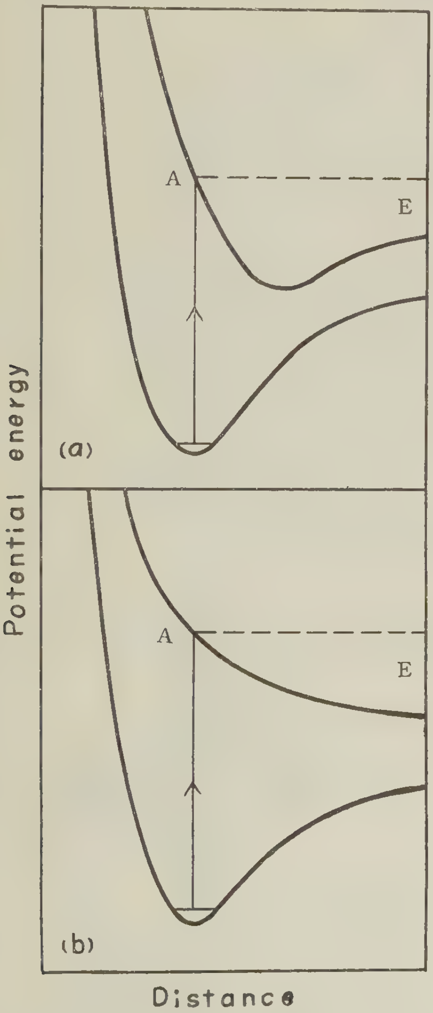

Fig. 7. Potential-energy curves for a diatomic molecule in its lowest state and in an excited state; excitation leads to dissociation.

Finally the authors wish to express their sincere thanks to Prof. T. Asada and Prof. T. Watanabe for placing the experimental facilities at their disposal. The authors have also pleasure in expressing their hearty thanks to Prof. M. Kotani of University of Tokyo and Prof. K. Niira of Tokyo Institute of Technology for their kind encouragements.

Nuclear Magnetic Resonance Experiment on Solid Hexamethyldisilane

By Teruo YUKITOSHI*, Hirosi SUGA**, Syûzô SEKI**,
and Junkichi ITOH*
*Department of Physics, and **Department of Chemistry,
Osaka University, Osaka

(Received December 24, 1956)

Proton magnetic resonance of solid hexamethyldisilane was studied. Line width and spin-lattice relaxation time were measured in temperature range from liquid air to room temperature. By analysing these quantities following results were obtained: Even at liquid air temperature, each CH_3 group reorientates about its three-fold symmetry axis so rapidly as to narrow the dipolar width due to three proton interactions within itself (activation energy 2.6 kcal/mole). Then at about −120°C, reorientation of CH_3-groups about the axis joining two silicon atoms becomes rapid enough to narrow the width further (activation energy 5.7 kcal/mole). Spin-lattice relaxation time varies qualitatively in accordance with the above considered reorientational motions. At −51.3°C, this crystal changes its structure and at the same time rapid reorientational motion of the molecular axis is excited, resulting discontinuous decrease in the line width and discontinuous increase in the spin-lattice relaxation time. Above the transition temperature, self-diffusion of molecule as a whole starts and the line width decreases gradually to zero (activation energy 10 kcal/mole). No change in the line width was observed at the melting point.

§ 1. Introduction

Hexamethyldisilane is known as a typical plastic crystal in the sense first proposed by J. Timmermans[1] and the following properties have been revealed from the previous thermal and X-ray measurements[2][3]. (1) There is a remarkable anomaly in heat capacity at −51.3°C. In the high temperature phase, the substance becomes transparent perfectly in absence of air. On the other hand, the appearance of the sample brought into the low temperature phase is a white and opaque mass apparently composed of small crystals, probably with many craks. (2) The entropy change ΔS at the transition point is 10.5 cal/deg., mole, and this value is much larger than that at the melting point (14.5°C) where ΔS is 2.51 cal/deg., mole. A large scale disorder of lattice or molecule might be reasonably expected in the high temperature phase. (3) In the high temperature phase, the crystal structure determined from Laue and oscillation photographs using single crystals is body-centered cubic with the lattice constant of 8.47 Å (at 0°C) containing two molecules and the molecular axes are orientated at random over four body diagonals. On the other hand, it is very difficult to obtain single crystals below the transition temperature, but Debye-Sherrer photographs suggest that the low

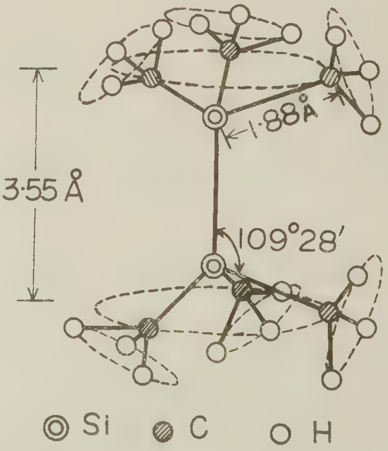

Fig. 1. Molecular structure of hexamethyldisilane in gaseous state determined by the electron diffraction measurement.

temperature modification is not at all "plastic" and belongs to lower symmetry.

It is the purpose of this work to investigate motions of the atomic groups or the molecule as a whole by the observations of the temperature dependence of proton magnetic resonance line width and spin-lattice relaxation time and also to relate them with the thermal and crystallographic data.

Electron diffraction study of the present molecule in gaseous state has been already published[4]. For the discussion of our experimental results, molecular parameters (shown in Fig. 1) determined by this electron diffraction experiment are assumed.

§ 2. Experimental Method and Procedure

The detection method of nuclear magnetic reasonance is similar to that of Watkins[5]. The sample (about 99.7% pure) was sealed by distillation under vacuum into a thin-walled glass tube (1 cm diameter and 3 cm long) which is inserted into the radio-frequency coil of a Watkins type oscillator. The experiments were carried out with the constant frequency of 5.35 Mc/sec., and by sweeping the magnetic field slowly, the derivatives of the absorption curves were recorded on a recording meter, after being amplified and detected by a phase sensitive detector. Most of the measurements were done by using a magnet whose inhomogeneity over the sample is about 0.1 gauss, and the magnetic field was modulated by 60 cycles per second.

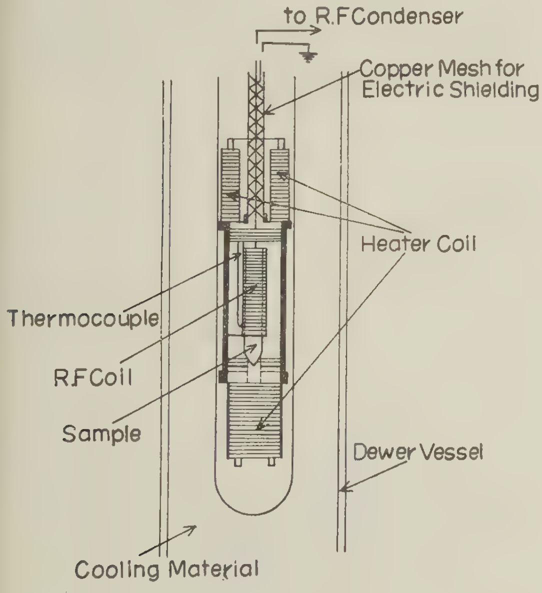

Fig. 2. The cryostat.

The cryostat used in our experiment is shown in Fig. 2. Liquid air or dry ice mixed with toluene was used as cooling material. The temperature of the sample was measured by means of a calibrated copper-constantan thermocouple located at a point very near the sample coil. Care was taken to assure good thermal equilibrium between the specimen and the surroundings and also to keep the temperature constant for enough time to do the measurements of line width or saturation curve. The specimen was cooled slowly by pouring cooling material into the Dewer vessel little by little and then was warmed gradually up to the desired temperature by increasing the currents of the heater coils. Data were taken after the temperature was in good equilibrium.

In the high temperature phase where the line width becomes very narrow, another highly homogeneous magnet was used for further precise measurement of the line width. The inhomogeneity of the magnetic field over the sample was about 6 milligauss. The magnetic field was modulated by 20 cycle per second to avoid distorsion of the resonance line by the modulation. In this case the temperature of the specimen was varied by the adjustment of the velocity of cold air flowing a glass tube surrounding the rf-coil. In order to avoid the occurrence of temperature gradient within the specimen, the specimen was sealed in a nearly spherical glass tube, about 6 mm in diameter.

The spin-lattice relaxation time T_1 was measured by usual saturation method, the sensitivity of the detector being calibrated by a calibrator of Watkins type[5]. The results obtained for long T_1 are not so reliable, because at very weak oscillator coil voltage, the detector output becomes very noisy. For the calibration of the oscillating field H_1, the line shape and saturation curve were measured for an aqueous solution of paramagnetic salt. Since the line shape is Lorentzian and $T_1=T_2$ in this case, we can calculate the value of H_1 using the formula given by Bloembergen, Purcell and Pound[6], which is found to be 9.4×10^{-2} oersted per unit coil voltage. Here the coil voltage was measured by a valve voltmeter. Although the relative values of the spin-lattice relaxation time are reliable, their absolute values may be in error within ±30%, for they imply many possible errors in the calibration of H_1, in the evaluation of T_2, and others.

§ 3. Experimental Results and Discussions

(*a*) The second moment

For the case in which similar nuclei are interacting with each other by magnetic dipole-dipole interactions and are considered to be rigid, the second moment of the absorption line is given by[7)8)]

$$<\Delta H^2>=\frac{3}{2}I(I+1)\,g^2\beta^2\frac{1}{N}\sum_{j>k}(3\cos^2\theta_{jk}-1)^2r_{jk}^{-3} \qquad (1)$$

where N is the number of nuclei interacting with each other, θ_{jk} is the angle between the external magnetic field and the line joining nuclei j and k, r_{jk} is the distance between nuclei j and k, I is the nuclear spin, and $g\beta I$ is the nuclear magnetic moment. For powder sample, taking the average over the angle θ_{jk} and inserting the numerical values for the case of protons, (1) becomes to be

$$<\Delta H^2>=7.16\times10^{-46}N^{-1}\sum_{j>k}r_{jk}^{-6}\,. \qquad (2)$$

Now, we shall consider the case of hexamethyldisilane molecule. The numerical value of the second moment for isolated rigid CH_3 group with H–H distance of 1.79 Å[9)] is $<\Delta H^2>=21.7$ gauss². The dipolar interactions between three CH_3 groups belonging to each one of silicon atoms are calculated by assuming that three protons lie randomly on a circle determined by three hydrogen atoms belonging to a CH_3 group, since the exact orientation of CH_3 group with respect to the three-fold symmetry axis, or, C_3 axis is not known. The second moment due to the interaction between CH_3 groups belonging to different silicon atoms in a molecule is calculated by assuming that relative orientations are at random, since exact molecular configuration, that is, cis, trans, or other type, is also not known.

When three protons in each CH_3 group reorientate about the C_3 symmetry axis, or, CH_3 groups reorientate about Si–Si axis (C'_3 axis), the reduced second moments are calculated by the formula given by Gutowsky and Pake[8)], or, by the equation (20) given in section (*C*). The calculated values of the second moments in each case are shown in Table I. The contribution of the intermolecular dipolar interactions to the second moment is impossible to be calculated exactly, owing to the lack of knowledge about the crystal structure. However, if we take body-centered cubic structure with the lattice constant of 8.47 Å which corresponds to that in the high temperature phase, and assume that the direction of the molecular axis is distributed randomly over the directions of four diagonals, we obtain about 1.0 gauss² as the second moment due to the intermolecular interactions. We assume tentatively this second moment also in the low temperature phase, because the packing of the crystal might not change violently

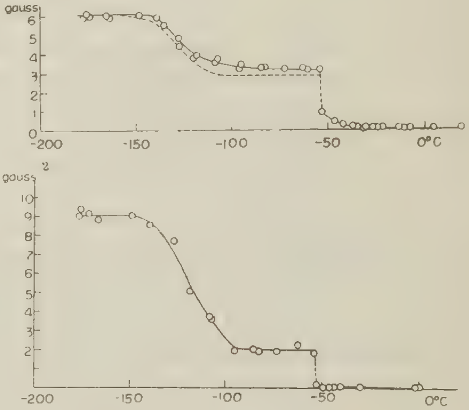

Fig. 3. Experimental line width between maximum and minimum slopes (upper curve) and the second moment for hexamethyldisilane plotted against temperature (lower curve). Dotted line represents the calculated curve.

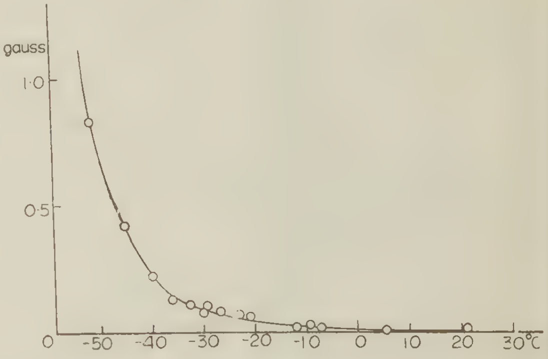

Fig. 4. Experimental line width of hexametyldisilane in high temperature phase measured by the use of homogeneous magnet.

Table I. The calculated second moments and the comparison with the experimental results.

Interaction / State of motion	Interaction between three protons in a methyl group	Interaction between protons belonging to three methyl groups bonded to one silicon atom	Interaction between protons belonging to methyl groups bonded to different silicon atoms	Inter-molecular interaction	Total	Exp.
	gauss^2					
Rigid	21.7	1.04	0.52	1.0	24.3	—
C_3-rotation	5.43	0.90	0.52	1.0	7.9	9.0
C_3'-rotation	0.64	0.23	0.33	0.6	1.8	2.0

by the transition. This value may be scarcely affected by the C_3 axis rotation, but it will be narrowed by the C'_3 axis rotation and we rather arbitrarily take the value 0.6 gauss^2 for the narrowed second moment.

From the experimentally obtained derivative curves, the second moments were computed and are shown in Fig. 3, together with the widths between maximum slopes. Fig. 4 shows the results of line width measurements in the high temperature phase, by the use of more homogeneous magnet. The second moment is constant in the temperature range between −180°C and −140°C, and also between −90°C and −55°C. These constant values are shown in Tab. I and are compared with the theoretical values.

From Tab. I, it is clear that even at the lowest temperature, this molecule cannot be considered to be rigid, since the measured second moment is much less than that calculated by the assumption of rigid lattice. On the contrary, the experimental second moment coincides nearly with the calculated one in the case of CH_3 group reorientating about its C_3 axis. Thus, it seems clear that even at liquid air temperature the methyl group reorientates about its C_3 axis with enough high frequency to narrow the line width due to dipolar interactions between three protons in each CH_3 group.

The gradual change in the line width which takes place around −125°C is due to some additional motion and this motion may be the reorientational motion of methyl groups about C_3' axis. In fact, the second moment in the temperature range between −90°C and the transition point coincides well with the caluculated value under the assumption of C'_3 axis rotation. Whether the structure of this molecule is cis, trans, or some other type is indeterminable by our experiments alone.

Just above the transition temperature*, the line width and also the second moment decrease suddenly to much smaller values, indicating that some additional rapid motion of the molecule or some groups in the molecule starts suddenly at the transition temperature. Now, in this higher temperature phase, X-ray determination of the crystal structure and lattice dimension have been already done, the result of which was given in the introduction. The caluclated second moment due to the intermolecular dipolar interaction alone, in the high temperature phase, yields about 0.55 gauss^2, if we assume that eighteen protons lie at the center of gravity of each molecule. If the line shape is Gaussian, the separation between the points of maximum and minimum slopes is calculated to be 1.4 gauss. Extrapolating the observed values in the high temperature phase to the transition point, 1.1 gauss is obtained for the line width. This suggests that the whole molecule will rotate around its center of gravity rapidly enough to average out the intramolecular interaction leaving only the intermolecular one. Narrowing of the line width above the transition temperature is caused by the self-diffusion of the molecule as a whole which will be discussed later.

(*b*) Spin-lattice relaxation time

Generally speaking, studies of the spin-lattice relaxation time will give more detailed informations about molecular motions. First, we shall give the results of some theoretical considerations about spin-lattice relaxation time, in this molecule.

---

* The temperature at which discontinuous change in the line width occurs is −53°C, which differs about 2°C from the thermal transition temperature. This discrepancy may probably arise from the errors in measuring the temperature of the sample in our measurement.

The spin-lattice relaxation time, T_1, due to molecular motion is expressed as follows:[9]

$$1/T_1=(3/2)\gamma^4\hbar^2 I(I+1)[J_1(\nu_0)+J_2(2\nu_0)] \qquad (3)$$

where γ is the gyromagnetic ratio and $J_1(\nu_0)$ and $J_2(2\nu_0)$ are the sum of the intensities of the Fourier spectra, of frequency ν_0 and $2\nu_0$, of $F_{1,ij}$ and $F_{2,ij}$ respectively, where

$$\left.\begin{aligned} F_{1,ij}&=\sin\theta_{ij}\cos\theta_{ij}\exp(i\phi_{ij})\, r_{ij}^{-3} \\ F_{2,ij}&=\sin^2\theta_{ij}\exp(2i\phi_{ij})\, r_{ij}^{-3} \end{aligned}\right\} \qquad (4)$$

Here $\boldsymbol{r}_{ij}$ is the vector joining the nuclei i and j with magnitude r_{ij}, θ_{ij} is the polar angle of $\boldsymbol{r}_{ij}$ taking the z-axis in the direction of the applied field, ϕ_{ij} is the azimuthal angle of $\boldsymbol{r}_{ij}$ measured from some fixed reference direction, and ν_0 is the Zeeman frequency. For the discussion of the change of the line width, which will begiven in the next section, one more function, $F_{0,ij}$ is needed, where

$$F_{0,ij}=(3\cos^2\theta_{ij}-1)\, r_{ij}^{-3} \qquad (5)$$

To each of these positional functions we can define a correlation function

$$K(\tau)=\langle F(t)\, F^*(t+\tau)\rangle \qquad (6)$$

where $F(t)$ represents any one of three functions, F_0, F_1 and F_2. Then the spectral intensity $J(\nu)$ is given by the sum of the Fourier transforms of $K(\tau)$:

$$J(\nu)=\sum_j \int_{\infty}^{-\infty} K(\tau)\exp(2\pi i\nu\tau)\, d\tau \qquad (7)$$

Next, we shall consider how the correlation function is expressed in the case of hindered rotation of methyl group. As for the narrowing of the line width, Powles and Gutowsky have already discussed the same problem[10]. We assume that the reorientation about C_3 axis among three equivalent orientations takes place stepwisely and the time spent during the rotation from one equivalent orientation to another one can be neglected, compared with the time during which the atomic group stays at an equivalent orientation. We shall define probabilities a_1, a_2 and a_3 for the molecule taking each of three equivalent orientations at a time t. Assuming that the direction of rotation is random, and that the rate per unit time of jumping is $1/\tau_c$, we can write

$$\frac{da_1}{dt}=\frac{1}{\tau_c}\left(-a_1+\frac{a_2}{2}+\frac{a_3}{2}\right) \qquad (8)$$

Two similar equations are obtained by cyclic permutations of the suffices. The solution of these equations, subject to the initial conditions, $a_1(0)=1$, $a_2(0)=0$ and $a_3(0)=0$, is

$$\left.\begin{aligned} a_1(t)&=(1/3)+(2/3)\exp[-(3/2)t/\tau_c] \\ a_2(t)=a_3(t)&=(1/3)-(1/3)\exp[-(3/2)t/\tau_c]. \end{aligned}\right\} \qquad (9)$$

In this case the correlation function is calculated to be

$$\begin{aligned} &\langle F(t)\, F^*(t+\tau)\rangle_{\mathrm{Av}} \\ &\quad=(1/3)[(a_1-a_2)(|F^1|^2+|F^2|^2+|F^3|^2)+a_2|F|^2], \end{aligned} \qquad (10)$$

where $F=F^1+F^2+F^3$ and F^i is the value of the position function F in the i-th orientation. Inserting (9) into (10), we obtain

$$\begin{aligned} &\langle F(t)\, F^*(t+\tau)\rangle_{\mathrm{Av}} \\ &\quad=|\langle F\rangle|^2+\{\langle|F|^2\rangle \\ &\qquad-|\langle F\rangle|^2\}\exp[-(3/2)\tau/\tau_c], \end{aligned} \qquad (11)$$

where $\langle\ \rangle$ means the average of the position function over three equivalent orientations. When $\tau\ll\tau_c$, $\langle F(t)F^*(t+\tau)\rangle$ is equal to $\langle|F|^2\rangle$ itself, while, when $\tau\gg\tau_c$, F itself is first averaged and the square of this averaged value remains.

Now, in the case of methyl group reorientating about its C_3 axis, (11) can be easily calculated as

$$\left.\begin{aligned} &b^6\langle F_0(t)F_0^*(t+\tau)\rangle \\ &\quad=(1/2)(3\nu_z^2-1)^2+(9/4)(1-\nu_z^2)^2\exp(-\tau/\tau_c') \\ &b^6\langle F_1(t)F_1^*(t+\tau)\rangle \\ &\quad=(1/2)\nu_z^2(1-\nu_z^2)+(1/4)(1-\nu_z^4)\exp(-\tau/\tau_c') \\ &b^6\langle F_2(t)F_2^*(t+\tau)\rangle \\ &\quad=(1/2)(1-\nu_z^2)^2 \\ &\qquad+(1/4)(1+6\nu_z^2+\nu_z^4)\exp(-\tau/\tau_c') \end{aligned}\right\} \qquad (12)$$

where ν_z is the cosine of the angle between the C_3 axis and the static magnetic field, b is the distance between protons in methyl group and

$$\tau_c'=(2/3)\,\tau_c\,. \qquad (13)$$

For crystal powder, taking average over the angles

$$\left.\begin{aligned} &b^6\langle F_0(t)\, F_0^*(t+\tau)\rangle_{\text{powder}} \\ &\quad=(2/5)[1+3\exp(-\tau/\tau_c')] \\ &b^6\langle F_1(t)\, F_1^*(t+\tau)\rangle_{\text{powder}} \\ &\quad=(1/15)[1+3\exp(-\tau/\tau_c')] \\ &b^6\langle F_2(t)\, F_z^*(t+\tau)\rangle_{\text{powder}} \\ &\quad=(4/15)[1+3\exp(-\tau/\tau_c')] \end{aligned}\right\} \qquad (14)$$

By (6) and (7), J in the case of crystal powder is calculated to be

$$\left.\begin{aligned} J_1(\nu_0) &= \frac{1}{5}\,\frac{2\tau_c'}{1+\omega_0^2\tau_c'^2}\,b^{-6} \\ J_2(2\nu_0) &= \frac{4}{5}\,\frac{2\tau_c'}{1+4\omega_0^2\tau_c'^2}\,b^{-6} \end{aligned}\right\} \tag{15}$$

where ω_0 is 2π times the Zeeman frequency.

Next, we shall consider the case when the C_3' axis rotation superposes on the C_3 axis rotation. In our case, since at the temperature where the C_3' axis rotation contributes to the narrowing of the line width or spin-lattice relaxation time, the C_3 axis rotation is already very rapid, the effects of the C_3 axis rotation and C_3' axis rotation can be treated separately. Then, (11) can be well applied also to the case of C_3' axis rotation, provided that F is replaced by $<F>_{c_3}$, where $<\ >_{c_3}$ means the average of F over C_3 axis rotation. If we write $<\ >_{c_3}'$ for the average over C_3' axis rotation, the correlation function in the case of the C_3' axis rotation can be expressed to be

$$\begin{aligned} &<F(t)F^*(t+\tau)>_{c_3,\,c_3'} \\ &\quad = |<<F>_{c_3}>_{c_3'}|^2+\{<|<F>_{c_3}|^2>_{c_3'} \\ &\qquad -|<<F>_{c_3}>_{c_3'}|^2\}\exp\left[-(3/2)\tau/\rho_c\right] \end{aligned} \tag{16}$$

where ρ_c is the correlation time for the C_3' axis rotation. (16) is a good approximation when $\rho_c \gg \tau_c$, and $\omega_0\tau_c \ll 1$. The powder averages of the correlation functions for three protons in one $\mathrm{CH_3}$ group are given by

$$\left.\begin{aligned} &b^6<F_0(t)F_0^*(t+\tau)> \\ &\quad =(1/10)[(1-3\cos^2\alpha)^2 \\ &\qquad +3(1+3\cos^2\alpha)(1-\cos^2\alpha)\exp(-\tau/\rho_c')] \\ &b^6<F_1(t)F_1^*(t+\tau)> \\ &\quad =(1/60)[(1-3\cos^2\alpha)^2 \\ &\qquad +3(1+3\cos^2\alpha)(1-\cos^2\alpha)\exp(-\tau/\rho_c')] \\ &b^6<F_2(t)F_2^*(t+\tau)> \\ &\quad =(1/15)[(1-3\cos^2\alpha)^2 \\ &\qquad +3(1+3\cos^2\alpha)(1-\cos^2\alpha)\exp(-\tau/\rho_c')] \end{aligned}\right\} \tag{17}$$

where α is the angle between the C_3- and C_3'-axis, and $\rho_c'=2\rho_c/3$. The spectral intensities can be calculated easily by (7) and (17).

Equations (11) and (16) are applicable also to more general cases. In the case of arbitrary reorientational motion of some atomic group, $<\ >$ in (11) should be taken as the average value of F over all equivalent orientations, and in (16), $<\ >_{c_3}$ and $<\ >_{c_3'}$ should correspond to the average value over equivalent orientations corresponding to the very fast rotation and that corresponding to the slower motion, respectively.

The spin-lattice relaxation time T_1 is given by

$$\frac{1}{T_1}=C\left[\frac{\tau_c'\ (\text{or}\ \rho_c')}{1+\omega_0^2\tau_c'^2(\text{or}\ \rho_c'^2)}+\frac{4\tau_c'\ (\text{or}\ \rho_c')}{1+4\omega_0^2\tau_c'^2\ (\text{or}\ \rho_c'^2)}\right] \tag{18}$$

where C is a constant which depends upon the configuration of the molecule and the mode of its motion, and is calculated easily by the expressions for J_1 and J_2. The numerical values of C calculated with the molecular parameters of hexamethyldisilane are shown in Tab. II. The intermolecular part is estimated by the same way as discussed in (*a*). It can be seen from Tab. I that the second moment calculated with the same parameters is about 14% smaller than the measured value. This discrepancy may arise from errors in the molecular parameters, such as H–H distance in each methyl group, or difference in the packing in the low temperature phase as compared with that in the high temperature phase, by which the intermolecular interaction will be changed. We tentatively correct the values of C by the amount just enough to compensate the discrepancy in the second moment. The corrected values are also shown in Tab. II.

Now, since in our case the molecular motion is the hindered reorientational one, we may

Table II. The calculated values of C.

Interaction / State of motion	Interaction between three protons in a methyl proup	Interaction between protons belonging to three methyl groups bonded to one silicon atom	Interaction between protons belonging to methyl groups bonded to different silicon atoms	Inter-molecular interaction	Total	Corrected

C_3'-rotation	2.2×10^9	0.4×10^9	0.1×10^9	0.2×10^9	2.9×10^9	3.3×10^9

assume that τ_c' (or ρ_c') varies with temperature as follows:

$$\tau_c' \text{ (or } \rho_c') = \tau_0' \text{ (or } \rho_0') \exp (E/RT). \quad (19)$$

The quantity E corresponds to the activation energy or the height of potential barrier hindering rotation. The values of E and τ_0' (or ρ_0') can be obtained by analysing the experimental results on T_1, as well as by analysing the narrowing of the line width which will be discussed in next section, and thus the confirmation of the mode of molecular motion can be done by comparing the values of E and τ_0' (or ρ_0') obtained from these two independent methods.

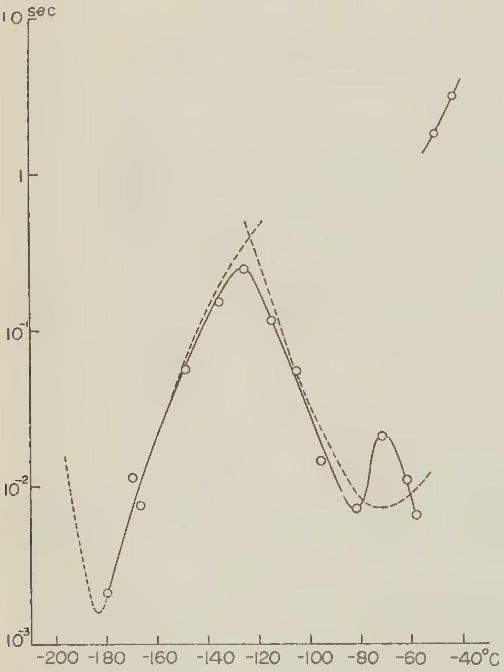

Fig. 5. Temperature dependence of the observed spin-lattice relaxation time, and the calculated curves with the parameters given in the text.

The experimental results of the measurement of T_1 is shown in Fig. 5. From the temperature dependence of T_1 in the temperature range between −180°C and −120°C and using the value of C in Tab. II, the activation energy and the value of τ_0' for the hindered rotation of each methyl group about its C_3 axis are determined to be 2.6 kcal/mole and 1.0×10^{-14} sec., respectively. Since the temperature range suitable for the determination of these quantities is rather narrow, error in E may be ±0.2 kcal/mole and correspondingly τ_0' may be in error within a factor of 5. Activation energy for this kind of motion has been estimated in various organic crystals by proton magnetic resonance method[8)10)11)] and their reported values are in agreement with each other and also with ours. At −180°C the correlation time τ_c is 1.1×10^{-8} sec. which is consistent with the narrowed line width discussed in (a). The calculated value of T_1 by the use of these values of E and τ_0' is shown in Fig. 5 by the dotted line, by which one might expect that there will be a minimum in T_1 around −185°C. It is hoped to carry out experiments below −180°C to ascertain the existence of this minimum and also to determine at what temperature the line width will broaden up to its full width corresponding to the rigid molecule.

According to the discussion in (a), the decrease of T_1 above −125°C will be caused by the hindered rotation of methyl groups about the C_3' axis, corresponding to the narrowing of the line width around −120°C. The general trend of the decrease of T_1 from −130°C to −90°C can be well accounted for by taking $E=5.7$ kcal/mole and $\rho_0'=1.4 \times 10^{-14}$ sec. with $C=3.3 \times 10^9$ (Tab. II). The calculated value of T_1 with these constants is shown in Fig. 5. However, there exists anomalous change of T_1 around −70°C which cannot be interpreted by any simple consideration of such reorientational motions as considered above. The actual behaviour of the molecular motion might be much more complicated than assumed here, especially in the vicinity of the transition temperature, by which the anomalous change of T_1 might be produced. But no further discussion can be made at the present stage. The inaccuracy in E and ρ_0' is comparatively large in the case of the C_3' axis rotation, about ±0.5 kcal/mole in E and a factor of 10 or so in ρ_0'. At −133°C, where the line width begins to narrow, ρ_c' is calculated to be 1×10^{-5} sec., which is just the same order as the inverse of the line width expressed in frequency scale, indicating our interpretation is the reasonable one.

As already described in (a), at the thermal transition point the line width and the second moment decrease suddenly, and above this temperature they continue to decrease until the width becomes narrower than 0.01 gauss. On the other hand, though we measured only two points, T_1 increases discontinuously at the transition point and it seems undoubtedly to increase with raising temperature. We found already from the analysis of the second moment that the vigorous reorientational motion of the molecular axis, which is enough to make the intramolecular interactions negligible, occurs abruptly at the transition point and then the width due to the intermolecular interaction decreases gradually with raising temperature by the self-diffusion of the molecules through the lattice. Just above the transition point, the rate of self-diffusion should not be so rapid as to narrow the intermolecular interaction appreciably. Therefore, the fact that T_1 increases with raising temperature above the transition point may suggest that the contribution to the relaxation of the reorientational motion of the molecular axis is larger than that of the self-diffusion. Some further discussion will be given in (*d*).

(*c*) The line width transition

The narrowing of the absorption line width due to the reorientational motion about the C_3 axis can be treated with just the same procedure as given in (*b*). The correlation function of $F_0=r^{-3}(3\cos^2\theta-1)$ is already given there. For a value of τ_c', the line width is given by[9]

$$(\Delta\omega)^2=2\log 2[(1/4)+(3/2\pi)\,\mathrm{arctg}\{(\pi\alpha/4\log 2)\,\tau_c'\Delta\omega\}]\langle\Delta\omega_0^2\rangle \tag{20}$$

where $\Delta\omega$ is the half of the half-value width, $\langle\Delta\omega_0^2\rangle$ is the second moment in the case of rigid configuration and α is a correction factor depending upon the line shape which is equal to 1 in the case of Gaussian shape. Actually, however, the line width is already narrowed at the lowest temperature of our measurements, and no discussion can be made concerning the C_3 axis rotation.

Narrowing of the line width around -120°C is caused by the reorientational motion about the C_3' axis, as already discussed in (*a*) and (*b*). In this case, the intra-methyl and also inter-methyl interactions are narrowed at the same time, as shown in Tab. I. The narrowing of the width can be calclulated in just the similar way as discussed in (*b*) for T_1, the result of calculation being given by

$$(\Delta\omega)^2=2\log 2\,[\langle\Delta\omega'^2_0\rangle+\{\langle\Delta\omega_0^2\rangle-\langle\Delta\omega'^2_0\rangle\}(2/\pi)\,\mathrm{arctg}\{(\pi\alpha/4\log 2)\,\rho_c'\Delta\omega\}] \tag{21}$$

where $\langle\Delta\omega^2\rangle$ and $\langle\Delta\omega_0'^2\rangle$ are the second moments before and after narrowing, respectively, and $\Delta\omega$ is the half of the half-value width corresponding to the correlation time ρ_c'. Expressing in magnetic field scale and using the experimental values 9.0 gauss^2 and 2.0 gauss^2 for the second moments before and after narrowing, the line width between maximum slopes is calculated with the values of E and ρ_0' obtained in (*b*), assuming the line shape is Gaussian. The best fit with the experimental results is obtained with $\alpha=2$, the calculted curve being shown in Fig. 3. Actually, the assumption of Gaussian shape is not exactly valid in the case of strong narrowing; after narrowing, the observed width between maximum slopes is 3.2 gauss which is not exactly equal to $2\sqrt{\langle\Delta H^2\rangle}=$ 2.8 gauss calculated from the observed second moment 2.0 gauss^2 with assumption of Gaussian shape, though, before narrowing, the line width 6.0 gauss is exactly equal to that calculated from the observed second moment 9.0 gauss^2. But the general discussion about the narrowing of the line width is not altered by this minute variation of the line shape.

The further decrease of the line width in the high temperature phase is considered to be caused by the self-diffusion of the molecule as a whole in a similar manner to that suggested by Andrew for cyclohexane and some other organic molecules[12]. At the transition point, the crystal structure undergoes the change from some structure of lower symmetry to body-centered cubic with large entropy change, 10.5 cal/deg. mole, and at the same time many vacancies might be produced in the crystalline lattice. Accordingly, in spite of comparatively large size of the molecule, the molecules change their equilibrium positions accompanying the still more rapid reorientation of the molecular axis, fast enough to affect the line width. Assuming that the self-diffusion has a correlation time τ_c', the equation (20) will be applicable also for the narrowing of the line width in this case. Using the calculated value of $\langle\Delta H^2\rangle$, which is 0.55 gauss^2, and assuming Gaussian shape, though it is not a good approximation, the activation energy and τ_0' for the self-diffusion are found to be 10 kcal/mole and 2.6×10^{-15} sec, respectively. Of course these values give only orders of magnitude. From the fact that the lattice energy of this subatance (sum of heat of vaporization and heat of fusion) is about 9.6 kcal/mole, this activation energy is considered to be reasonable in order*.

In addition, the line width at about 4°C (lower than the melting point, 14.4°C) where this crystal is still in a solid state, is as narrow as the one in liquid state (6 to 8 milligauss between maximum slopes which arises almost from the magnetic field inhomogeneity). Therefore, even in solid state these molecules behave effectively in the similar manner as Brownian motions in liquid state.

(*d*) Relaxation time at the high temperature phase and self-diffusion.

Assuming that the intramolecular interaction is completely averaged out, the spin-lattice relaxation time by self-diffusion is calculated by the formula given by Torrey[13] to be about 20 sec. at −46°C, using the correlation time obtained from the analysis of line width narrowing. Actually, however, just above the transition temperature, the contribution to the spin-lattice relaxation arises from two origins, the diffusion of the molecule as a whole, and the reorientational motion of the molecular axis. The observed T_1 at −46°C is about 2.5 sec., which is considerably smaller than the value calculated above by the self-diffusion alone, indicating that the reorientational motion of the molecular axis is probably the main origin of the spin-lattice relaxation. If the correlation time of this reorientational motion is of the order of 1×10^{-10} sec. at this temperature, the calculated value of T_1 can be brought to coincide with the experimental one. As the temperature increases, it is expected that T_1 will reach a maximum, then decrease to a minimum value and finally increase again, by the competation of the two contributions to T_1 arising from the motion of the molecular axis and of the self-diffusion. Unfortunately, however, it was impossible to measure the saturation curves above −40°C by our apparatus, because of long T_1 and narrow line width.

Recently, Nachtrieb and his collaborators[14] have proposed an experimental relation for self-diffusion in metals and also in molecular crystals which is

$$\Delta H_{\text{act}} = CL \qquad (22)$$

where ΔH_{act} is the activation enthalpy for self-diffusion, L is the latent heat of fusion and C is a constant having a value of 16.5 for body-centered cubic and face-centered cubic lattices. Inserting the observed value of latent heat of fusion 720 cal/mole into equation (22), ΔH_{act} is estimated to be 11.9 kcal/mole. This is consistent with the value obtained in the preceding section, 10 kcal/mole.

We may notice that the experiment of self-diffusion by the radioactive tracer method is planned to check the conclusion of our magnetic resonance experiments and to obtain more reliable activation energy.

In conclusion, we would like to thank Miss. H. Ibamoto for her collaboration in some part of the experimental work.

* In X-ray investigation, a slight inflection exists in the thermal expansion coefficient vs temperature curve at −30°C (ref. 2). In our proton magnetic resonance experiment, however, no such anomaly was observed at this temperature. We might be able to detect some change if we could measure spin-lattice relaxation time.

Magnetic Properties of Perovskites Containing Strontium

I. Strontium-Rich Ferrites and Cobaltites

By Hiroshi WATANABE

Research Institute for Iron, Steel and Other Metals,
Tohoku University

(Received January 28, 1957)

Magnetic susceptibilities and electrical conductivities of (La, Sr)(Fe/Co)O_x samples sintered in vacuo or in oxygen stream are measured here. Samples containing tetravalent magnetic ions in general have Curie contants smaller than those containing only trivalent ions. This fact and the high conductivity in the former specimens strongly support the combined effect of the double exchange and the usual exchange mechanism in these compounds. The parallel alignment of spins of magnetic ions due to double exchange is partly or completely hindered by the presence of the strongly negative trivalent-trivalent interionic interactions.

§ 1. Introduction

Since the ferromagnetic compounds with perovskite structure were discovered by Jonker and van Santen1), a considerable number of researches have been made on related compounds2–7), both on the experimental side and the theoretical side. The ferromagnetism is attributed to the positive exchange interaction between magnetic ions, and the magnetic properties of these compounds are generally affected strongly by the temperature and the atmosphere under which they have been prepared, since these factors influence the amount of oxygen in the crystal lattice, hence the valency of magnetic ions.

In their studies, Jonker and van Santen confined their samples to those "correctly prepared", as they call. For instance, $LaMnO_3$, when prepared correctly, should contain no Mn^{4+} ions, whereas $SrMnO_3$ shold have no Mn^{3+} ions. It is generally easy to obtain correct samples when the compound are rich in trivalent rare earth ions, whereas it is rather difficult to obtain correct samples from compounds with a large amount of divalent alkaline earth ions. This might be one of the reasons why Jonker and van Santen used samples with limited compositions of alkaline earth metals.

In the present study, we have selected the specimen without such a restriction, by studying the effect of sintering-atmosphere on the properties of a sample which has given cation composition. The effect becomes more remarkable according to an increase of the alkaline earth ions8); pure $SrFeO_x$ contains practically no Fe^{4+} ion, when sintered in vacuo, whereas it does contain 58% Fe^{4+}, if it is sintered and cooled in oxygen atmosphere. As a result there is a striking difference between these samples in their magnetic properties.

The second purpose of this study is to investigate the high temperature susceptibility of these compounds. Zener has proposed a mechanism of parallel alignment of spins of magnetic ions, called double exchange, and explained the ferromagnetism found in manganites. Anderson and Hasegawa9) pointed out that according to such a mechanism a behavior of the susceptibility above the Curie temperature would be different from that when merely usual exchange interactions are present. In a recent paper Jonker[10] states that no such effect can be found for manganites, and he seems to be inclined to put less weight on Zener's mechanism. We have examined this point for other compounds.

As a perliminary step for these purposes we have chosen (La, Sr) ferrites and (La, Sr) cobaltites as our samples. As was expected, the electrical conductivity is much increased with the coexistence of trivalent and tetravalent magnetic ions, and also the susceptibilities above the Curie temperature are changed from those where merely trivalent ions are present. This is not contradictory to the mechanism of double exchange, although complete alignment of ionic spins would not be realized in this case.

§ 2. Experimental Procedure and the Nature of the Samples

1. *Preparation of the samples*

All the samples were prepared by the usual ceramic method; the starting materials were pure La_2O_3, $SrCoO_3$, Fe_2O_3 prepared from FeC_2O_4, and Co_3O_4 prepared from cobalt sulphate. The starting materials were mixed in the desired proportions and milled in an agate mortar, prefired for two hours in air at about 1200°C, and then quenched. Then they were milled again and heated in air at about 1250°C for several hours. As for $SrFeO_x$, final heat treatments were carried out in various ways, in order to observe the change in character of this substance with x. For other compounds, the products were heat-treated in vacuo or in oxygen for several hours at 1100–1200°C. $SrCoO_x$, sintered in vacuo, showed a melting point lower than that of other compounds, and the sintering temperature was accordingly lowered (~1150°C). It showed a strong tendency to absorb oxygen in air even at room temperature, especially in the form of fine powder.

2. *Chemical analysis*

The chemical analysis was carried out by means of the procedure sketched in Yakel's paper[5] in the chemical analysis department of our institute. The result is listed in Tables I and II.

3. *X-ray powder patterns*

Crystal symmetry was studied for all the samples by means of the X-ray powder pat-

Table I. The relation between the amount of tetravalent ions and the crystal symmetry of $SrFeO_x$ samples.

No.	Heat-treated in	Chemical analysis		Crystal Symmetry
		% Fe^{4+} in tot. Fe	x	
1	Vacuo, 1300°C	0.49	2.50	Monoclinic
2	Vacuo, 1000°C	11.6	2.56	1+5
3	Air, 900°C	30.0	2.65	1+5
4	Air stream, 1150°C	45.3	2.73	1+5
5	Oxygen stream, 600°C	58.3	2.79	Neary cubic (Slightly tetragonal)

Table II. Crystal symmetry and the results of chemical analysis of (La, Sr)(Fe/Co)O_x samples.

Substance	Crystal symmetry		% Fe^{4+} or % Co^{4+}	
	Heat-treated in		Heat-treated in	
	Vacuo	Oxygen	Vacuo	Oxygen
$SrFeO_x$	Monoclinic	Neary cubic	0.5	58.3
$La_{0.5}Sr_{0.5}FeO_x$	Cubic	Cubic	0	47.6
$SrCoO_x$	Undetermined	Cubic	6.3	59.3
$La_{0.5}Sr_{0.5}CoO_x$	Undetermined	Cubic	11.3	61.0

tern technique, using a Fe anticathode tube and a 9 cm diameter camera. The result is listed in Tables I and II, together with that of the chemical analysis. It can be seen from Table I, that $SrFeO_x$ is monoclinic when x is small, but is almost cubic at the maximum value of x attained in our preparation. In the intermediate range of x values, the compounds were mixtures of both of the materials. The lattice parameters of the monoclinic and the nearly cubic phase, represented with respect to a single perovskite cell, were found to be:

monoclinic: $a \sim b = 3.95\text{Å}$, $c = 3.87\text{Å}$, $\gamma = 91°32'$;
nearly cubic (tetragonal): $a = 3.87\text{Å}$, $c = 3.85\text{Å}$.

The samples of $La_{0.5}Sr_{0.5}FeO_x$ are cubic, the lattice constants being

$La_{0.5}Sr_{0.5}FeO_x$ heat-treated in vacuo: $a = 3.90\text{Å}$;
$La_{0.5}Sr_{0.5}FeO_x$ heat-treated in oxygen stream: $a = 3.88\text{Å}$.

The powder patterns of these samples are shown in Photo. 1.

As for cobaltites, the difference in crystal structure was remarkable between samples heat-treated in vacuo and those heat-treated in oxygen stream. The latter samples are cubic, while we could not determine the crystal symmetry of the former. The system $SrCoO_x$ is more complicated than $SrFeO_x$, and

$SrFeO_x$, heat-treated in vacuo.

the phase diagram has not yet been studied in detail at present. The powder patterns in this case is shown in Photo. 2. The lattice constants of the cubic samples are:

$SrCoO_x$ heat-treated in oxygen stream: $a=3.85$Å;

$La_{0.5}Sr_{0.5}CoO_x$ heat-treated in oxygen stream: $a=3.83$Å.

4. *Magnetic measurements*

A. High temperatures. Magnetic measurements above room temperature were carried out with a pendulum magnetometer and a de Bois type electromagnet. The sample was heated by a small platinum furnace and the temperature was read with a Pt-PtRh thermocouple. The sample container for samples treated in vacuo was a small hollow spherical silica globe with a small cock, attached to one end of the pendulum beam. It was detachable from the beam and could be evacuated after the sample was put in.

This container, however, could not be used for samples not treated in vacuo, since the oxygen in the crystal lattice of the sample was apt to escape from it during heating. To protect samples from oxygen emission, we had to use another type of container, which was sealed off leaving a dead space as small as possible. Then, the results of the measurements became almost reversible on heating from room temperature to 900°C and subsequent cooling, except for $SrCoO_x$, in which case heating above 600°C gave irreversible results.

B. Low temperatures. The low temperature magnetizations were measured with a magnetic balance and a cyclotron type electromagnet installed in the low temperature laboratory of our institute. The magnetic field used was about 15000 Oe. The temperature was read with a Cu-constantan thermocouple.

5. *Conductivity measurements*

Samples for the measurements of electrical conductivity were made from the sintered products stated in *1*. They were pressed in the form of rectangular bars of $5\,mm^2 \times 3\,cm$. Potential terminals were thin platinum wires inserted in the pressed bricket through pressing. These brickets were heat-treated under the same condition as when they had been prepared. After the heat-treatment, the attachment of the terminals to the specimen became very tight. It was only the specimen $SrCoO_x$ treated in vacuo that caused some difficulty in making such brickets. It was apt to disintegrate in the course of heat-treatment. So we used a melted mass with electrodes attached to it in a similar manner.

Measurements below room temperature were carried out in vacuo, whereas, those above room temperature were done in vacuo or in oxygen stream, according as the sample had been treated in vacuo or in oxygen. All of the results were reversible in heating and cooling in the temperature range of measurement.

§ 3. Experimental Results

1. *Magnetic properties*

Fig. 1 shows the effect of heat treatment on the susceptibilities of $SrFeO_x$. As can be seen from the figure, this substance, when it is poor in oxygen (specimen 1 of Table I) has an antiferromagnetic character with the Néel point near 400°C. As given in Table I, it contains practically no Fe^{4+} ion, *viz.*, its chemical formula is $SrFeO_{2.5}$, so the antiferromagnetism may be attributed to $Fe^{3+}-Fe^{3+}$ interaction in the substance. On the contrary, when it is rich in oxygen (specimen 5 of Table I), it has an approximate composition of $SrFeO_{2.8}$, and does not have any Néel point, while its susceptibilities are much greater. In

accordance with the phase relation given in Table I, the susceptibilities of the substances of intermediate values of x are what is to be expected for mixtures of those of $x=2.5$ and 2.8. In an earlier paper10), the specimens were quenched or slowly cooled in air, and these correspond to the intermediate mixtures. There the measurements were made with an open sample container. We have, however, ascertained that the results of the measurements were completely irrespective of the rate of cooling provided that the measurements were carried out with a sealed sample container as described in *4*. of § 2.

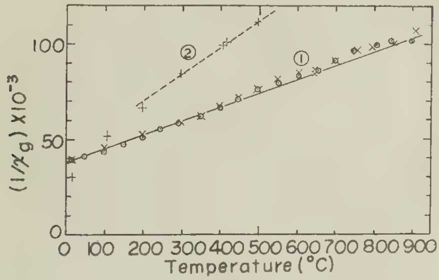

Fig. 3. $(1/\chi_g)$ *vs* temperature curves of $SrCoO_x$ samples, heat-treated in
① vacuo.
② oxygen stream

As for $La_{0.5}Sr_{0.5}FeO_x$, both the samples treated in vacuo and in oxygen is weakly ferromagnetic (Fig. 2). The origin of the ferromagnetism is not clear at present, but it is evident that it is the same as that found in $LaFeO_3$10),11). If we assume this ferromagnetism to be something like the parasitic ferromagnetism of α-Fe_2O_3, its Curie temperature might be identified with the Néel temperature. The behavior of the susceptibilities above this temperature for the substance treated in vacuo suggests that it is strongly antiferromagnetic, since its paramagnetic Curie temperature is as low as −2100°K. When the specimen is treated in oxygen, the Néel temperature becomes lower, and the high temperature susceptibilities become greater.

samples, heat-treated in oxygen stream.

In the case of cobaltites, samples treated in vacuo are probably antiferromagnetic, since they have negative paramagnetic Curie temperatures. (Figs. 3 and 4) On the contrary,

those treated in oxygen have spontaneous magnetization below room temperature. (Fig. 5) The reciprocal susceptibility *vs* temperature curves are straight lines for samples treated in vacuo, whereas they are slightly curved and have a greater overall inclination against temperature axis for samples treated in oxygen. These data are summarized in Table III.

2. *Electrical conductivity*

There is a great difference in the magnitude of electrical conductivity between various substances (Figs. 6 and 7). $SrFeO_x$ treated in vacuo has a high activation energy and a high electrical resistivity, whereas that treated in oxygen has a low activation energy and a low electrical resistivity. Also, $La_{0.5}Sr_{0.5}FeO_x$ treated in vacuo had extremely high resisti-

Table IV. Electrical resistivity of (La, Sr)(Fe/Co)O_x samples.

Substance	20°C (Ω cm) Heat-treated in vacuo	20°C (Ω cm) Heat-treated in oxygen	Max. Act. Energy (eV) Heat-treated in vacuo	Max. Act. Energy (eV) Heat-treated in oxygen
$SrFeO_x$	2.3×10^5	3.3×10^{-1}	0.183	0.021
$La_{0.5}Sr_{0.5}FeO_x$	Very high	4.9×10^{-2}	Very high	0.143
$SrCoO_x$	8.9×10^6	3.9×10^{-4}	0.211	0.021
$La_{0.5}Sr_{0.5}CoO_x$	4.9×10^2	6.9×10^{-4}	0.138	Metallic

vity, and accurate measurement was impossible in our experiment, whereas that treated in oxygen could easily be measured, though it had fairly high resistivity at low temperatures.

As for $SrCoO_x$ the difference between samples treated in vacuo and in oxygen is even greater than in $SrFeO_x$. This might partly be due to the differences in crystal structure. Also the samples containing La behave just in the same way as ferrites, but here the temperature coefficient of resistivity is positive in accord with Jonker's result. These data are summarized in Table IV.

§ 4. Discussion and Conclusion

The ferromagnetism observed in the system of manganites has been ascribed by Zener to the double exchange between Mn^{3+} and Mn^{4+} ions. This type of exchange would be expected not only between manganese ions, but also between other transition metal ions. Jonker has found this for cobaltites, although the values of saturation magnetization are far below those predicted from the total contribution of spins of Co^{3+} and Co^{4+} ions. As for ferrites, ferromagnetism which can be considered to be caused by the interplay of Fe^{3+} and Fe^{4+} has not been found.

Such a situation would be considered to be as follows. In the case of manganites, not only the interaction $Mn^{3+}-Mn^{4+}$ is positive, but also the interaction $Mn^{3+}-Mn^{3+}$ is weakly positive in the cubic phase[10]. In the case of cobaltites, however, the interaction $Co^{3+}-Co^{3+}$ is negative, and may partly counteract the double exchange interaction $Co^{3+}-Co^{4+}$. With this idea, Kishi[12] has calculated the magnetism of manganites and cobaltites, taking into account the formation of triangular spin arrangement. His calculation, basing on the molecular field approximation, should be criticized, since it does not treat positive interaction of double exchange correctly. The low saturation values of cobaltites deduced from his theory, however, might be essentially correct. Since the negative interaction $Fe^{3+}-Fe^{3+}$ is very strong in ferrites, it is natural that the ferromagnetism due to double exchange is completely hidden.

From our data on electrical conductivity, it is highly probable that there is a positive interaction of double exchange between trivalent and tetravalent ions in cobaltites and ferrites. This can be seen apparently from the difference in conductivity between $La_{0.5}Sr_{0.5}FeO_x$ treated in vacuo and in oxygen. Here the crystal structure is the same for both samples, and also the difference in the lattice parameter, hence that in the interionic distance is very small. The high conductivity in the sample treated in oxygen is evidently caused by the coexistence of Fe^{3+} and Fe^{4+}.

From the data on paramagnetic susceptibilities, it can be seen that samples treated in vacuo obeys the Curie-Weiss law above their Curie temperatures, and the effective Bohr magneton numbers are not far from what would be expected for the spin-only values of magnetic ions. (Table III) On the contrary, the effective Bohr magneton numbers of samples treated in oxygen are smaller than those of the corresponding samples treated in vacuo, and, in cobaltites, there is an evidence that reciprocals of susceptibilities do not obey the Curie-Weiss law, but exhibit a slight curvature as found in ferrimagnetism. Such a behavior of susceptibilities may be accounted for either from the standpoint of double exchange, as calculated by Anderson and Hasegawa, or by the theory of ferrimagnetism. As for ferrimagnetism there are again two possibilities. One is that it may be due to a formation of unbalanced antiferromagnetic sublattices, tetravalent ions occupying preferably one of the sublattices. The other is that it may be due to the formation of triangular arrangement of spins of magnetic ions, as proposed by Kishi.

We have at present no definite grounds for supporting one mechanism in preference to the other between these possibilities. It should be noticed, here, that the susceptibilities showed no appreciable change on rapid cooling from high temperatures (provided the cooling was done without change in the value of x) This would mean that the time required for the redistribution of magnetic ions is much shorter than that required for technical cooling, because the redistribution involves only electron jumping. Then the distribution of trivalent and tetravalent ions is a unique function of temperature, determined by electrostatic energies, magnetic interaction energies, &c. In the mechanism of double exchange, the ions adjust their positions according to the positive magnetic interaction and temperature. This is the origin of the deviation from the Curie-Weiss law. On the contrary, this effect is completely neglected in Kishi's theory. The author believes that the theory would give an adequate explanation of experimental data, if it is corrected as to this neglection.

It is quite certain from our experiment that the interaction $Fe^{3+}-Fe^{4+}$ is positive, irrespective of which standpoint we adopt. Also we can expect the interaction $Co^{3+}-Co^{4+}$ to be positive from the standpoint of double exchange, However, we cannot deduce any definite conclusions about sign and strength of tetravalent—tetravalent interionic interactions, since the materials treated in our experiment do not contain a sufficient amount of tetravalent ions.

In conclusion, the author wishes to express his thanks to Prof. T. Hirone for his valuable advices, and also to Mr. K. Ito for his assistance in the experiments. This work has been supported in part by the Scientific Research Expenditure of the Ministry of Education.

Nuclear Magnetic Resonance Experiment on Metal Cadmium*

By Yoshika MASUDA

Department of Physics, Kobe University

(Received January 29, 1957)

The Knight shift, the line width and shape, and the spin-lattice relaxation time of the resonance line in metal cadmium are measured employing a nuclear magnetic resonance technique. The resonance line is asymmetric indicating an anisotropy of the Knight shift. From the analysis of these line shapes, the asymmetry in p-character of the conduction electron is estimated. The shift perpendicular to the c-axis is 0.42 percent and the shift parallel to the c-axis is 0.46 percent. The isotropic shift is 0.43 percent. In appendix, skin effect in metallic foil is discussed.

§ 1. Introduction

Knight[1] discovered that the resonance frequency is higher for nuclei in metals than for that of the same isotope in a non-conducting material in the same magnetic field. Townes[2] pointed out that the enhancement of a local field produced at the position of the nucleus is attributable to the hyperfine interaction between the nuclear magnetic moment and the conduction electron in s state. Besides this isotropic shift, in non-cubic crystals, non s-character (p-, d-, etc.) of the electron orbitals gives rise to an anisotropy of the Knight shift.[3] Such an anisotropy usually leads to an anomalous broadening and asymmetry of resonance line, and this anisotropic Knight shift gives the measure of asymmetry in p-character of electron at the top of the conduction band.

The fact that the nuclear magnetic resonance line width in heavier metals may be broader than expected from magnetic dipole interaction alone was pointed out by Bloembergen and Rowland[4] for metal thallium and tin, and by us[5] for metal cadmium. Besides the line broadening by anisotropic Knight shift, this extra broadening could be attributed to the indirect exchange coupling between neighboring nuclei which involves conduction electrons. Additional broadening for nuclei with spin $I>1/2$ might be caused by the nuclear quadrupole interaction but cadmium nuclei with $I=1/2$ have zero quadrupole moment so that the quadrupolar effects are excluded. Natural cadmium contains, as the magnetic isotopes, Cd^{111} (abundance ratio 12.86 percent) and Cd^{113} (abundance ratio 12.34 percent).

We measured the Knight shift, the line width and shape, and the spin-lattice relaxation time of nuclear magnetic resonance in metal cadmium.

§ 2. Experiment

The experimental procedures and equipments employed for the measurement have been described elsewhere.[6] The Knight shift is defined as $(H_r-H_s)/H_r$ for a constant resonance frequency, where H_r and H_s are the magnetic fields necessary for resonance for the reference and the sample, respectively. The reference was an aqueous solution of the cadmium nitrate. The experiment was performed at the field of 6200 gauss with a permanent magnet described previously[6] whereas at 3900 gauss, with the other permanent magnet which was newly constructed by NKS-3 steel of 50 kgs and has a gap of 4 cm and the pole faces of 13 cm in diameter. Experiment at a higher field of 8350 gauss was carried out with a usual electromagnet.

The sample was consisted of fine powders which were passed through a 320 mesh sieve permitting the size small compared to the skin depth, and were suspended in paraffin oil. Other samples were consisted of foils rolled to a thickness of about 15 μ. Layers of foil were separated by insulating paper. Fe less than 0.01 percent was the dominant impurity, which does not affect the width and shape of the resonance.

---

* A report of this work was given at the annual meeting of the Physical Society of Japan, Sendai, July, 1956. Recently, T. J. Rowland reported the Knight shift for metal cadmium, in Phys. Rev., **103** (1956) 1670, independently. His results agree with ours within experimental error.

Table I. Experimental results in metal cadmium.

	Knight shift $\Delta H_{\mathrm{iso}}/H_0$	Line width (δH) max. sl.			T_1
		3900 gauss	6200 gauss	8350 gauss	
Cd^{111}	4.3×10^{-3}	1.8 ± 0.2 gauss	2.3 ± 0.2 gauss		0.5×10^{-3} sec
Cd^{113}	4.3×10^{-3}	1.9 ± 0.2	2.4 ± 0.2	2.9 ± 0.3 gauss	0.5×10^{-3}

§ 3. Results and Discussion

Experimental results are shown in Table I. The derivative curve of nuclear magnetic resonance line of metal cadmium is shown in Fig. 1 and its integrated line shape in Fig. 2.

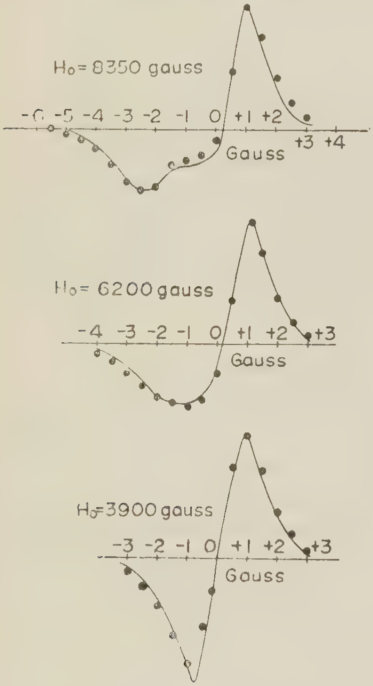

Fig. 1. The derivative of the Cd^{113} resonance line: comparison of theory and experiment. Solid curve: Derivative of the theoretical line shape. Dots: Experimental points taken from a typical recording beter plot.

The absorption curve is markedly asymmetric indicating an anisotropy of the Knight shift. Data were obtained at the field of 3900, 6200, and 8350 gauss and it is shown in Fig. 3 that the overall width is proportional to the applied field. Resonance figure of metals often becomes asymmetric due to the skin effect.[7] Asymmetry here observed is distinguished from the skin effect by two points; (1) Sharp rise of the resonance figure is in the high field side which is opposite to the case of the skin effect. (2) While the skin effect asymmetry is sensibly affected by the thickness of the foil, the asymmetry now in problem is not. In appendix we analyzed the asymmetry due to the skin effect both theoretically and experimentally.

Cadmium is a divalent metal, and it is expected that the electrons at the Fermi level have p-character considerably. The crystal structure of cadmium is the hexagonal close-packed whose c/a ratio being 1.886 is exceptionally much deviated from the ideal one (1.633). Each atom has twelve neighbors of which the six in the plane perpendicular to the c-axis are at the distance of 2.973 Å while the others at 3.286 Å. Naturally it has an axial symmetry about the c-axis but not a spherical symmetry.

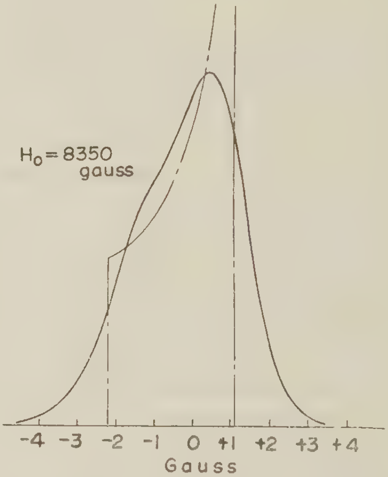

Fig. 2. The integrated experimental line shape of the Cd^{113} resonance is given by the full-drawn curve. The chain-line is the theoretical shape for powders with axial symmetry.

The electron in the solid may be adequately described by one-electron wave function of the Bloch type,

$$\Psi_k = e^{ik\cdot r}U_k(r)\,. \tag{1}$$

$U_k(r)$ has the periodicity of the lattice, and within the atomic polyhedron, it is assumed to be consisted of mixture of s- and p-type wave functions of the form

$$U_k(\mathbf{r}) \rightarrow a_s\varphi_s + a_1\varphi_{p_x} + a_2\varphi_{p_y} + a_3\varphi_{p_z}\ , \qquad (2)$$

where

$$|a_s|^2 + |a_1|^2 + |a_2|^2 + |a_3|^2 = 1\ .$$

In case of axial symmetry we can expect that

$$\langle |a_1|^2 \rangle = \langle |a_2|^2 \rangle = \eta\ ,$$

and by the way we put

$$\langle |a_s|^2 \rangle = \xi \quad \text{and} \quad \langle |a_3|^2 \rangle = \zeta\ ,$$

where $\langle\ \rangle$ means the average over the Fermi surface.

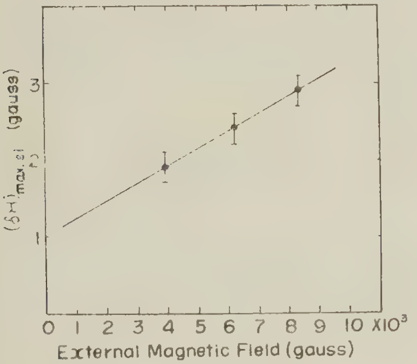

Fig. 3. The line width, measured between points of maximum slope, in the Cd^{113}, vs. the external magnetic field.

The Hamiltonian for the nuclear spin-electron spin interaction is given by

$$\mathscr{H} = \frac{16\pi}{3}\beta\beta_N g_N \mathbf{I}_i \cdot \mathbf{S}\delta(\mathbf{r}_i)$$

$$+ 2\beta\beta_N g_N \mathbf{I}_i \cdot \{\mathbf{S}r_i^{-3} - 3r_i^{-5}(\mathbf{S}\cdot\mathbf{r}_i)\mathbf{r}_i\}\ , \qquad (3)$$

where $\mathbf{r}_i$ is the radius vector of the electron with the nucleus at the origin and β is the Bohr magneton.

a) *Isotropic Knight shift*

The isotropic Knight shift is produced by the Fermi-type hyperfine interaction of the nuclear spin with the electron spin in s-state and is given by the first term of the Hamiltonian (3). It results in

$$\frac{\Delta H_{iso}}{H_0} = \frac{16\pi}{3}\beta^2\kappa\langle |u_k(0)|^2 \rangle \Omega N(E_0)\ , \qquad (4)$$

where κ is the relativistic correction (1.28 for $5s$, ${}^2S_{1/2}$), Ω is the atomic volume, and $N(E_0)$ is the density of states, the number of states per unit volume and per unit energy interval, at the Fermi level. $N(E_0)$ may be known, if available, from paramagnetic susceptibility χ_p or electronic specific heat C_v. Although the experimental value of χ_p of cadmium is listed in the reference (8), we estimated $N(E_0)$ by the formula

$$\Omega N(E_0) = \frac{3}{2}E_0^{-1}\ ,$$

which is deduced for divalent metal by the free electron model. Using the collective description of electron interaction introduced by Bohm and Pines,[9] E_0 was estimated to be 0.409 ry. It leads to χ_p of 1.36×10^{-6} c.g.s. volume unit whereas χ_p derived from the complete free electron model is 1.02×10^{-6} and the experimental value derived from measurement of electronic specific heat is 0.753×10^{-6}. Introducing Eq. (2), $|u_k(0)|^2$ in Eq. (4) is reduced to

$$|u_k(0)|^2 = \xi|\varphi_s(0)|^2\ .$$

It is very hard to obtain the exact wave functions φ_s and φ_p of metal cadmium and hereafter we will replace them, as a crude approximation, by the atomic s- and p-functions. Cadmium has two free electrons per atom and each will move in the field partially shielded by an another electron. φ_s seems to be better approximated by atomic $5s^2$ function of Cd I ${}^1S_0$-state than $5s^1$ of Cd II ${}^2S_{1/2}$-state but we refered to the states of Cd II because the atomic functions of Cd II are rather reliable than those of Cd I owing to the simple structure (one valence electron) of the former. In Table II the calculated value of $|\varphi_s(0)|^2$ are listed using the standard formula[10] for non-hydrogenic wave function. As a reference, the hyperfine splitting of the atomic spectrum $\lambda(8067)$ ($6s\ {}^2S_{1/2} - 6p\ {}^2P_{3/2}$) of Cd II was evaluated by the same way resulting in good agree-

Table II.

Atomic state	$\|\varphi_s(0)\|^2$	$\left\langle \frac{1}{r^3} \right\rangle$	ξ	η	ζ
Cd I	5.63×10^{25} cm^{-3}	3.00×10^{25} cm^{-3}			
Cd II	7.26×10^{25}	4.35×10^{25}	0.20	0.20	0.40

ment with the experimental value[11)] of $\Delta\nu=0.11\,\text{cm}^{-1}$. Using the experimental value of $\Delta H_{iso}/H_0$ and the calculated values of $|\varphi_s(0)|^2$ and $\Omega N(E_0)$, we determined the s-content ξ of the wave function to be about 20 percent. The fact that the p-character of the free electron of cadmium in the Fermi surface is as large as 80 percent is not so surprising as compared with the values: 65 percent for Na[12)] and more than 50 percent for Sn[3)].

b) *Anisotropic Knight shift*

The anisotropic Knight shift is produced by the nuclear spin-electron spin dipolar coupling when the charge distribution of electron is deviated from spherical symmetry about a nucleus and is deduced from the second term of the Hamiltonian (3). This anisotropic Knight shift is superimposed on the isotropic Knight shift. Since in first-order approximation only the component of the internal field parallel to the external field will affect the resonance, $\Delta H_{\parallel}$ and $\Delta H_{\perp}$, the shifts parallel and perpendicular to the c-axis, respectively, are given by the following formulae in case of axial symmetry:

$$\Delta H_{\parallel}=\Delta H_{\text{iso}}+2\beta^2\Omega N(E_0)qH_0\,,$$

$$\Delta H_{\perp}=\Delta H_{\text{iso}}-\beta^2\Omega N(E_0)qH_0\,,$$

and

$$\frac{\Delta H_{\parallel}-\Delta H_{\perp}}{H_0}=3\beta^2\Omega N(E_0)q\,, \qquad (5)$$

where

$$q=\left\langle\int u_k^*\frac{3\cos^2\theta-1}{r^3}u_k d\tau\right\rangle_{\kappa'}$$

$$=\frac{4}{5}\kappa'\left\langle\frac{1}{r^3}\right\rangle_p(\zeta-\eta)\,, \qquad (6)$$

is the quadrupole moment of the electrons near the Fermi level and κ' is again the relativistic correction (1.21 for $5p\ {}^2P_{1/2}$). The ratio of $(\Delta H_{\parallel}-\Delta H_{\perp})$ to ΔH_{iso} does not contain the ambiguous quantity $\Omega N(E_0)$ in its expression

$$\frac{\Delta H_{\parallel}-\Delta H_{\perp}}{\Delta H_{\text{iso}}}=\frac{9}{20\pi}\,\frac{\kappa'\left\langle\frac{1}{r^3}\right\rangle_p}{\kappa|\varphi_s(0)|^2}\,\frac{\zeta-\eta}{\xi} \qquad (7)$$

$(\Delta H_{\parallel}-\Delta H_{\perp})$ was determined by the experiment as discussed in section c) and it revealed that q is positive and hence $\zeta>\eta$. We again approximated the metallic p function by the atomic $5p$ function of Cd I, ${}^3P_1$-state or Cd II, ${}^2P_{1/2}$ and estimated $\left\langle\frac{1}{r^3}\right\rangle_p$ by the standard formula[10)] using the optically determined fine structure separation, $\delta({}^2P_{3/2}-{}^2P_{1/2})=2485\,\text{cm}^{-1}$ and $\delta({}^3P_2-{}^3P_0)=1714\,\text{cm}^{-1}$. In Table II are listed the values of $\left\langle\frac{1}{r^3}\right\rangle_p$ thus obtained as well as η and ζ estimated from Eq. (7) and the normalization condition of a's. The fact $\zeta>\eta$ corresponds to the charge distribution of the electron in the Fermi surface being elongated to the c-direction so that the atomic polyhedron is filled up by electron as uniformly as possible.

c) *Line shape and width*

The line shape in a polycrystalline sample is dominated by the anisotropic Knight shift when $(\Delta H_{\parallel}-\Delta H_{\perp})$ is larger than the symmetric width due to the dipole coupling and so on. Spatially random distribution of the crystalline axes determines the line shape whose analytic form in case of axial symmetry was given by Bloembergen,[3)]

$$I(H)\backsim(H-H_0-\Delta H_{\perp})^{-1/2}\ \text{if}\ \Delta H_{\perp}<H-H_0<\Delta H_{\parallel}\,, \qquad (8)$$

$I(H)=0$ outside this interval.

One may obtain true line shape by dressing a symmetric line broadening δ on the skeleton of the anisotropic shift given by Eq. (8). By proper choice of the magnitude of $(\Delta H_{\parallel}-\Delta H_{\perp})/H_0$ and δ, we can fit the theoretical line shape to all of the experimental lines at 3900, 6200, and 8350 gauss as shown in Fig. 2. The best fitted values are;

$$(\Delta H_{\parallel}-\Delta H_{\perp})/H_0=0.039\ \text{percent}$$

$$\delta\ \text{max. sl.}=1.5\ \text{gauss.}$$

Then the relative anisotropy of the Knight shift is as follows;

$$\frac{\Delta H_{\parallel}-\Delta H_{\perp}}{\Delta H_{\text{iso}}}=9.3\ \text{percent.}$$

This value was used for the determination of the anisotropy in p-character as stated in section b).

The second moment of the symmetric broadening δ assuming the Gaussian shape is 0.59 gauss^2 and is ten times as large as the second moment of the nuclear dipole coupling, 0.05 gauss^2. Subtracting further broadening by the field inhomogeneity and by T_1, there remains 0.52 gauss^2 which suggests the other origins of the broadening such as the indirect exchange coupling or the pseudo-dipolar coupling.[4,13)]

The indirect exchange coupling $A_{ij}\mathbf{I}_i\cdot\mathbf{I}_j$ is the coupling between the magnetic moments of two nuclei via their hyperfine interaction with the conduction electron. Taking $m^*=m$ and $\xi=1$, we estimated A_{ij} between nearest neighbors of Cd^{113} to be 2.78 gauss. If one takes ξ to be 0.65, the indirect exchange coupling would yield just the extra broadening 0.52 gauss^2 but if 0.20 it can interprete only one percent of the broadening. Since the second moment is proportional to the fourth power of ξ, its uncertainty affects so seriously to the broadening.

Pseudo-dipolar coupling between the spins i and j is given by

$$\mathscr{H}_{ij}^{\mathrm{dip}}=\{\mathbf{I}_i\mathbf{I}_j-3\mathrm{R}_{ij}^{-2}(\mathbf{I}_i\cdot\mathbf{R}_{ij})(\mathbf{I}_j\cdot\mathbf{R}_{ij})\}\mathrm{B}_{ij}$$

The coefficient B_{ij} is hardly estimated unless the band structure is known but the ratio B_{ij} to A_{ij} is, in its order of magnitude, given by the formula similar to Eq. (7),

$$\frac{\mathrm{B}_{ij}}{\mathrm{A}_{ij}}\sim\frac{9}{20\pi}\frac{\kappa'\left\langle\frac{1}{r^3}\right\rangle}{\kappa|\varphi_s(0)|^2}\frac{1-\xi}{\xi}\,.$$

The ratio was estimated to be 0.3 so that the pseudo-dipolar coupling will contribute to the broadening to some extent.

d) *Relaxation time*

The nuclear relaxation in metals is usually determined by interaction between nuclear spins and conduction electron spins. If one takes into account only the Fermi-interaction, the relation between the relaxation time and the Knight shift is usually refered to as the "Korringa relation",[14)]

$$T_1T(\varDelta H/H_0)^2=\frac{h}{\pi k}\left(\frac{\beta}{\gamma\hbar}\right)^2.$$

From the experimental value of the Knight shift, the relaxation time T_1 was estimated to be 1.1×10^{-3} sec. For the direct measurement we employed the ordinary saturation method and evaluated T_1 using the T_2 as determined from the symmetric line broadening δ. It results in T_1 of 0.5×10^{-3} sec. for Cd^{113} which is one half of the calculated one. This deviation from the Korringa relation may be due to the contribution of p-electron to the relaxation as suggested by Bloembergen.[15)]

In conclusion, the author wishes to express his hearty thanks to Professor T. Kanda for kind guidance and stimulating discussion throughout the course of this research. He is also indebted to Mr. T. Kojima for many helpful discussion, Dr. Y. Kitano for performing the chemical analysis of the sample, and Mr. K. Kuninobu for his technical assistance. This work has been supported in part by the Scientific Research Expenditure of the Ministry of Education.

Appendix

Note on the Skin Effect of the Magnetic Resonance Absorption in Metals.

It is well known that, in the nuclear magnetic resonance in metals, when the characteristic dimensions of the sample are not less than the rf skin depth, the line shape is distorted, whence the exact center of resonance is uncertain. This effect was analyzed by Bloembergen[7)], who pointed out that the phase shift of the rf fiield within the metal surface produces a mixture of the absorption and the dispersion components of the resonance.

We shall discuss only the case of the flat plate, which is of a convenient shape both experimentally and theoretically. The metal is considered to be infinite in the x and y directions, thus it occupies the region $-d\leqslant z\leqslant d$, where $2d$ is the thickness of the plate. We assume that the fields depend on z only so that the problem may be essentially one dimensional, and also that the magnetic field is equal on both sides of the plate. The power absorbed per unit area—the power is flowing in from both sides—is given by[7)]

$$W=Re\left(\frac{i\omega\mu}{4\pi K}H_0^2\tanh Kd\right), \qquad (9)$$

where K is the propagation constant,

$$K^2=(4\pi i\sigma\omega\mu-\omega^2\varepsilon\mu)/c^2\,.$$

The dielectric constant $\varepsilon=\varepsilon'-i\varepsilon''$ and the permeability $\mu=\mu'-i\mu''=1+4\pi\chi'-4\pi i\chi''$ may be complex. The classical skin depth is usually defined as $\delta^{-1}=ReK$. It is given approximately by

$$\delta=c/(2\pi\sigma\omega)^{1/2}\,,$$

where σ is the conductivity of the metal. Now, putting $d/\delta=x$, Eq. (9) becomes

$$W=\frac{\delta\omega H_0^2}{8\pi}\{(\mathscr{R}-\mathscr{J})+4\pi\chi'(\mathscr{R}-\mathscr{J})+4\pi\chi''(\mathscr{R}+\mathscr{J})\}, \qquad (10)$$

where

$$\left.\begin{aligned}\mathscr{R}&=\frac{\frac{1}{2}\sinh 2x}{\cosh^2 x\cos^2 x+\sinh^2 x\sin^2 x}\,,\\ \mathscr{J}&=\frac{\frac{1}{2}\sin 2x}{\cosh^2 x\cos^2 x+\sinh^2 x\sin^2 x}\,.\end{aligned}\right\}\qquad(11)$$

The experimentally observed quantity is the derivative of absorbed power with respect to the frequency and is given by the next formula under an assumption of the Lorentzian shape of resonance line:

$$\frac{dW}{d\omega}=-\frac{\delta\omega H_0^2}{4}\chi_0\omega_0T_2\left\{\frac{[1-T_2^2(\omega-\omega_0)^2]T_2}{[1+T_2^2(\omega-\omega_0)^2]^2}(\mathscr{R}-\mathscr{J})+\frac{2T_2^2(\omega-\omega_0)}{[1+T_2^2(\omega-\omega_0)^2]^2}(\mathscr{R}+\mathscr{J})\right\}\qquad(12)$$

where ω_0 is the resonance frequency satisfying the conditition $\hbar\omega_0=g\beta H_0$.

Employing Eq. (12), we can calculate the change with the thickness of the plate, of maximum slope separation, of the degree of asymmetry and of the position at which the derivative curve cuts the horizontal line. In Fig. 4 are given the calculated curves as well as the experimental points obtained by five kinds of samples consisted of well annealed aluminum foil of thickness 6, 15, 25, 50, and 100 μ respectively. When the resonance frequency is held constant, as x increases, the separation of the maximum slope increases and the resonance line shifts to the high field side. In pure aluminum no decrease in intensity after cold work was observed. The fact that the resonance in pure aluminum shows no effect of quadrupole broadening has been known.[15] The resonance line gained by very thin foil of pure aluminum is symmetric showing the lack of the anisotropy of the Knight shift and moreover the width is in good agreement with that calculated by pure dipolar coupling neglecting the atom diffusion. Accordingly, the line shape anomaly of the thick foil must be due only to the skin effect and, as seen in Fig. 4, it is completely interpreted by the simple theory of the skin effect.

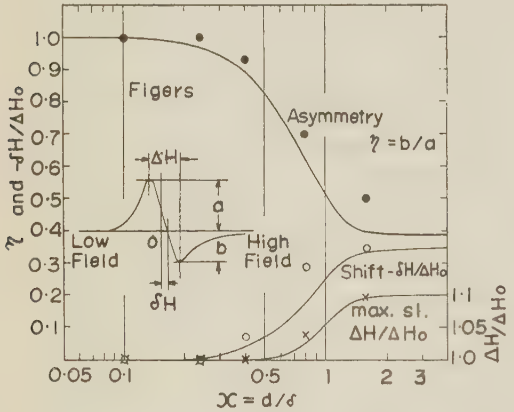

Fig. 4. Asymmetry η, shift $\delta H/\Delta H_0$, and max. slope separation $\Delta H/\Delta H_0$ vs. $x=d/\delta$.

On the Buckling of an Eliptic Plate with Clamped Edge, II

By Yoshio Shibaoka
Institute of Polytechnics, Osaka City University

(Received January 16, 1957)

The buckling of a uniform thin elliptic plate with clamped edge is dealt with in case when its periphery is subject to a uniform normal pressure in the plane of the plate, and the relationship between the critical buckling load and the eccentricity of the elliptic plate is shown graphically.

§ 1. Introduction

In a previous paper[1)], the fundamental normal mode of the buckling of a uniform thin elliptic plate with clamped edge was discussed formally in an exact manner in case when its periphery is subject to a uniform normal pressure in the plane of the plate. No detailed numerical discussions were carried out, however, and only an approximate formula giving the relationship between the critical buckling load and the eccentricity of the elliptic plate was derived correct to the fourth power of the eccentricity which may be adequately used in case when the eccentricity is not so large.

In the present paper, we have carried out rather laborious numerical calculations and the relationship between the critical buckling load of the fundamental normal mode of the buckling and the eccentricity of the elliptic plate is shown graphically.

§ 2. General Solution of the Fundamental Equation

Let the rectangular coordinate axes (x, y) be taken in the middle plane of an elliptic plate of uniform thickness, d, in such a way that the origin coincides with the centre of the plate and the axes are along the major and minor axes of the ellipse respectively. We denote Young's modulus and Poisson's ratio of the material of the plate, which is assumed to be homogeneous and isotropic, by E and σ respectively.

Then if w be the transverse displacement of a point on the middle plane, the differential equation for determining the deflection of the buckled plate subject to a uniform normal pressure P per unit length on its periphery is given by

$$\left.\begin{aligned} D\left(\frac{\partial^4 w}{\partial x^4}+2\frac{\partial^4 w}{\partial x^2\partial y^2}+\frac{\partial^4 w}{\partial y^4}\right) &= -P\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial y^2}\right), \\ \text{with}\quad D=Ed^3/\{12(1-\sigma^2)\}\ . & \end{aligned}\right\} \tag{1}$$

If, for simplicity, we write $k_1{}^2=P/D$, equation (1) becomes

$$\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+k_1{}^2\right)w=0\ . \tag{2}$$

Denoting the focal length of the ellipse by $2h$, we now introduce the elliptic coordinates (ξ, η) defined as:

$$x+iy=h\cosh(\xi+i\eta)\ .$$

Then, as explained in the previous paper[1)], if we restrict our attention to the normal mode of buckling in which the displacement is symmetrical about both axes, a formal general solution of equation (2) can be written in the form

$$w=\sum_{m=0}^{\infty}\left\{C_{2m}\cosh 2m\xi+\sum_{l=0}^{\infty}\overline{C}_{2l}A_{2m}^{(2l)}\,\mathrm{Ce}_{2l}(\xi,q)\right\}\times\cos 2m\eta\ , \tag{3}$$

with

$$q=\frac{1}{4}k_1{}^2h^2=\frac{P}{4D}h^2\ , \tag{4}$$

where C_{2m} and $\overline{C}_{2l}$ are arbitrary constants. If the clamped edge of the elliptic plate be expressed by $\xi=\xi_0$, the boundary conditions at this edge are given by

$$(w)_{\xi=\xi_0}=0\ ,\qquad \left(\frac{\partial w}{\partial\xi}\right)_{\xi=\xi_0}=0\ , \tag{5}$$

and substituting the expression (3) for w into these conditions, we have

$$\left.\begin{aligned} &\sum_{m=0}^{\infty}\left\{C_{2m}\cosh 2m\xi_0+\sum_{l=0}^{\infty}\overline{C}_{2l}A_{2m}^{(2l)}\mathrm{Ce}_{2l}(\xi_0,q)\right\}\\ &\qquad\qquad\times\cos 2m\eta=0\,,\\ &\sum_{m=0}^{\infty}\left\{2mC_{2m}\sinh 2m\xi_0\right.\\ &\quad\left.+\sum_{l=0}^{\infty}\overline{C}_{2l}A_{2m}^{(2l)}\mathrm{Ce}_{2l}'(\xi_0,q)\right\}\cos 2m\eta=0\,.\end{aligned}\right\} \tag{6}$$

In order that these two relations should be satisfied for all values of η between $-\pi/2$ and $\pi/2$, we must have, for any positive intergral value of m, zero inclusive,

$$\left.\begin{aligned} &C_{2m}\cosh 2m\xi_0+\sum_{l=0}^{\infty}\overline{C}_{2l}A_{2m}^{(2l)}\mathrm{Ce}_{2l}(\xi_0,q)=0\,,\\ &2mC_{2m}\sinh 2m\xi_0+\sum_{l=0}^{\infty}\overline{C}_{2l}A_{2m}^{(2l)}\mathrm{Ce}_{2l}'(\xi_0,q)=0\,.\end{aligned}\right\} \tag{7}$$

If we eliminate the constants C_{2m}'s from these equations, we get a system of simultaneous linear equations for determining the constants $\overline{C}_{2l}$'s. Thus

$$\sum_{l=0}^{\infty}a_{lm}\overline{C}_{2l}=0\,,\qquad (m=0,\,1,\,2,\,3,\,\cdots) \tag{8}$$

with

$$\begin{aligned} a_{lm}=A_{2m}^{(2l)}\{&2m\sinh 2m\xi_0\mathrm{Ce}_{2l}(\xi_0,q)\\ &-\cosh 2m\xi_0\,\mathrm{Ce}_{2l}'(\xi_0,q)\}\,.\end{aligned} \tag{9}$$

The solution of this system of simultaneous linear equations would in general yield the result that all the $\overline{C}_{2l}$'s are zero; but if a certain special relationship exists between the dimensions of the plate and the strength of the load P, namely, if the relation obtained by eliminating all the $\overline{C}_{2l}$'s from the system of simultaneous linear equation (8) exists, we can obtain a displacement in the normal mode of buckling, and with the aid of the said relationship the critical buckling load can be determined as a function of the dimensions of the plate and the elastic constants of the material of the plate.

By eliminating all the $\overline{C}_{2l}$'s from (8), we have the required relationship as:

$$\Delta=\begin{vmatrix} a_{00} & a_{10} & a_{20} & a_{30} & \cdots\\ a_{01} & a_{11} & a_{21} & a_{31} & \cdots\\ a_{02} & a_{12} & a_{22} & a_{32} & \cdots\\ a_{03} & a_{13} & a_{23} & a_{33} & \cdots\\ \vdots & \vdots & \vdots & \vdots & \end{vmatrix}=0\,. \tag{10}$$

If we obtain the numerical value of the root q of this infinite determinantal equation, the numerical value of $\sqrt{\frac{P}{D}}a$ can be obtained from the relation:

$$\sqrt{\frac{P}{D}}a=2\sqrt{q}/\varepsilon\,, \tag{11}$$

which follows immediately from (4), where a and ε are respectively a half-length of the major axis and the eccentricity of the ellipse.

When a, ε and D are fixed the only variable remaining in the determinant Δ is q, which is connected with the critical buckling load P by the relation (11), so that the smallest root of (10) will give the critical load of the fundamental normal mode of buckling, with which we are mainly concerned in the present paper.

The solution expressed by (10) is, however, merely formal. To find out whether it can be used to determine the actual value of buckling we must examine its convergence. For this purpose, we may form, as in Professor Tomotika's treatment of the transverse vibration of a square plate clamped at its four edges[2], a series of finite determinants Δ_1, Δ_2, Δ_3, $\cdots$, Δ_N by taking 1, 2, 3, $\cdots$, N rows and columns starting at the left-hand top corner of Δ, so that $\Delta_1=a_{00}$, $\Delta_2=\begin{vmatrix} a_{00} & a_{10}\\ a_{01} & a_{11}\end{vmatrix}$, etc. If it is found that the smallest root of $\Delta_N=0$ converges to a definite limit as N increases this root gives the required critical load of the fundamental normal mode of buckling of the elliptic plate under consideration.

§ 3. Search for Roots of $\Delta=0$

The writer has calculated the smallest roots q of $\Delta_1=0$, $\Delta_2=0$ and $\Delta_3=0$ in three cases in which the values of a/b are equal to 5/4, 2/1 and 3/1 respectively, with a view to finding out whether they converge to a definite limit, where b is a half-length of the minor axis of the ellipse.

Table I. Values of q_R.

a/b	ε	q_R
5/4	0.6	1.82
2/1	0.866	8.26
3/1	0.943	22.02

To this end, the values of Δ_1, Δ_2 and Δ_3 have been calculated for different values of q close to q_R, an approximate value of the smallest root, which can be found easily from Woinovsky-Krieger's results[3]. The values of q_R are shown in Table I. Then, plotting these values

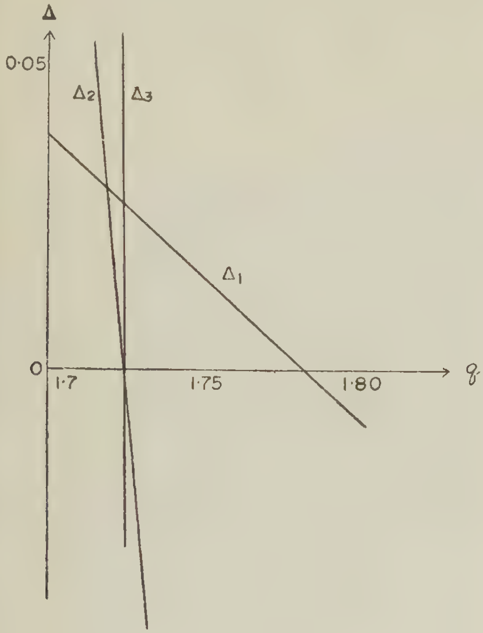

Fig. 1.

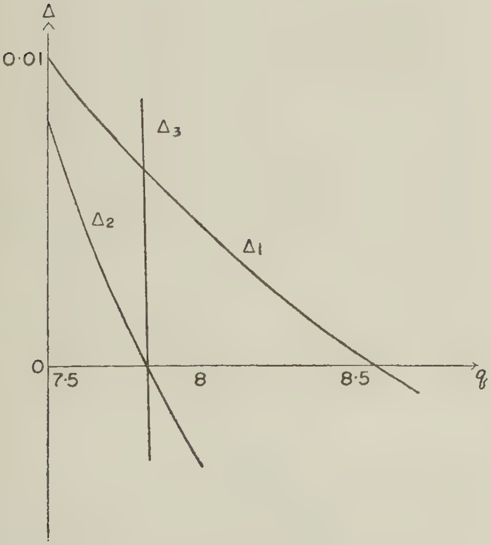

Fig. 2.

of Δ_1, Δ_2 and Δ_3 against q, the roots of the equations $\Delta_1=0$, $\Delta_2=0$ and $\Delta_3=0$ have been determined graphically as show in Figs. 1, 2 and 3*. The results are shown in Table II.

It may be added here that for the numerical calculations of the modified Mathieu functions $\mathrm{Ce}_{2n}(\xi_0, q)$ contained in the elements a_{in}'s of the determinant Δ use has been made of the following product series expressions because of their rapid convergency.

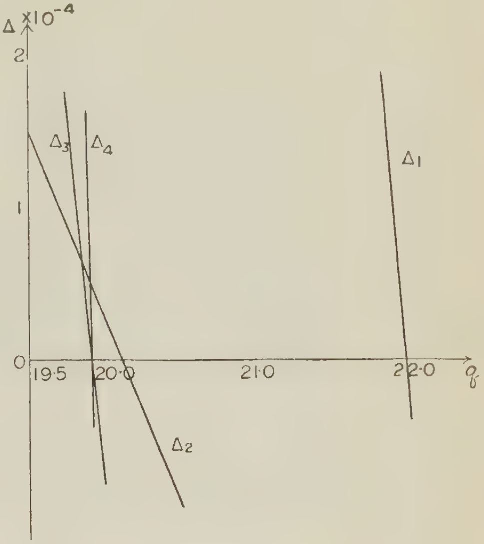

Fig. 3.

Table II. Roots of $\Delta_N=0$.

a/b	ε	Root of $\Delta_1=0$	Root of $\Delta_2=0$	Root of $\Delta_3=0$	Root of $\Delta_4=0$
5/4	0.6	1.785	1.725	1.725	—
2/1	0.866	8.57	7.825	7.825	—
3/1	0.943	22.0	20.13	19.93	19.91

$$\mathrm{Ce}_{2n}(\xi_0, q)=\frac{p_{2n}}{A_0^{(2n)}}\sum_{r=0}^{\infty}(-1)^r A_{2r}^{(2n)} J_r(v_1) J_r(v_2)\,,$$

where

$$v_1=\sqrt{q}\,e^{-\xi_0}\,,\qquad v_2=\sqrt{q}\,e^{\xi_0}\,,$$

$$p_{2n}=\mathrm{ce}_{2n}(0, q)\,\mathrm{ce}_{2n}\left(\frac{\pi}{2}, q\right)\Big/A_0^{(2n)}\,,$$

ξ_0 being connected with the value of a/b as:

$$\cosh\xi_0=\frac{a}{\sqrt{a^2-b^2}}=\frac{1}{\varepsilon}\,.$$

From Figs. 1, 2, 3 and Table II it will be seen that as N increases, the roots q of the equation $\Delta_N=0$ converge to 1.725 when $a/b=5/4$, to 7.825 when $a/b=2/1$ and to 19.91 when $a/b=3/1$.

Thus, substituting these limiting values of q into (11), we obtain ultimately the most probable values of $\sqrt{\frac{P}{D}}a$ as shown in Table III below.

---

* The values of Δ_4 have also been calculated in case when a/b is equal to 3/1 and the root of $\Delta_4=0$ has been obtained.

Table III. Valves of $\sqrt{\frac{P}{D}}a$.

a/b	ε	$\sqrt{\frac{P}{D}}a$
5/4	0.6	4.38
2/1	0.866	6.47
3/1	0.943	9.46

The curve of $\sqrt{\frac{P}{D}}a$ plotted against the eccentricity ε is shown by a thick-line curve in Fig. 4, where is also shown for reference the well-known values of $\sqrt{\frac{P}{D}}a$ equal to 3.8317 for a circular plate ($\varepsilon=0$) with clamped edge$^{4),5)}$.

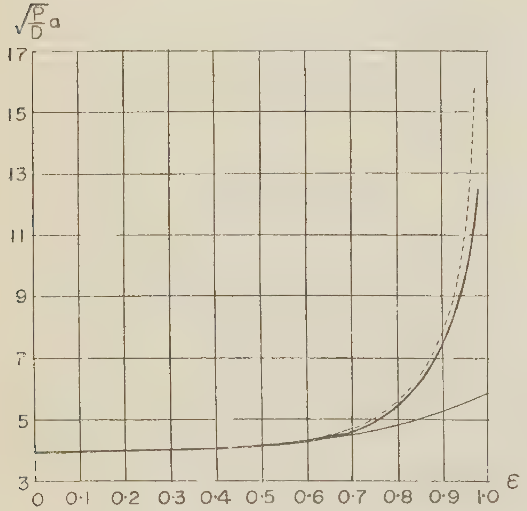

Fig. 4.

- present method
- expansion formula
- S. Woinovsky-Krieger's result (Rayleigh-Ritz method)

In the previous paper[1] we obtained an approximate formula for the relationship between the critical buckling load and the eccentricity of the elliptic plate. The result is

$$\sqrt{\frac{P}{D}}a=3.8317+0.9579\varepsilon^2+1.0382\varepsilon^4 . \tag{12}$$

The values calculated by using this expansion formula are shown by a thin-line curve in Fig. 4. The dotted-line curve shows the results that was obtained by S. Woinovsky-Krieger by the use of Rayleigh-Ritz method.

It will be seen that the expansion formula (12) is particularly useful for calculating the numerical values of $\sqrt{\frac{P}{D}}a$ in case when the plate is nearly circular.

§ 4. Summary

The fundamental normal mode of buckling of a uniform elliptic plate clamped at its edge is investigated in an exact manner. Carrying out detailed numerical calculations in three cases in which the eccentricity ε of the ellipse is equal to 0.6, 0.866 and 0.943 respectively, the relationship between $\sqrt{\frac{P}{D}}a$ and ε is shown graphically, where P is the strength of the critical load, a a half-length of the major axis of the ellipse and $D=Ed^3/\{12(1-\sigma^2)\}$, E and σ being respectively Young's modulus and Poisson's ratio of the material of the plate and d being the thickness of the plate.

§ 5. Acknowledgment

The present problem has been carried out at the suggestion of Professor S. Tomotika. The writer wishes to express his sincere gratitude to him for his helpful guidance and continual encouragement throughout this work and especially for his kind inspection of the manuscript. The writer's thanks are olso due to Professor K. Tamada for his many valuable advices and to Professor T. Okuda for his encouragement.

Finally, the writer is indebted to the Ministry of Education for a grant-in-aid for fundamental scientific researches.

Measurements of Pressure Fluctuation in the Wake of Cylinder

By Yasujiro KOBASHI

Faculty of Science, Hiroshima University

(Received February 4, 1957)

With a view to observing pressure fluctuations in turbulent flow of fluid, a new apparatus was constructed by using a condenser microphone as a transducer with a ratio-discriminator. The frequency response of the apparatus was calibrated by means of Kármán vortices produced by a circular cylinder. The Helmholtz resonance and the loss in the pressure duct were compensated electrically by a band-rejection filter and a high-frequency booster. By these devices, the overall frequency response of the pressure-measuring apparatus was made flat between 50 and 1500 cycles per second. Using the apparatus in combination with a single rotary type hot-wire anemometer, it proved succesful in determining the intensity of static pressure fluctuation as well as the correlation between pressure and velocity fluctuation. Consequently all the terms in the energy equation became measurable, and the energy equation for the fluctuating quantities was ascertained experimentally for the first time in the wake of a circular cylinder, 1 cm in diameter, placed in an airstream of the speed 14 m/s, at a section 42 times the cylinder diameter downstream.

§ 1. Introduction

Many experimental works[1),2),3),4)] have been done with fruitful results on the turbulence characteristics in the wake of a cylinder. All these experiments, however, were carried out by using the hot-wire technique. Consequently the quantities measured so far are concerned only with the temperature and velocity fluctuations. But a thorough understanding of the fundamental features of nonisotropic turbulence necessitates the knowledge of the contribution of other quantities, among which the most important seems to be that of pressure fluctuation. Indeed, Rotta[5),6)] has made an interesting theoretical approach, which has thrown light on the contribution of pressure to the trubulence mechanism.

From the experimental point of view, however, no attempt has ever been made to investigate the phenomena directly, because of the lack of an adequate apparatus for detecting the static pressure fluctuations. As a result, it was necessary for Townsend[7)] to determine the contribution of pressure fluctuation to the energy balance by the indirect method, in which all the terms in the energy equation except the pressure term were measured.

In view of these circumstances, the author has attempted to measure some turbulence characteristics in the wake of a cylinder by using a new pressure pick-up combined with a hot-wire anemometer. The pick-up consists of a condenser microphone and a fine duct, the latter being necessary for picking up a pressure signal at a small localized region. The effects due to Helmholtz resonance and due to the duct loss at high frequency range were eliminated by suitable electrical devices. Further, a new method of calibration was developed. The measured correlation between pressure and velocity agrees satisfactorily with that estimated from the equation of energy balance.

§ 2. Symbols

c: sound velocity
D: diameter of cylinder
f: frequency of fluctuation
f_r: frequency of Helmholtz resonance
f_o: cut-off frequency
G: amplification factor of hot-wire network
G_k: amplification factor of pressure pick-up network
H_θ: output of hot-wire anemometer
h_θ: input to hot-wire anemometer
K: output of pressure pick-up
k: input to pressure pick-up

l: length of static pressure tube
M: time constant
p: pressure fluctuation
q: velocity vector
q_n: velocity component normal to hot-wire
$\tilde{q}_n$: a.c. component of q_n
R_e: Reynolds number
S: Strouhal number
s: cross sectional area of pressure duct
S_θ: sensitivity of hot-wire
S_k: sensitivity of pressure pick-up
U_0: speed of general flow
U: mean longitudinal velocity
u: fluctuating velocity component in the direction of general flow
V: mean transverse velocity
v: fluctuating velocity component transverse to the general flow
w: fluctuating velocity component in the direction parallel to the cylinder
x: distance measured in the direction parallel to general flow
y: distance measured in the direction normal to general flow
z: distance measured in the direction parallel to cylinder
α: residual coefficient
ρ: air density
ν: kinematic viscosity
θ: angle of rotation of the hot-wire measured from yz-plane
φ: angle between z-axis and axis of rotation of hot-wire
Φ: error factor for single rotary type hot-wire anemometer

§ 3. Equipment and Procedure

(a) General description of the measuring apparatus

The experiments were carried out in the 50 cm × 30 cm open-jet wind tunnel at the Faculty of Science, Hiroshima University. The wind speed could be changed from about 0.5 m/s to 17 m/s.

The measurements of the turbulence characteristics were made in the airstream of the speed 14 m/s in the cross section 42 cm downstream of a circular cylinder of 1 cm diameter mounted at the exit of the nozzle.

The velocity distribution was measured with a total head tube of 1 mm outer diameter and a hot-wire anemometer. The latter was used especially for measuring the transverse component.

The fluctuating quantities were measured with a pressure pick-up in combination with a single rotary type hot-wire anemometer placed close to the pick-up tubing.

The hot-wire and the pressure pick-up were mounted on a microscrew mechanism which is movable along x-, y-, and z- directions. Here x-axis is in the direction of the general flow, z-axis in the direction parallel to the cylinder, and y-axis normal to x- and z-axes (Plate. 1).

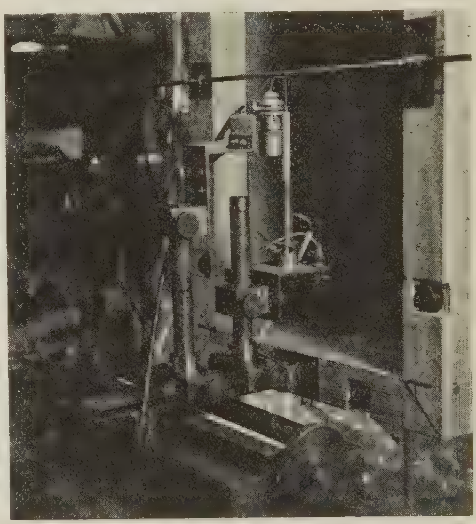

Plate 1. Arrangement of equipment.

The electric circuit for the pressure pick-up is composed of a ratio-detector type *F-M* discriminator and of an ordinary amplifier furnished with a band-rejection filter and with a compensating network. The circuit for the hot-wire anemometer is the same as that of Kovásznay.[8] Special computing networks are used for calculating various statistical quantities. The block-diagram of the circuit is shown in Fig. 1.

(b) Pressure measuring apparatus.

As a pressure transducer the condenser microphone with a ratio-detector type *F-M* discriminator is used because of its excellent sensitivity and reliability. But, in order to be used as a pick-up of local pressure in a wake, it must be combined with a tubing as a pressure duct. The scheme of the apparatus is shown in Fig. 2. Part A in the figure is a condenser microphone which serves as a transducer. The membrane A_1 made of aluminum sheet about 10 μ thick, is isolated electrically from the opposite electrode A_3 by the insulating sheet A_2 made of Valflon.* To control the sensitivity of the microphone, the space A_4 between the membrane and electrode can be varied by changing the thickness of A_2. The tension of the membrane A_1 is varied to a desired degree by screwing up the electrode A_3, thus shifting its resonance frequency to as high as 10,000 c/s. Part B shows the system of pressure duct, where the tube B_1 of 1.5 mm outer diameter has small static pressure holes B_2 on both sides. The combination of parts A and B leaves a small cavity B_3 between the membrane and the tubing.

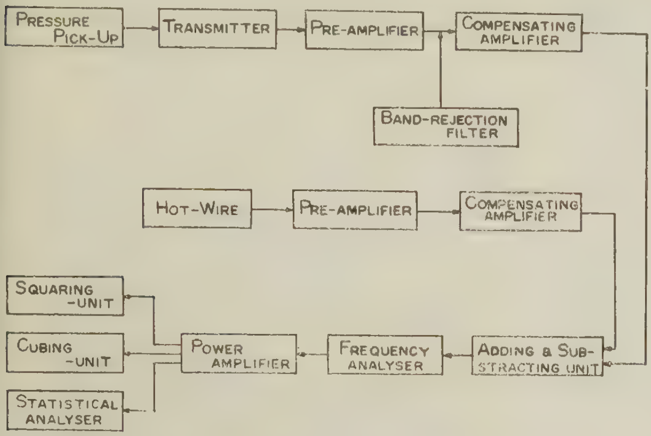

Fig. 1. Block diagram of circuit

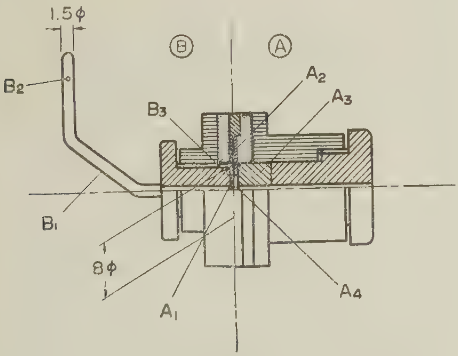

Fig. 2. Scheme of pressure pick-up.

In such a construction of the pressure pick-up, Helmholtz resonance and the duct loss cause secondary effects. The Helmholtz resonance[9] occurs theoretically at the frequency

$$f_r = \frac{c}{2\pi}\sqrt{\frac{s}{l V_{B_3}}}, \qquad (1)$$

where f_r is the resonance frequency of the cavity of volume V_{B_3} combined with a fine duct of length l and of cross section s, and c is the sound velocity. The loss by the tubing is expected to have the same characteristics as that of a hot-wire anemometer, increasing proportionally to the frequency at the high frequency range.[10]

In order to use such a pick-up as a measuring apparatus, these secondary effects must be compensated. For this purpose the following two ways can be considered:

(1) To shift the resonance frequency to the higher frequency range and to reduce the peak and the attenuation by changing the construction of the pick-up.

(2) To cancel out the resonance and the attenuation electrically by appropriate compensating networks.

In order to shift the resonance point to the higher frequency range, the dimension of the pick-up, especially the volume of the cavity B_3, must be reduced, and the duct must be made large in diameter and short in length. On the other hand, to reduce the resonance peak value, the duct must be made fine and long. These requirements not only contradict each other, but also reduce the sensitivity of the pick-up and therefore necessitate considerable improvement in the sensitivity of the subsequent circuits. This problem is now under study.

In the present work the second method was adopted by using a band-rejector and a compensating amplifier. The circuit of the band-rejector is shown in Fig. 3; the frequency band and degree of rejection can be varied at will.

Each amplifier is the same as that of Kovásznay with the exception that the circuit furnishes a cubing network in the output stage. The frequency characteristic of the amplifier is shown in Fig. 4 together with the response of the compensating network. In the same figure, the combined frequency response of the amplifier and discriminator is also shown, which is sufficiently flat over the range from 60 c/s to 3,000 c/s.

(c) Calibration of the pressure pick-up

Various calibrating methods have been proposed to examine the dynamic response of the pressure pick-up. Some of the methods, based on mechanical principles, are inadequate for our purpose because they are limited to lower frequency range. On the other hand, acoustical methods, which are useful for a wider range, cannot be applied here because of the difficulty of getting a source of constant pressure. The method adopted by the author is to measure Kármán vortices in a wake of a circular cylinder.

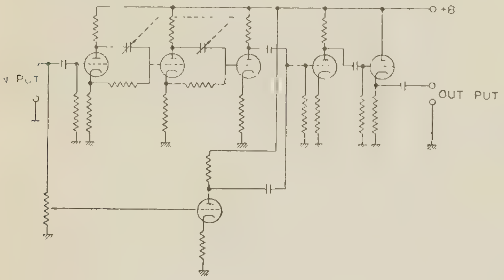

Fig. 3. Circuit of band-rejection filter.

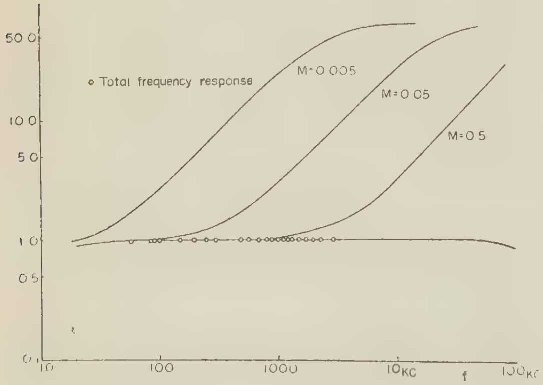

Fig. 4. Frequency characteristics of amplifier together with combined frequency response of amplifier and discriminator.

The frequency of Kármán vortices produced from a circular cylinder of diameter D is given by[11),12)]

$$f=S\frac{U_0}{D}\,, \tag{2}$$

where U_0 is the speed of general flow and S is the so-called Strouhal number which is nearly constant for the cylinder Reynolds number $R_e=\frac{U_0D}{\nu}$ between 10^2 and 10^4. The intensity of the vortex, $\overline{u}^2$, can be expressed in the form

$$\frac{1}{2}\rho\overline{u}^2\Big/\frac{1}{2}\rho U_0{}^2=F\left(R_e,\ \frac{x}{D},\ \frac{y}{D}\right), \tag{3}$$

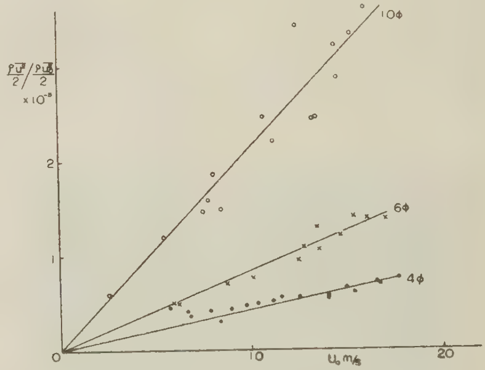

Fig. 5. Kármán vortex intensity measured by hot-wire anemometer.

where x and y are the distances measured in the directions parallel and normal to the general flow respectively. The results obtained by the hot-wire anemometer for various cylinder diameters are shown in Fig. 5, which suggests that the vortex intensity is proportional to the third power of U_0, that is

$$\overline{u}^2 \propto U_0{}^3\,. \tag{4}$$

Eq. (2) then gives

$$\overline{u}^2 \propto f^3\,. \tag{5}$$

For an isolated vortex, there must be a relation between its pressure defect p and its intensity $\overline{u}^2$ of the form[13)]

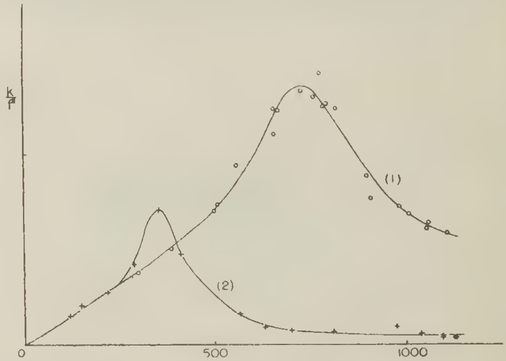

Fig. 6. Kármán vortex intensity measured by pressure pick-up without compensation.

$$p \propto \bar{u}^2 . \qquad (6)$$

If this is also valid in our case, we can expect

$$p \propto f^3 . \qquad (7)$$

Itokawa[14)] measured the pressure fluctuations in a separated flow from a flat plate inclined to the uniform flow, and some of his results seem to support our expectation.

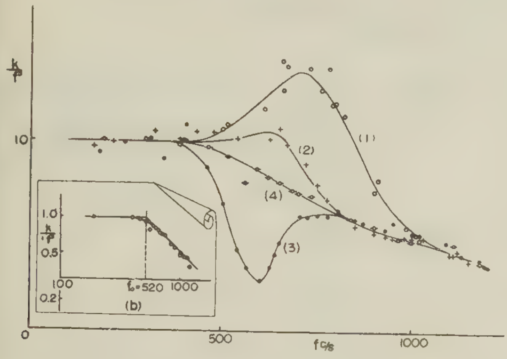

Fig. 7. Kármán vortex intensity measured by pressure pick-up with various rejection.

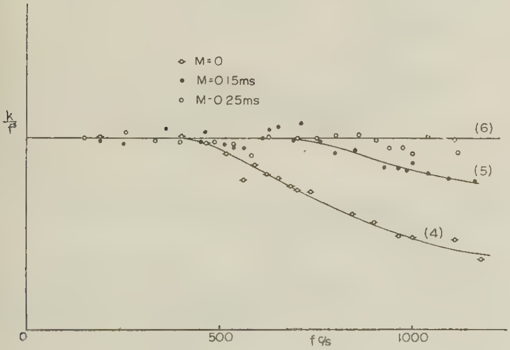

Fig. 8. Kármán vortex intensity measured by pressure pick-up with adequate compensation.

In Fig. 6 are shown the measured values of the pressure fluctuations at the same points at which the hot-wire measurements of Fig. 5 were obtained. The symbol k in the figure represents the input of the pressure pick-up, which is considered to be the sum of static pressure fluctuation and dynamic one arising from the velocity component normal to the holes. If the eqs. (5) and (7) are valied simultaneously, k must be proportional to f^3. The scale of the ordinate of the figure is taken arbitrarily for k/f^2. The two curves in the figure correspond to the different values of the cavity volume B_3. Each curve consists of three parts, namely, the part in which k/f^2 is proportional to f, the part of resonance, and the part in which attenuation is noticeable.

In Fig. 7 a, the curve (1) is the replot of the curve (1) of Fig. 6 while the curves (2), (3) and (4) correspond to the cases of over-rejection, under-rejection, and adequate rejection respectively. The curve of adequate rejection (4) is redrawn in logarithmic scale in Fig. 7 b, which shows

$$k/f^3 = \text{const} . \qquad (8)$$

in the low frequency range, and

$$k/f^3 \propto \frac{1}{f} \qquad (9)$$

in the high frequency range. This characteristic is to be expected from theoretical considerations, being quite similar as that of the hot-wire anemometer. The time constant of the pressure pick-up calculated from the curve (4) is

$$M = \frac{1}{2\pi f_0} = 0.3 \text{ ms} , \qquad (10)$$

which is of the same order of magnitude as that of the usual hot-wire anemometer. Here M is the time constant of the pressure pick-up and f_0 is the cut-off frequency. In Fig. 8, the curve (4) is the replot of the curve (4) of Fig. 7 a and the curves (5) and (6) are the results when the degree of compensation is changed. These results show a satisfactorily compensated response of the pick-up. Attention should also be paid to the phase characteristics, but in our case its effect is negligibly small.

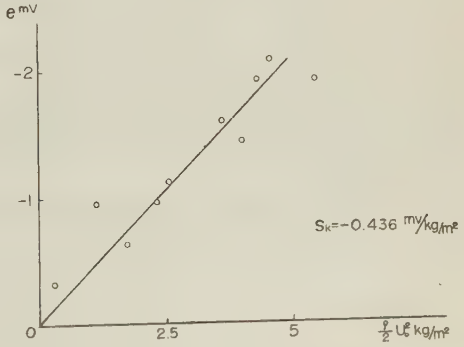

Fig. 9. Sensitivity of pressure pick-up.

In order to calibrate the sensitivity of the pressure pick-up, a static method was used. When the pick-up is used for fluctuating phenomena, a slight error may result because of the effect of compressibility. But the error is considered to be reduced by drilling a hole through the electrode as shown in Fig. 1, which allows the air in the cavity A_3 to pass freely. In Fig. 9 an example of the calibration curve is given, which shows that the sensitivity is fairly constant over a wide range of pressure change.

(d) Single rotary type hot-wire anemometer

The hot-wire anemometer used in our experiment is a single rotary type. The wire is carefully arranged so that its center coincides with the axis of rotation. This type of the hot-wire anemometer, although complicated for use and liable to introduce systematic errors when treated inadvertently, can be utilized for measuring various fluctuating quantities with high reliability if it is mounted and calibrated with the greatest care.

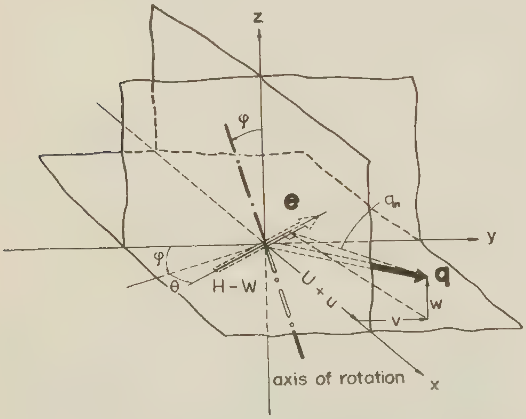

Fig. 10. Principle of measurement of turbulence characteristics by hot-wire anemometer.

The principle of measuring turbulence characteristics by a hot-wire anemometer of this type is described in the following together with the estimation of the error and of the limit of application.

Let the mean flow be in the direction of x-axis, and the hot-wire be rotated around the axis placed in the yz-plane (Figs. 10, 11). The angle between z-axis and the axis of rotation of the hot-wire is denoted by φ and the angle between the hot-wire and yz-plane by θ. If the instantaneous velocity vector is given by $\boldsymbol{q}$ and the direction of the hot-wire by the unit vector $\boldsymbol{e}$, the velocity component normal to the wire is

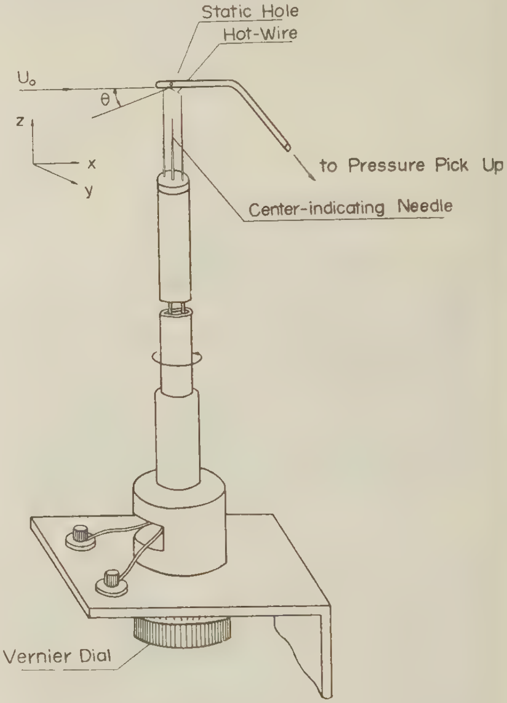

Fig. 11. Arrangement of pressure pick-up and hot-wire anemometer.

$$q_n = |\boldsymbol{q} \times \boldsymbol{e}| \, . \tag{11}$$

Since

$$\boldsymbol{e} = -\sin\theta\boldsymbol{i} + \cos\theta\cos\varphi\boldsymbol{j} + \cos\theta\sin\varphi\boldsymbol{k} \, ,$$

and

$$\boldsymbol{q} = (U_0 + u)\boldsymbol{i} + v\boldsymbol{j} + w\boldsymbol{k} \, ,$$

we have

$$q_n = U_0\cos\theta\left[\begin{array}{l} 1 + \dfrac{2}{U_0}(u + v\tan\theta\cos\varphi + w\tan\theta\sin\varphi) + \dfrac{1}{U_0}\{u^2 + v^2(\tan^2\theta + \sin^2\varphi)\} \\ +w^2(\tan^2\theta + \cos^2\varphi) + 2(uv\tan\theta\cos\varphi + uw\tan\theta\sin\varphi - vw\cos\varphi\sin\theta) \end{array}\right]^{1/2} . \tag{12}$$

Expanding the Eq. (12) into series, we obtain

$$q_n = U_0\cos\theta\left[\begin{array}{l} 1 + \dfrac{1}{U_0}(u + v\tan\theta\cos\varphi + w\tan\theta\sin\varphi) + \dfrac{1}{2U_0{}^2\cos^2\theta}(v^2\sin^2\varphi \\ +w^2\cos^2\varphi - 2vw\sin\varphi\cos\varphi) + \mathrm{o}(u^3) \end{array}\right] . \tag{13}$$

The a.c. component of q_n, denoted by $\tilde{q}_n$, is given by

$$\tilde{q}_n=(u\cos\theta+v\sin\theta\cos\varphi+w\sin\theta\sin\varphi)$$
$$+\left[\frac{1}{2U_0\cos\theta}(v^2\sin^2\varphi+w^2\cos^2\varphi-2vw\sin\varphi\cos\varphi)+\mathrm{o}(u^3)\right]. \tag{14}$$

If the term in the square bracket of Eq. (14) is neglected against the first term, the maximum error is estimated by the following equation.

$$\text{Error}=\frac{1}{2U_0\cos\theta}\frac{\overline{u^2}\sin^2\varphi+\overline{w^2}\cos^2\varphi\pm2|\overline{vw}|\sin\varphi\cos\varphi}{\sqrt{\begin{array}{l}\overline{u^2}\cos^2\theta+\overline{v^2}\sin^2\theta\cos^2\varphi+\overline{w^2}\sin^2\theta\sin^2\varphi\\ \pm(|\overline{uv}|\sin^2\theta\cos\varphi+|\overline{vw}|\sin^2\theta\sin^2\varphi+\overline{wu}\sin^2\theta\sin\varphi)\end{array}}} \tag{15}$$

The maximum errors can be evaluated provided appropriate assumptions are made conserning the magnitudes of cross products of the velocity components. For example, the estimated errors for typical cases are

(i) for isotropic turbulent flow

$$\left\{\begin{array}{l}\overline{u^2}=\overline{v^2}=\overline{w^2}\,,\ |\overline{uv}|=|\overline{vw}|=|\overline{wu}=0|\\ (\text{Error})_{\max}=\dfrac{1}{2\cos\theta}\dfrac{\sqrt{\overline{u^2}}}{U_0}\equiv\Phi_1(\theta,\varphi)\dfrac{\sqrt{\overline{u^2}}}{U_0}\end{array}\right. \tag*{(15)$'$}$$

(ii) for two-dimensional shear flow

$$\left\{\begin{array}{l}\overline{u^2}=\overline{v^2}=\overline{w^2}\,,\ |\overline{uv}|=0.4\overline{u^2}\,,\ |\overline{vu}|=|\overline{wu}|=0\\ (\text{Error})_{\max}=\dfrac{1}{2\cos\theta}\dfrac{1}{\sqrt{1-0.4\sin^2\theta\cos\varphi}}\dfrac{\sqrt{\overline{u^2}}}{U_0}\equiv\Phi_2(\theta,\varphi)\dfrac{\sqrt{\overline{u^2}}}{U_0}\end{array}\right. \tag*{(15)$''$}$$

(iii) for three-dimensional shear flow

$$\left\{\begin{array}{l}\overline{u^2}=\overline{v^2}=\overline{w^2}\,,\ |\overline{uv}|=|\overline{vw}|=|\overline{wu}|=0.4\overline{u^2}\\ (\text{Error})_{\max}=\dfrac{1}{2\cos\theta}\dfrac{1+0.4\sin^2\varphi}{\sqrt{1-0.4\{\sin^2\theta(\cos\varphi+\sin\varphi)+\sin\theta\sin^2\varphi\}}}\dfrac{\sqrt{\overline{u^2}}}{U_0}\equiv\Phi_3(\theta,\varphi)\dfrac{\sqrt{\overline{u^2}}}{U_0}\end{array}\right. \tag*{(15)$'''$}$$

The values of Φ_1, Φ_2 and Φ_3 are calculated and given in Table I. If we use the values of φ and θ in the domain bounded by thick lines in the table, then the error becomes less than the value of $\left|\dfrac{\sqrt{\overline{u^2}}}{U_0}\right|$.

From the input $h_{\theta,\varphi}$ corresponding to the angles φ and θ,

$$h_{\theta,\varphi}=u\cos\theta+(v\cos\varphi+w\sin\varphi)\sin\theta \tag{16}$$

values of $h^2_{\theta,\varphi}$ and $h^3_{\theta,\varphi}$ are computed electrically by the squaring and cubing networks respectively, and with the aid of these quantities various products of second and third orders can be obtained.

(e) Principle of obtaining the pressure fluctuation and its correlation to velocity fluctuation.

Let the output of the hot-wire anemometer, whose axis of rotation is parallel to the z-axis, be H_θ, and that of the pressure pick-up be K, then the input to each apparatus can be calculated respectively by

$$\left.\begin{array}{l}\dfrac{H_\theta}{S_\theta G}=h_\theta=u\cos\theta+v\sin\theta\,,\\ \dfrac{K}{S_k G_k}=k=p+\dfrac{\rho}{2}\alpha(v^2-\overline{v^2})\,.\end{array}\right\} \tag{17}$$

Here S_θ and G are the sensitivity and the amplification factor of the hot-wire, and S_k and G_k those of the pressure pick-up. The nondimensional coefficient α lies between zero and unity according to the stagnating effect of the hole. But since the value of p is of the order of

$\rho u U_0$ and usually large compared to $\frac{\rho}{2}(v^2-\bar{v}^2)$, as confirmed by our measurement, we can approximately put $p=k$ independent of the value of α. Thus α may be conveniently put zero for calculating the pressure fluctuation.

When the pressure pick-up is used with a hot-wire anemometer which is mounted close to the static pressure hole, the correlation between pressure and velocity components can be obtained by

$$\left.\begin{aligned}\overline{pu}&=\frac{[(k+h_{\theta+})^2-(k-h_{\theta+})^2]+[(k+h_{\theta-})^2-(k-h_{\theta-})^2]}{8\cos\theta_+}-\frac{\rho}{2}\alpha\overline{uv^2}\\ \overline{pv}&=\frac{[(k+h_{\theta+})^2-(k-h_{\theta+})^2]-[(k+h_{\theta-})^2-(k-h_{\theta-})^2]}{8\sin_{\theta+}}-\frac{\rho}{2}\alpha\overline{v^3}\end{aligned}\right\}\qquad(18)$$

where θ_+ and θ_- denote the angles measured clockwise and anticlockwise respectively. Here the residual coefficient α can again be put equal to zero for the sake of convenience, since the contribution of the second term on the right-hand side of eq. (18) is negligible even if the value of α assumes its maximum value of unity.

§ 4. Results of Measurements in the Wake of a Cylinder

From the measurement at the cross section 42 cm downstream from a cylinder of 1 cm diameter, which was mounted in a uniform flow of the speed 14 m/s, the following quantities were obtained;

turbulent intensities: $\overline{u^2}, \overline{v^2}, \overline{w^2}$,

mean square of velocity derivative: $\overline{\left(\frac{\partial u}{\partial x}\right)^2}$

double velocity correlation: $\overline{uv}$,

triple velocity correlation: $\overline{u^3}, \overline{v^3}, \overline{u^2v}, \overline{w^2v}$,

pressure-velocity correlation: $\overline{pu}, \overline{pv}$.

Because of the two-dimensionality of the flow, the terms containing odd powers of w reduce to zero.

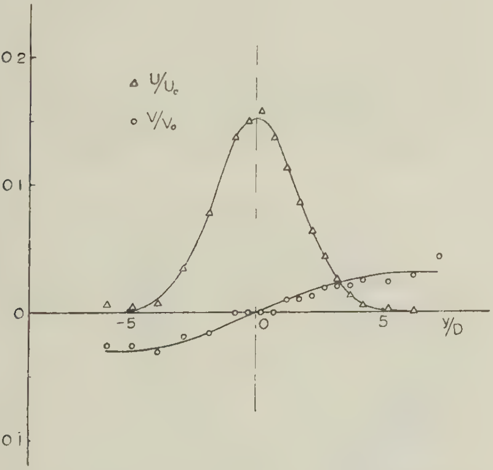

Fig. 12. Distribution of mean velocity components in nondimensional form.

In Fig. 12 are shown the distributions of mean velocity components $\frac{U}{U_0}$ and $\frac{V}{U_0}$. The figure shows that the jet velocity, V, is noticeable at the edge of the wake.

In Fig. 13 are shown in nondimensional forms the distributions of the components of the turbulent intensity and those of its diffusion.

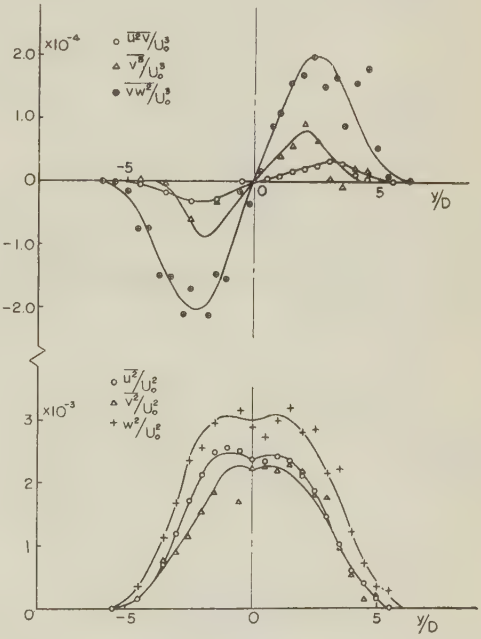

Fig. 13. Distribution of components of turbelent intensity and of its diffusion.

The distributions of turbulent intensity and its diffusion are shown in Fig. 14. In the same figure the turbulent intensity multiplied by the jet velocity is also shown. If the turbulent energy is transported by the jet velocity, as proposed by Townsend, the following relation must be expected

$$\overline{u^2v}+\overline{v^3}+\overline{w^2v}=V(\overline{u^2}+\overline{v^2}+\overline{w^2})\,. \qquad (19)$$

The measured results seem to support this proposition.

In Fig. 15 quantities such as $\overline{uv^2}$ and $\overline{v^3}$ are shown, which are used later for computing the pressure contributions.

The measured values of pressure fluctuation are shown in Fig. 16, in which $\frac{\rho}{2}\overline{v^2}\times 10$ is also given for comparison. The results show that the contribution of the dynamic pressure term to the pick-up input is so small that we can safely put $k=p$ as already mentioned in § 3. The figure also shows that the pressure fluctuation is of the order of $\rho U_0 u$ and has a bell-shaped distribution in the wake.

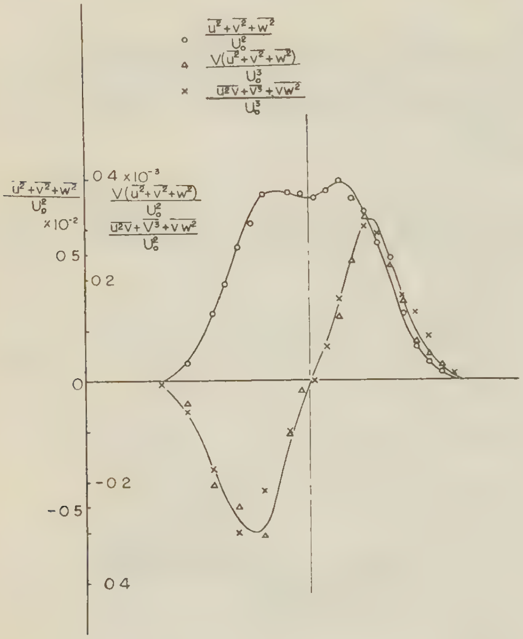

Fig. 14. Distribution of turbulent intensity and its diffusion.

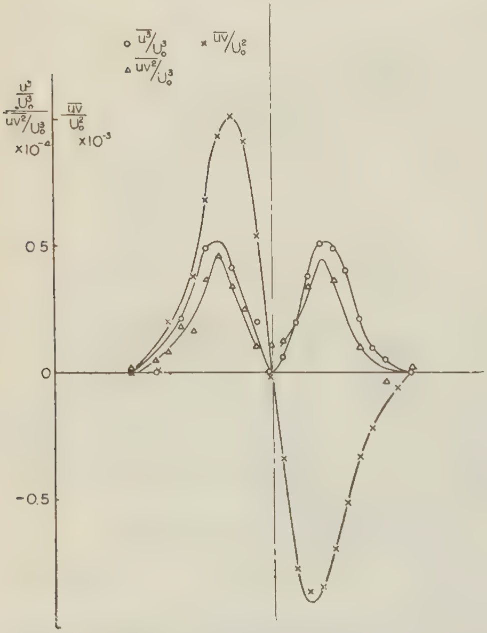

Fig. 15. Distribution of various turbulence characteristics in non dimensional form.

Fig. 17 shows the correlations between pressure fluctuation and velosity components.

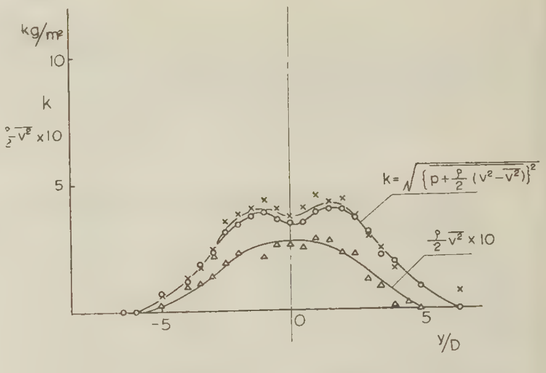

Fig. 16. Distribution of pressure fluctuation and energy component.

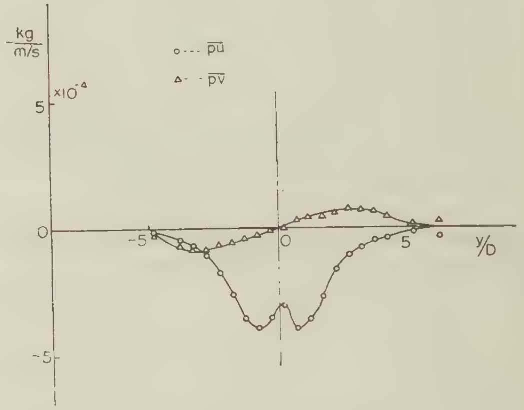

Fig. 17. Distribution of correlations of Pressure fluctuation to velocity components.

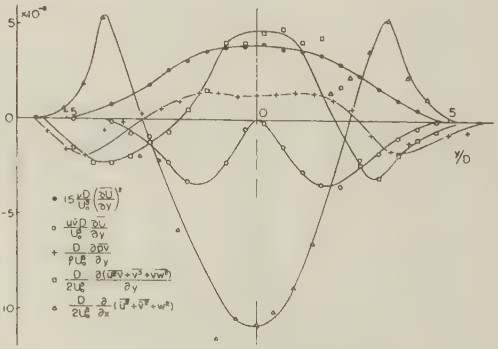

Fig. 18. Energy balance in non-dimensional form.

An interesting trend of the results is that $\overline{pu}$ has the sense such that a positive p corresponds to a negative u, while $\overline{pv}$ has the sense such that a positive p corresponds to a positive v. This tendency seems to be correlated with the fact that the increase in v corresponds to the decrease in u to produce a positive shear stress in the wake.

Since the turbulent energy must be conserved at each point in the wake, the equation of energy is expressed as

$$\left.\begin{aligned} &15\nu\overline{\left(\frac{\partial u}{\partial x}\right)^2}+\frac{U_0}{2}\frac{\partial}{\partial x}(\overline{u}^2+\overline{v}^2+\overline{w}^2)+\overline{uv}\frac{\partial U}{\partial y} \\ &+\frac{1}{2}\frac{\partial}{\partial y}(\overline{u^2v}+\overline{v}^3+\overline{w^2v})+\frac{1}{\rho}\frac{\partial\overline{pv}}{\partial y}=0 \end{aligned}\right\} \qquad (20)$$

on the assumption of the boundary-layer approximation and of local isotropy. Each term of the equation represents dissipation, advection, shear production, local diffusion and pressure flow, respectively. All these terms are plotted in nondimensional forms in Fig. 18, from which the validity of the relation (20) is confirmed. This in turn gives support to the reliability of the result obtained by the pressure pick-up.

§ 5. Concluding Remarks

The detailed description of the new pressure pick-up was given. The characteristics of the condenser microphone, the tubing and their combination was studied. The methods of compensating the secondary effects were considered and a band-rejection filter for the resonance and a compensating amplifier for the attenuation at the higher frequency range were introduced. By these means an apparatus with a sufficiently flat freqency response was obtained.

For the calibration of the apparatus, a new method was adopted in which Kármán vortices were used as reference, and the results were found to be satisfactory.

The principle of measuring turbulence characteristics by combined use of pressure pick-up and single rotary type hot-wire anemometer was discussed and the error and the limit of application were estimated.

The experimental results obtained are as follows;

(1) The pressure fluctuation is of the order of $\rho U_0 u$; this gives support to the fact that the input to the pick-up is equal to the pressure signal itself.

(2) The nature of the correlation between pressure and velocity fluctuation such as $\overline{pu}$ and $\overline{pv}$ is revealed for the first time both in the sense and the magnitude.

(3) The balance between gain and loss of various kinds of turbulence energy at a section in the wake is confirmed by the measurements of all terms in the energy equation. This fact, in turn, gives support to the reliability of the pressure pick-up.

Acknowledgement

The author wishes to express his thanks to Prof. I. Tani of Tokyo University for his kind advice and suggestion, especially for bringing the importance of the problem to his notice. His acknowledgement is also due to Prof. T. Maekawa for the continued interest and encouragement throughout the work.

The author is indebted to Mr. N. Kono and Mr. T. Nishi for their efficient assistance in carrying out the experiments. The work was partially supported by a research grant of the Ministry of Education.

Experimental Studies on the Stability of the Transonic Flow past Airfoils

By Fumio TAMAKI

Institute of Industrial Science, University of Tokyo

(Received February 7, 1957)

Local flow fluctuations near the airfoil surface have been measured in the speed range near critical Mach number, by using a Mach-Zehnder interferometer and a rotating-drum camera. Airfoils tested are Tomotika-Tamada airfoil, NACA-0012 and 10 per cent thick elliptic cylinder. Experiments show that amplitude and frequency of oscillation that appears when the local sonic speed is exceeded on the surface depend on the shape of the profile. In the cases of T.T.- and 0012-airfoils, the oscillation is of small amplitude and high frequency when the maximum local Mach number on the surface is not much above unity, and the time-mean pressure distribution on the surface is smooth and shows no appreciable distortion due to shock waves. In the case of the elliptic cylinder, slow oscillation of large amplitude involving distinct shock waves appears, as soon as sonic speed is exceeded on the surface.

§ 1. Introduction

Transonic flow with embedded supersonic region has been investigated theoretically by many authors, and it has been shown that a smooth, irrotational flow containing both subsonic and supersonic regions exists for some special shapes of the flow boundary. Wind tunnel experiments, however, contradict these theoretical findings in that the flow over the body surface either becomes unsteady or involves shock waves when the local sonic speed is exceeded anywhere on the surface. There have been many attempts to explain the reason for this discrepancy. (See references (1)–(5)). However, it seems to the present author that detailed experiments are still lacking in order to check these theories and to understand clearly the flow behavior at such critical speeds.

In the present paper, experiments are described, which have been carried out for obtaining some quantitative data as to the stability or instability of the flow in the local supersonic region and the process of formation of a steady shock wave.

§ 2. Experiments

Experiments were carried out in the I.I.S. high speed induced wind tunnel having a rectangular test section of 6 cm × 9.2 cm (Fig. 1). Compressed air was supplied to the injector from a reservoir of 10 m^3 volume and 10 atms. pressure. In order to prevent the flow at the test section from being influenced by the flow fluctuation at the injector slot, a variable throat was inserted between the test section and the slot, so as to make the flow sonic at the minimum section. Control of flow speed was effected by changing its area.

Models tested are: (1) Tomotika-Tamada airfoil$^{6)}$ for which a smooth irrotational flow with substantial supersonic region has been predicted; (2) NACA-0012; and (3) 10 per cent thick elliptic cylinder. Each has a chord of 3 cm and a span of 6 cm, which is equal to the tunnel width. Airfoil profile of Tomotika and Tamada changes with free-stream Mach number, but the profiles given for three Mach numbers, M=0.717, 0.745 and 0.752 differ quite little from each other, so only the profile for M=0.745 has been adopted for the model. The theoretical profile has a cusp at the trailing edge, but the model has a thickness of 0.2 mm there. Each model has a pressure hole on the surface, its position being 42, 40 and 50 per cent chord from the leading edge for airfoils (1), (2) and (3) respectively.

A Mach-Zehnder interferometer with a light source of high pressure mercury vapor lamp was used for measuring the density field. A monochromatic filter (5461 Å) was used for photographing the whole field, but it was removed for recording the flow fluctuations, in order to secure sufficient light intensity.

Flow fluctuations that appeared when the sonic speed was approached or exceeded on the surface were recorded by a rotating-drum camera. For this purpose, a diaphragm with a narrow slit was introduced into the light path, thus only the image of the fringes corresponding to a strip region parallel or perpendicular to the chord line was focused on a film wound on a rotating drum. (See Fig. 7). Fluctuations of flow in the wake were recorded by the same method. Width of the strip in the real flow field was 5 per cent of the chord. Peripheral speed of the drum was 19 m/sec, and the film length was 76 cm.

Experiments on the T.T.- and 0012-airfoils were carried out at zero incidence. A slight asymmetry was inevitable between the flow on the upper and the lower surface due to the presence of the support on the lower surface. Experiments on the elliptic cylinder were at first made for the case of small incidence ($\alpha \fallingdotseq 1°$), because the maximum speed of our tunnel was not high enough for obtaining a flow with any appreciable shock wave in the case of zero incidence. It will be called the A-case later on. Experiments at zero incidence were tried afterwards, by reducing the tunnel section to 6 cm × 8.6 cm. This will be called the B-case. In this case, however, the tunnel chokes as soon as the sonic speed is exceeded on the surface, so this case should be considered as a channel flow rather than a flow around a body in free air.

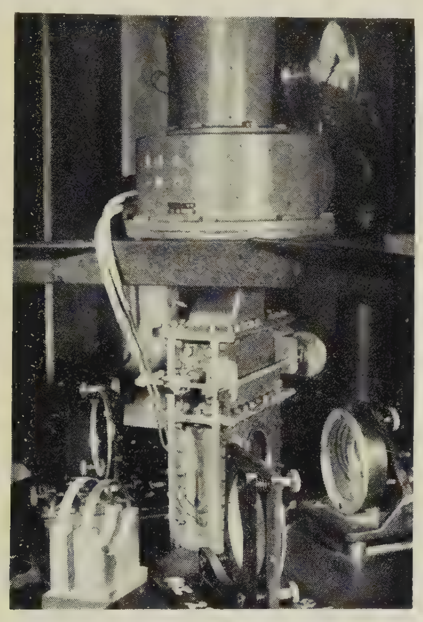

Fig. 1. Wind tunnel.

Reynolds number based on chord length was 4×10^5 at $M=0.75$. Boundary layer was in general laminar, and separation occurred immediately behind the point of minimum pressure. As such a flow was not suitable for any comparison with theory, the boundary layer was made turbulent by sticking a cellophane strip of 1 mm width and 0.1 mm thickness to each side of the airfoil near the leading edge. This caused an additional peak of negative pressure on its back; accordingly, its position and thickness were selected such that the sonic speed should not be exceeded there. It should be remarked that when the sonic speed is exceeded there, a shock wave appears and causes flow separation. For this reason, the trip was not applied to the elliptic cylinder.

§ 3. Discussion of Results

i) *Velocity distribution on the airfoil surface*

Fig. 2 shows one of the interferograms of the flow field. Distributions of pressure and velocity around the airfoil were determined from the density by assuming the isentropic relation. Even when the flow involves shock waves, the error due to entropy change is small, because we are only dealing with the case of weak shock waves in the present experiments. Figs. 3, 4 and 5 show examples of the velocity distribution on the airfoil surface. Here q is the velocity divided by the critical sound speed. In Fig. 3a, which represents the case of T.T. airfoil with boundary layer trip, theoretical curves for three Mach numbers are also included. Strictly speaking, these curves belong to three different profiles, but we may consider that these curves represent approximately the velocity distributions

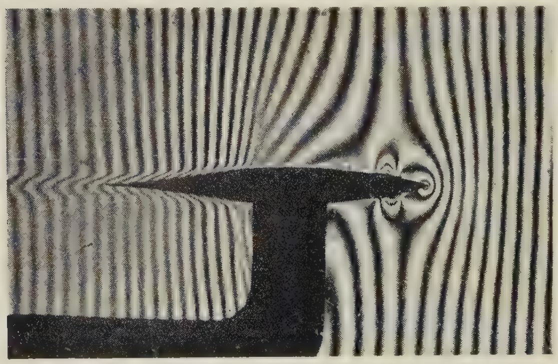

Fig. 2. Interferogram of the flow past T.T. airfoil ($M=0.754$).

on a fixed profile at different Mach numbers. It can be seen that experimental points lie fairly close to the corresponding theoretical curves. In the case without trip, experiments do not agree with theory as shown in Fig. 3b.

(b) without trip

Fig. 3. Velocity distribution on the surface: T.T. airfoil.

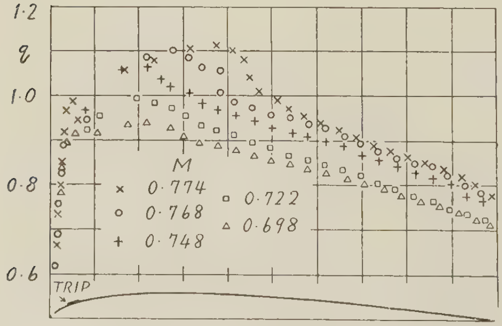

Fig. 4. Velocity distribution on the surface: NACA-0012 (with trip).

Fig. 5 represents the A-case of the elliptic cylinder, at which the pressure gradient along the surface is positive. The flow on the surface at M slightly above 0.80 fluctuates considerably due to the oscillating shock waves, as shown by the two different distributions for $M=0.803$.

ii) *Extent of the supersonic region*

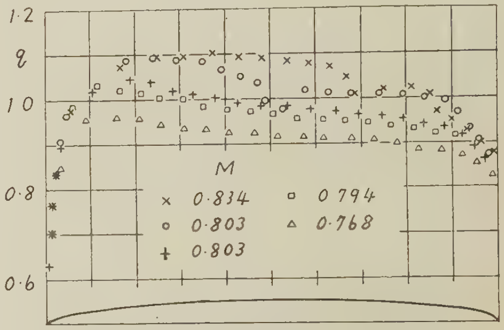

Fig. 5. Velocity distribution on the surface· 10 per cent thick elliptic cylinder ($\alpha \doteqdot 1°$).

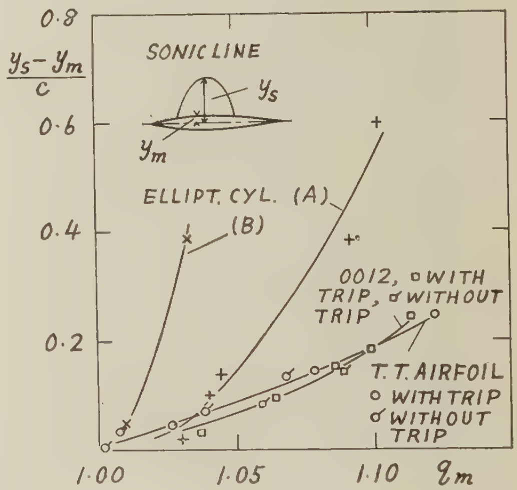

Fig. 6. Height of the sonic line.

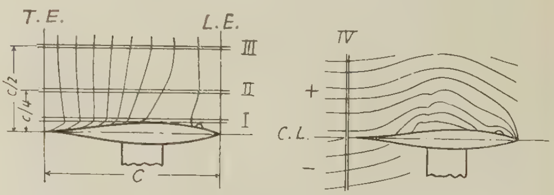

Fig. 7. Locations of the strip regions.

Based on the measurement of the density distribution in the whole field, equal-velocity contours have been drawn for each case. In Fig. 6, the height of the sonic line from the surface is plotted against the maximum velocity q_m on the surface. In this figure, y_s is the distance between the top of the sonic line and the chord line, y_m is the maximum ordinate of the profile and c the chord length.

Fig. 8. Records of the fringe fluctuations.

iii) *Flow fluctuations near the surface*

Fringe fluctuations in the strip regions shown in Fig. 7 were recorded by a rotating-drum camera. Short cuts of these records are shown in Fig. 8. These pictures correspond to the time interval of 3 milliseconds. Here $\bar{q}_m$ is the time mean of the maximum velocity on the surface estimated from the fringe analysis and the measurement of the static pressure at the hole. Accuracy of its value is rather poor when it approaches 1.1. Fringe records for the strip region tangential to the surface at the point of maximum thickness may be considered to represent approximately the flow fluctuations on the surface itself. These fluctuations are in general aperiodic and irregular, and the analysis is not easy. However, the following facts have been found.

(I) When the maximum velocity on the surface is subsonic but near to the sonic speed, there appears on the surface a series of weak unsteady shock waves traveling against the stream. This phenomenon has been already noticed by Hilton and Fowler[7]. Our preliminary experiments using spark photography also confirm this fact. Frequency of the unsteady shock is of the order of 5000 cps, as shown for example in Figs. 8a1 and b1. Fringe records for the strip perpendicular to the chord at the trailing edge show that the low frequency component in the wake has nearly the same frequency as the above-mentioned. From this, it may be concluded that these traveling shocks have their origin in the wake. Fig. 8a5 shows that there are also fluctuations of 10,000 to 20,000 cps behind the model support, but these do not affect the flow upstream due perhaps to their rapid decay.

(II) When the local sonic speed is slightly exceeded on the surface of T.T.- and 0012-airfoils, a flow oscillation occurs with a frequency lower and an amplitude larger than mentioned in (I). (Figs. 8a2 and c1). The frequency is 1000–1500 cps for the T.T. airfoil, and about 500 cps for the 0012. This type of oscillation does not occur on the elliptic cylinder; in the A-case, oscillation of the type that will be mentioned in (III) occurs, and in the B-case, a steady shock appears as soon as the sonic speed is exceeded on the surface.

(III) When the maximum local Mach number on the surface of T.T.- and 0012-airfoils approaches 1.1, there appears an oscillation whose frequency is of the order of 100 cps. In the A-case of the elliptic cylinder, the frequency is 30–40 cps. The flow involves oscillating shock waves, as shown in Figs. 8a3, b2 and c2, though these photographs are cut too short to see the whole periods.

(IV) These oscillations cease when the flow speed is raised further, and a flow involving a steady shock is formed (Fig. 8a4).

The oscillation mentioned in (II) may be considered as the repetition of the following processes. When the sonic speed is exceeded on the surface, the traveling shocks tend to accumulate at a certain point, but their pressure rise can be transferred upstream through the subsonic region outside, where the upstream movement of these shocks is still possible. This raises the pressure ahead of the accumulation point and smoothes the pressure jump. After that the flow returns to its initial state and repeats the same process.

The accumulation of the traveling shocks resembles the process described in Kuo's stability analysis (references (3) and (5)), but it should be noted that the process does not lead directly to the formation of a steady shock but causes flow oscillation at first. In view of the isolated character of the mixed potential flow, it is of course probable that the accumulation of the disturbances in the sense of Busemann's theory takes place at the end of the supersonic region, but it is impossible to distinguish it from the accumulation of the traveling shocks.

The above-mentioned two-dimensional shock diffusion exists also in stage (III), as clearly seen in Fig. 8b4 which shows the flow fluctuation in the subsonic region distant from the surface of the elliptic cylinder. Its effect on the flow ahead of the shock may be correlated to the extent of the local supersonic region. As shown in Fig. 6, it is much wider for the elliptic cylinder than for the two other airfoils. This seems to explain why a rapid oscillation of type (II) does not occur on the elliptic cylinder.

Fig. 9 shows the pressure fluctuations at certain points near the surface of the T.T. airfoil. Here p' is the fluctuation about the mean pressure and p_0 is the stagnation pressure. Two curves in the right of each diagram are the pressure distributions corresponding to the extreme values of p'. Pressure distribution on the surface is smooth as a time mean, and approximately agrees with the theoretical prediction, as shown by the interferograms taken under the exposure of the order of 1/100 sec. Also, the pressure distribution at the case when the steady shock appears nearly agrees with the theoretical one at the breakdown of the potential flow.

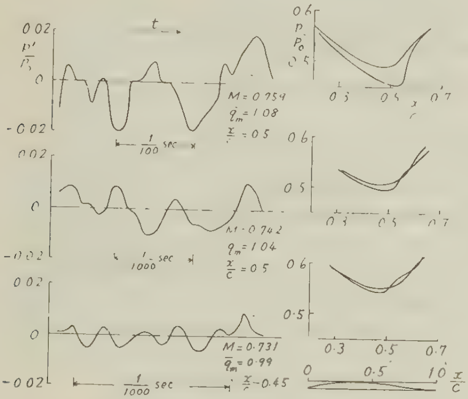

Fig. 9. Pressure fluctuation near T.T. airfoil (Strip region I).

Finally the maximum amplitude Δp of the pressure fluctuation in the region downstream of the point of minimum pressure is shown in Fig. 10. Steep rise of Δp corresponds to the appearance of the oscillation of type (III), and sudden fall corresponds to the settling down of the shock wave. Fluctuations on the 0012 are a little smaller than on the T.T. airfoil when q_m is near unity, but get larger as q_m is increased. It should be added here that in the case without the boundary layer trip fluctuations in the local supersonic region contain a considerable amount of high frequency components of about 5000 cps or more due to laminar separation, but the amplitude of low frequency oscillation is small (Fig. 8a6).

All these results have been obtained by using very small models. A certain kind of scale effect is expected to exist with respect to the frequencies and amplitudes of these oscillations. Such an effect will be a subject of future investigation.

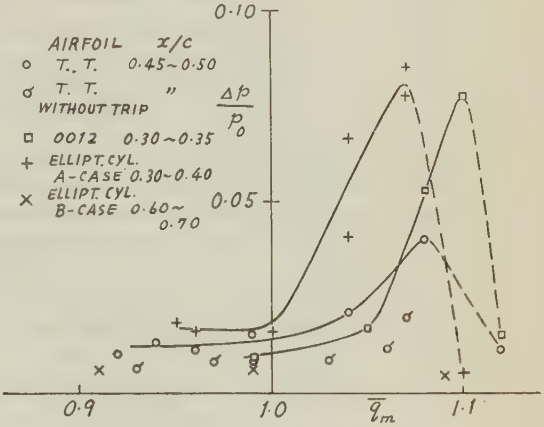

Fig. 10. Amplitude of the pressure fluctuation (strip region I).

The author wishes to express his cordial thanks to Mr. S. Nagai for his assistance during the course of the present work. This work has been partly aided by the fund of the Ministry of Education for scientific researches.

Studies on the Hypersonic Flow Using a Double-Diaphragm Shock Tube

By Fumio TAMAKI

Institute of Industrial Science, University of Tokyo

and KIM Chul-Soo

Department of Physics, Faculty of Science, University of Tokyo

(Received February 7, 1957)

A shock tube having two partition diaphragms is devised for generating a hypersonic flow free from air-liquefaction. The tube consists of a high and a medium pressure chambers of equal cross-section and a low pressure chamber with a narrow, slit-shaped inlet and a large area divergence. Hypersonic flow is generated by the expansion into the low pressure chamber of the air, which is initially contained in the medium pressure chamber and compressed to high pressure and temperature by the nearly clossed-wall reflection of the shock wave created by the rupture of the diaphragm between high and medium pressure chambers.

Flow of Mach number 6.4 with a duration of 1 millisecond is obtained and used for the studies of the flow past elliptic-nosed plates. Axis-ratios tested are 8, 1 (semi-circular nose) and 0 (square nose). Pressure distribution over the surface and head drag coefficient are determined by using a Mach-Zehnder interferometer.

§ 1. Introduction

One of the difficulties in hypersonic wind-tunnel techniques lies in the prevention of air-liquefaction caused by a considerable drop of temperature due to a large degree of adiabatic expansion. Supply air must be heated to a high temperature in order to be kept above the dew line after the expansion.

A shock tube method, utilizing a shock wave for heating the expanding air, has been devised by Hertzberg[1)], and a certain modification has been reported by Nagamatsu[2)]. An idea of a double-diaphragm shock tube with constant cross-section has been proposed by Bernstein[3)]. Although his method is excellent as to the gain in temperature at high Mach numbers, it requires considerable tube length, and so far as the present authors are aware, the experimental results have not been reported yet.

A divergent shock tube, having a diaphragm adjacent to the entrance of the divergent channel of the low pressure chamber, has been previously used by the present authors[4),5)] for the studies of supersonic flows of Mach numbers less than 6. In this shock tube, supersonic flow is obtained by the expansion of the air which is initially contained in the high pressure chamber, so the pre-heating of the air is necessary in order to use this shock tube for high Mach numbers. Addition of one more stage of high pressure chamber for this purpose has led us to a double-diaphragm shock tube somewhat different from the above mentioned. In order to obtain a flow of very high Mach number, maintaining its state above the dew line, and to secure sufficient duration of steady flow, it is of course necessary to use a long medium pressure chamber. The tube length is however shorter than the Bernstein's and the pressure adjustment of the low pressure chamber seems to be easier.

The shock tube here constructed has been used for the investigation of the flow past elliptic-nosed plates at $M \doteq 6.4$. Such experiments at low and moderate supersonic speeds have been reported by Holder and Chinneck[6)], A. Ferri[7)] and others[8),9)]. In the present experiments, the same types of the leading edge shape as those of Holder and Chinneck have been dealt with. As the Reynolds numbers in both experiments are nearly the same, the comparison of the results is significant and enables us to understand the Mach number effect on the flow character near the leading edge, particularly on the nose drag of the body moving with supersonic speed.

§ 2. Equipments

The schematic diagram of the present shock tube and dimensions of the main parts are shown in Fig. 1. High and medium pressure channels are of equal cross-section. Medium pressure channel is bent in rectangle, due to the limit in the available height of the room. Low pressure chamber consists of a rectangular tube and a receiver of a large volume. Straightly diverged nozzle is formed by wooden liners inside the tube. Test chamber has a rectangular cross-section of 15×6 cm². This cross-section is continued by a duct inserted into the receiver nearly to its mid-point. As for the partition diaphragms, three or four sheets of cellophane of 40 micron thickness are used for D_1, and a thin cellophane of 18 micron thickness is used for D_2. D_1 is broken by a needle, and D_2 by the shock wave.

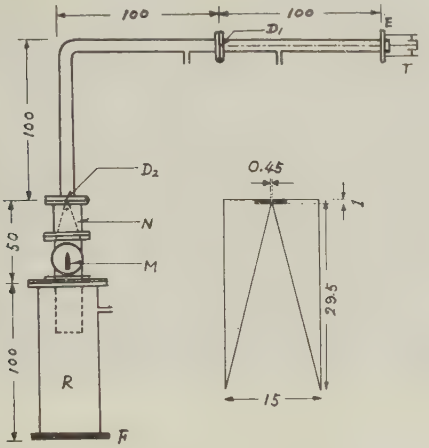

Fig. 1. Schematic diagram of hypersonic shock tube. T (Trigger), D_1 (1st draphragm), D_2 (2nd diaphragm), N (Nozzle), M (Model), R (Receiver), ED_1 (High pressure chamber), D_1D_2 (Medium pressure chamber), D_2F (Low pressure chamber), Dimensions in centimeter.

Models tested are three elliptic-nosed plates of axis-ratios $\lambda=2L/t=8$, 1 (semi-circular nose) and 0 (square nose). All the plates are 8 mm thick, and supported by thin stings attached to their mid-span. Mach-Zehnder interferometer with a light source of magnesium spark has been used for optical measurements. The shock tube has been operated at a Mach number of 6.4, and Reynolds number is 1.35×10^5 per centimeter.

§ 3. Theoretical Consideration

As shown in Fig. 1 the whole tube is divided into three parts by two diaphragms D_1 and D_2. The first two chambers constitute an ordinary shock tube. Actually, there is a bent at the middle of the second chamber, but it is simply neglected in the present consideration, assuming that the weakening of the incident shock and the disturbance to the flow behind it are small. Then, the shock generated in the second chamber by the rupture of D_1, together with the flow state behind it, can be predicted by the usual shock tube theory. Fig. 2 shows a wave diagram for the case of initial pressure ratio $p_2/p_1=13/4$, where p_2 and p_1 denote the initial pressure in high and medium pressure chambers, respectively. Abscissa is the distance x along the tube axis, and ordinate is the time t multiplied by the sound speed a_1 corresponding to the initial temperature. (It is assumed that the initial temperature is the same for all the chambers.)

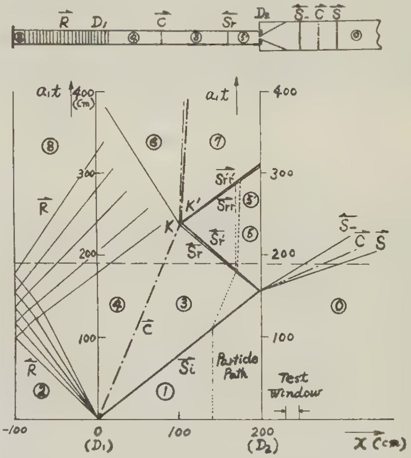

Fig. 2. Wave diagram.

The second diaphragm D_2 is situated at the end of the second chamber, i.e., just in front of the slit-shaped inlet of the third, low pressure chamber. There the shock is reflected, and at the same time, D_2 is broken by the pressure rise due to the shock reflection, and a certain amount of air compressed to high pressure and temperature expands through the divergent channel to a hypersonic speed. Shock reflection at the position of D_2 can be calculated by using shock polars under the assumptions: flow is sonic at the throat and one-dimensional steady flow relation holds between the throat and the upstream tube, and the shock reflection takes place so as to satisfy the condition that the flow Mach number behind the reflected shock is equal to the value determined by the area ratio A_*/A_1 of the throat to the upstream tube. As A_*/A_1 is small, we may expect that the shock reflection does not differ much from that at a closed wall. Assuming the initial pressure ratio $p_2/p_1=13/4$, we have, for the closed-wall reflection, $p_5/p_1=2.97$, $\rho_5/\rho_1=2.16$ and $T_5/T_1=1.38$, where 5 denotes the quantities behind the reflected shock; while in the case of real reflection, we have $p_{5'}/p_1=2.87$, $\rho_{5'}/\rho_1=2.11$, $T_{5'}/T_1=1.37$ and $u_{5'}/a_1=0.02$, where $u_{5'}$ is the flow velocity behind the reflected shock. Here and in Fig. 2, primes attached to the letters denote the case when the mass flow through the nozzle is taken into account. In this calculation, the effective value of A_* has been assumed to be 1.28 cm^2, which is about a half of the geometrical area of the nozzle inlet. This value of A_* has been estimated from the fact that a quasi-steady flow of $M=6.4$, which is considerably higher than expected from the geometrical area ratio of the test section to the nozzle inlet, has been obtained at the test section. This fact, which may be attributed to the viscosity effect at the throat was also experienced in our previous single-stage divergent shock tube[4),5)].

The wave propagation and the associated flow in the low pressure chamber can be calculated by the method of characteristics. However, for a rough estimation of the time of establishment of the quasi-steady flow at the end of the divergent channel, it is sufficient to approximate the continuous area change by one or two discontinuous steps. Procedure for such a calculation is given by Rudinger[10)]. Wave diagram in the right part of Fig. 2 has been obtained by replacing the whole area change by a single step at the inlet of the divergent channel. In this diagram, the initial condition is $p_2:p_1:p_0=13$ atms: 4 atms: 2 mmHg and $T_2=T_1=T_0=285°$K. A quasi-steady flow of high Mach number is obtained in the test section after the passage of the primary shock, contact surface and the secondary shock. Temperature of this flow is about 42°K for $M=6.4$ which is actually obtained in the experiment. This is nearly equal to the air-liquefaction temperature estimated by an extrapolation of Hausen's T-S diagram[11)]. However, since a certain degree of supersaturation is expected, there may be no fear of air-liquefaction.

§ 4. Results

Schlieren photographs showing the flow history at the test section are given in Fig. 3. These photographs have been obtained under the condition: $p_2=13$ atms, $p_1=4$ atms and $p_0=2$ mmHg. Fig. 3a shows the primary shock advancing toward the wedge. Fig. 3b shows the flow near the contact surface. Here the wide zone of mixing of cold and hot airs appears instead of a thin contact surface. Fig. 3c shows the flow near the secondary shock. After the secondary shock is swept downstream, a quasi-steady flow of $M=6.4$ is established with a duration of 1 milli-second. This is shown in Fig. 3d.

Mach number of the stationary flow has been determined by the measurement of Mach angle. For this purpose, several strips of cellophane tape have been sticked to each of the diverging walls, and the angle between the wave fronts originating from each side has been measured. This gives the value of $M=6.4$ for the initial condition given above. The same condition has been kept through the experiments.

The flows past elliptic-nosed plates have been investigated by schlieren method and interferometer. Photographs for the case of $\lambda=8$, 1 and 0 are shown in Figs. 4a, 4b and 4c, respectively. Results will be discussed separately according to the axis-ratio, and will be compared with the experiments of Holder and Chinneck at low supersonic speeds.

$\lambda=8$: Distribution of the static pressure p on the surface expressed in non-dimensional form by dividing it by the total pressure p_n behind a normal shock is given in Fig. 5. Results of Holder and Chinneck for $M=1.42$ and 1.79 are shown in the same figure. As seen in this figure, pressure falls monotoniously from the value at the nose, which is close to the theoretical total head p_n behind the normal shock, to the free stream value p_∞ far back on the plate. In Fig. 6, the pressure distribution along the surface in non-dimensional forms of $(p-p_\infty)/p_\infty$ is plotted against y, the coordinate normal to the free-stream direction. Dotted lines in the neighborhood of

the nose denote our experimental values of $(p-p_\infty)/p_\infty$ for a circular cylinder, whose radius is taken to be equal to the radius of curvature at the nose. Chain lines in this figure and thin lines in Fig. 5 give the theoretical values of $(p-p_\infty)/p_\infty$ and p/p_n, respectively, calculated by Busemann's second order theory assuming that the pressure at the shoulder is equal to the free-strerm value. Even in the case of $M=6.4$, Busemann's theory shows good agreement with experiments except in the neighborhood of the nose.

$\lambda=1$: Experiments of Holder and Chinneck at low supersonic speed show that the minimum pressure occurs near the shoulder due to the over-expansion around it. But in our case, no striking peak of negative pressure is observed. (Fig. 7)

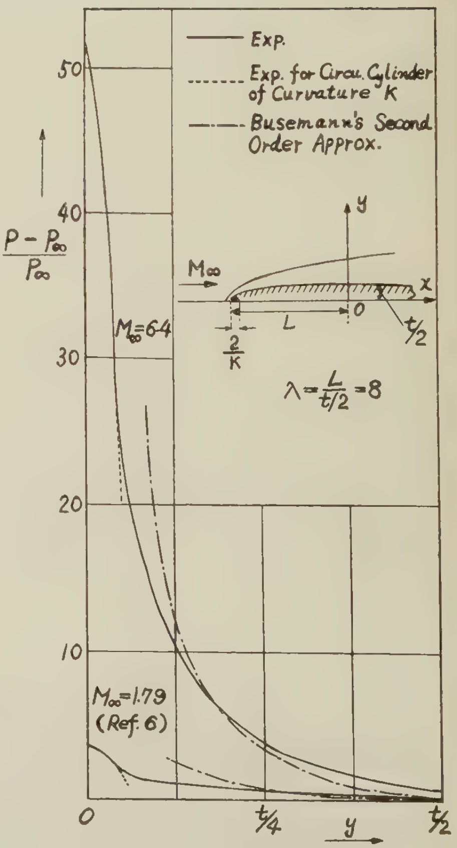

Fig. 6. $(p-p_\infty)/p_\infty$ vs. y ($\lambda=8$).

$\lambda=0$: In the low supersonic flow, negative pressure near the shoulder becomes more and more pronounced as the nose becomes blunter

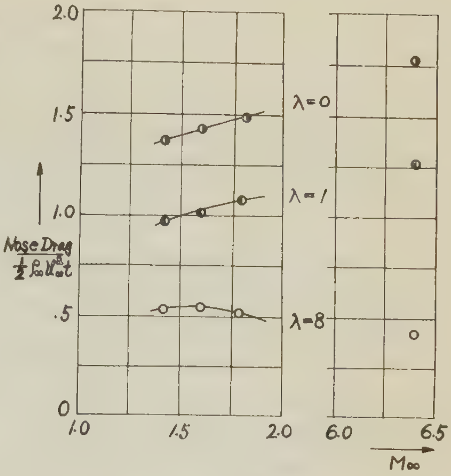

Fig. 9. C_{DN} vs. M.

and a distinct bubble caused by the separation and the reattachment of the flow appears at the shoulder. But in our case, these phenomena become less distinct due to a considerable thickening of the boundary layer. The pressure on the surface is shown in Fig. 8.

The nose drag coefficients defined by $C_{DN}=$ nose drag$/\frac{1}{2}\rho_\infty u_\infty^2 t$, where ρ_∞ and u_∞ are the density and the flow velocity of the free stream and t the thickness of the plate, are calculated from the pressure distribution, and are plotted aginst M together with the values at low supersonic speeds (reference 12) in Fig. 9. Since our interferograms for the case of $\lambda=0$ are rather indistinct as shown in Fig. 4c, the determination of the pressure distribution on the frontal surface is almost impossible, so the value of C_{DN} for this case is obtained by assuming that the pressure at the stagnation point is equal to the theoretical value and that the velocity increases linearly with the distance along the surface to the sonic speed at the shoulder. Experiments of Holder and Chinneck show that nose drag coefficient increases or decreases according to whether the nose is blunt or sharp, as expected from Ackeret's formulas. Our results show that this tendency holds even in the hypersonic flow. However, the change of C_{DN} with M seems to be smaller than in the low supersonic flow.

The Absorption Spectra of Ruby

By Y. TANABE

Department of Applied Physics, Tokyo University, Tokyo

and S. SUGANO

Department of Physics, Tokyo University, Tokyo

(Received March 16, 1956)

The absorption spectrum of Ruby (Cr^{3+}; Al_2O_3) in the opical region is quite analogous to that of Cr alum; it consists of two bands (obs. max. 18,000 cm^{-1}, 25,000 cm^{-1}) and several groups of lines situated at 14,000 cm^{-1} and 21,000 cm^{-1}.[1] Ruby shows, however, remarkable dichroism,[2] which is not clearly observed in the case of alum.

From the crystal structure of Al_2O_3, we see that the Cr^{3+} ion which substitutes the Al^{3+} ion is surrounded by six O^{2-}'s nearly octahedrally and therefore subjected to the strong cubic field as in the case of octahedral complex ion, besides the strong trigonal field which was weak in the latter.

This resemblance and the difference of the environment of the Cr^{3+} ion in these two cases lead us to expect that we can provide a firmer foundation of the theory of the absorption spectra of complex ions[3] by analyzing the spectra of dichroic Ruby.

We quote here several features of the spectrum.

(1) The first band and the characteristic doublet R_1 and R_2 show similar behaviour for linearly polarized light, i.e., the absorption is maximum for the light whose electric vector E is $\perp C_3$ (the optical axis) and minimum for $E//C_3$.[4] The emitted light of R_1 and R_2 is also polarized in the plane $\perp C_3$.[1][2]

(2) The sharp doublet R_1 (14,418 cm^{-1}) and R_2 (14,447 cm^{-1}) both show the Zeeman effect.[5] The pattern consists of an unshifted line and two nearly equally displaced side components when $H_0//C_3$ and $E\perp C_3$ (σ component). Contrary to the case of free ion spectra, the central component is stronger than the side components. When $H_0\perp C_3$ and $E\perp C_3$ (σ and π component), the pattern consists of four almost equally spaced components, their intensity being almost equal. Aside from several small differences for R_1 and R_2, these are features common to the Zeeman pattern of both R_1 and R_2.

We want to interprete these facts by using the model for the complex ion.

(1) The existence of sharp lines: The sharpness of the lines is probably due to the lack of the first order interaction between electron and nuclear motion in both the exited and ground state. That fact is peculiar to the half filled shell.

(2) The optical anisotropy: According to the theory of the absorption of the complex ion, the intensity of R_1, R_2 is stolen from that of the first band, so that it is quite reasonable that they show similar dichroism. The anisotropy of the first band is explained by assuming that the transition is that of the electric dipole coupled with the trigonal field V (F_{1uz}) whose exis is C_3. This assumption also explains the anisotropy of the second band. Thus we feel that the assignment (1st band: ${}^4A_2 \rightarrow {}^4F_2$, 2nd band: ${}^4A_2 \rightarrow {}^4F_1$) made in the previous paper is now almost established.

(3) The Zeeman pattern: The features of the Zeeman pattern enables us to conclude that R_1 and R_2 correspond respectively to the transition from the ground quartet to the doubly degenerate level (denoted as E') and the degenerate two levels (2A′) (Kramers' degeneracy) which are split from ${}^2E$ level by the interplay of the effects of the trigonal field and the spin orbit interaction. The g-values of these two exited states are anisotropic: $|g_{//}|=2$, $g_{\perp}=0$ for both of the levels. This explains the number of Zeeman components when $H_0//C_3$ and $H_0\perp C_3$. (The g-value of the ground quartet is almost isotropic and ~ 2.) The appear ance of the central line in the σ component when $H_0//C_3$ is explained by $g \sim -2$ for E' (R_1) and the transformation property of $2A'$ state wave function $\left(\sim \exp\left(\pm \frac{3}{2} i\varphi\right)\right)$ in spite of $g_{//} \sim 2$ for $2A'$ (R_2). Furthermore the intensity distribution in Zeeman pattern is nicely explained by this assignment. The observed asymmetry of the pattern can also be explained by taking the ground state natural splitting into account.

Details will be given in a later communication.

The Absolute Intensities of Cosmic Rays at 2840 Meters and Geomagnetic Latitude 25°N

By Masakazu MURAKAMI and Toshiro MAEDA
Department of Physics, Kobe University

(Received January 26, 1957)

In a previous note[1], refered to hereafter as (A), the absolute intensities of cosmic rays at sea level ($\lambda=25°$N) were reported by Kitamura and Minakawa.

Those at Mt. Norikura (altitude 2840 m. $\lambda=25°$N) were measured in the fall of 1955 by the same apparatus[2] as that used in (A).

The procedure of measurement and notation of counting rate are identical with those in (A), except for slight differences in both cases*.

The explanation of the notation and the corresponding energy intervals are tabulated in Table I, and the results are summalized in Table II and Fig. 1, where t is the average atmospheric pressure during the period of our experiment; i.e. 745.2 gr/cm².

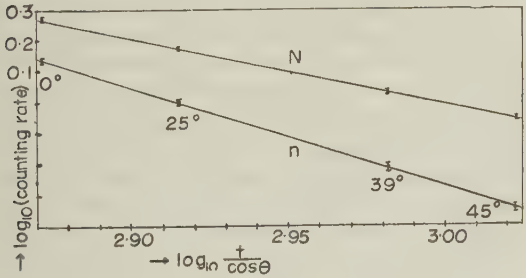

Fig. 1

In Fig. 1, it will be noted that the zenithal distribution of intensities are reported by the power of $\cos\theta$ between 0° and 45°, the exponent being 2.1±0.1 and 3.1±0.2 for the hard and soft components respectively.

We put $I_{(\theta)}=K\cdot N_{(\theta)}$, then the value of K's in respective cases were calculated as follows.

$K=1/2.65$ for the hard component
$K=1/2.58$ for the soft component

Using these relations, we obtained the following absolute intensities at 2840 m elevation;

$I_v=(1.17\pm0.01)\times10^{-2}\ \mathrm{cm^{-2}\,sec^{-1}\,sterad^{-1}}$ for the hard component

$I_v'=(0.90\pm0.02)\times10^{-2}\ \mathrm{cm^{-2}\,sec^{-1}\,sterad^{-1}}$ for the hard component

$I_v''=(2.07\pm0.02)\times10^{-2}\ \mathrm{cm^{-2}\,sec^{-1}\,sterad^{-1}}$ for the total

Table I. The explanation of the notation

notation	explanation
N	Counting rate per minute of hard component, which are mainly proportional to the number of protons and μ-mesons capable of penetrating 160 gr/cm² lead, whose energies are above 385 Mev and above 210 Mev for protons and mesons respectively.
n	Counting rate per minute of soft component, which are proportional to the number of protons, slow mesons and electrons capable of penetrating 4 gr/cm² aluminium but incapable of penetrating 160 gr/cm² lead. The energy ranges are between 385 Mev and 60 Mev, between 210 Mev and 23 Mev and above 6 Mev for protons, slow mesons and electrons respectively.
n'	Counting rate per minute of very soft component, mainly consisting of electrons, whose energies lie between 6 Mev and 1.5 Mev.

Table II. The results of counting rate against zenith angles

	0°	25°	39°	45°
$N+n$	3.28±0.03	2.46±0.02	1.69±0.02	1.36±0.01
N	1.87±0.01	1.49±0.01	1.08±0.01	0.90±0.01
n	1.39±0.03	0.97±0.03	0.62±0.02	0.47±0.02
n'**	1.12±0.06	0.60±0.05	0.77±0.03	0.44±0.03
$n+n'$	2.51±0.07	1.57±0.05	1.39±0.04	0.91±0.03

The above results are compared with those at sea level in (A) in Table III.

Precise Frequency of the 3,3 Inversion Line of Ammonia

By Koichi Shimoda

Department of Physics, Faculty of Science, University of Tokyo

(Received March 8, 1957)

Recent runs of the absorption type Stark-Zeeman ammonia clock[1] during a period from March to November 1956 give the frequency of the 3,3 line on UT2 as

$$\nu_a=23,870,131.05\pm0.05 \text{ kc/sec.}$$

Since the center frequency was found to shift to higher frequency by $\Delta\nu_a=a\Delta\nu_p$, where $\Delta\nu_p$ is the width due only to pressure broadening*, the value of frequency extrapolated to zero-pressure is given above.

A note on the frequency of a molecular beam maser oscillator has appeared, reporting the value on UT2 (Sept. 1956) as[2]

$$\nu_m=23,870,129.42\pm0.05\pm0.12 \text{ kc/sec,}$$

which is 1.63 kc/sec or 7×10^{-8} smaller than ν_a.

In comparing these values frequency shift due to different distribution of populations in quadrupole hyperfine levels, $F_1=2$, 3 and 4, must be considered. This type of shift was not described in reference 3, since it had already been shown by Gordon[4]. Assuming that eqQ in the lower inversion state is 4 ± 1 kc/sec larger than that in the upper, the center line of the 3,3 line corresponding to the transition $\Delta F_1=0$ is made up of three components as shown in Fig. 1.

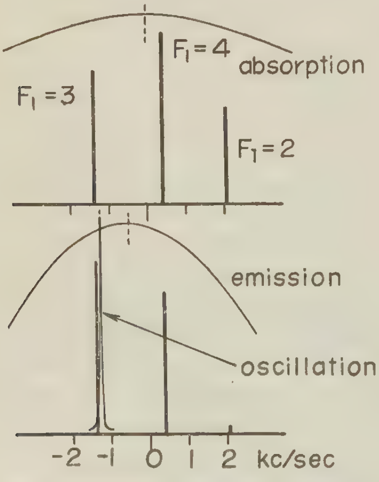

Fig. 1. Spectra of absorption, emission and oscillation of the 3,3 inversion line.

The ratio of intensities of components with $F_1=3$, 4 and 2 in the absorption line is 7:9:5, and hence the weighted average frequency coincides exactly with that undisplaced by hyperfine structure. The relative intensities of these components in a maser is determined by the relative number of focused molecules in the hyperfine levels. Since the focusing force is roughly proportional to M^2, an approximate intensity ratio of components with $F_1=3$, 4 and 2 is 45:37:2. Then the unresolved center of the emission line is shifted by $\Delta\nu_e=-0.48\pm0.12$ kc/sec. The situation in a maser oscillator is still different. Because of the regenerative amplification, the oscillation in a long cavity must start at a frequency much closer to the strongest emission line, $F_1=3$. Then the frequency shift of oscillation near the threashold would be closer to -1.24 ± 0.31 kc/sec. With increasing focuser voltage rf amplitude in the cavity increases and the saturation of $F_1=3$ component tends to introduce more contribution of ccmponents with $F_1=4$ and 2, which results in the shift approaching to $\Delta\nu_e$. The detail will be published.

Moreover, frequency shift caused by the presence of traveling wave is rather large for a long cavity as shown by (57) in reference 3. Because rf enery released from the beam is proportional to t^2 or z^2 in weak rf field, while the loss of rf energy is symmetrically distributed along the length of the cavity, the net flow of rf energy is opposite to the direction of the beam so that the frequency shift is negative. Taking $Q_t=1\sim2\times10^4$, $L=30$ cm, and $Q_l=10^7$, the shift caused by the traveling wave is $\Delta\nu_t=-(0.48\sim0.24)$ kc/sec.

Therefore, the frequency shift of the maser oscillator is estimated to be -1.6 kc/sec near the threshold and it is -0.7 kc/sec near the saturation limit. It may be concluded that the absorption line might be a better etalon in view of absolute accuracy, while each maser shows better resettability. The only so far uninvestigated source of systematic error of the absorption frequency is the shift relating to wall collision. But it does not vary with operating conditions. Accurate comparison of the absorption line with the maser has been planned in our laboratory. Since our maser can start oscillation at the focuser voltage of only 2.4 kV, while allowing the maximum of 21 kV, the above mentioned shifts will be studied in detail.

Technique of Obtaining a Minute Pinhole in a Metal Plate

By Tadasi NUMATA
Nagasaki University, Ohasi-Machi, Nagasaki

(Received April 15, 1957)

Hitherto, minute pinholes have been bored in metal by some methods[1]. By the following new method, the author was able to obtain easily very small circular pinholes of about 50 to 10 μ diameter in such metal plates as lead and Wood's metal. The pinholes obtained by this method may be applicable for optical and X-ray researches. The method is as follows:

(1) First fine long glass fibres of about 50 to 10 μ in diameter are produced by drawing out a larger hard glass rod not having bubbles and striae by usual ways[2]. Next among these fibres a fine straight glass fibre with a desirable diameter and a circular cross section is chosen by observing with a microscope. Then the needle of a fine straight glass fibre in length of about 3 cm is cut off from this selected long glass fibre.

(2) One end of a glass rod is tapered and the above needle is fixed on the tapered part of the glass rod parallel to the axis of the rod with a small piece of picein wax. Then the needle is cut again in a suitable length (2~0.5 cm), and the surface of the needle is covered with oil film by putting the needle into suitable oil. The picein wax connecting the needle with the glass rod is wrapped with cotton wetted by water in order to avoid softening of the picein wax. Then, the microscope in a travelling microscope instrument is replaced with the glass rod using rubber plug as a jointer.

(3) A circular hole of about 3 to 2 mm in diameter in a suitable metallic base plate of high melting point is covered with a molten metal of low melting point. The needle is then put into the molten metal at the center of the hole, until the tip of the needle comes out of the base metal plate, by lowering down carefully the needle perpendicular to the surface of the molten metal with the aid of the screw of the travelling microscope instrument.

(4) After congelation of the molten metal, the needle is slowly pulled up by turning the screw. In most cases, the needle smoothly comes out of the metal without snap of the needle. (Tensil strength of a glass fibre of 20 μ diameter is approximately 70 Kg/mm^2.)

By the above method, very small straight circular pinholes of about 50 to 10 μ diameter can be easily obtained on a metal plate. These pinholes have, of course, the same sizes and forms as those of the needles used. This method can be applied to the metals which have lower melting points than the strain temperature of the glass used.

Elastic Scattering of 5.7 Mev Protons from Ni and Cu

By Minoru TAKEDA, Michiya KONDO, Syohei KATO,
Chuin HU, Ryuzo NAKASIMA and Shotaro YAMABE
Department of Physics, Osaka University, Osaka

(Received February 11, 1957)

Using 5.7 Mev protons from the cyclotron, we have studied the angular distributions of protons elastically scattered from Ni and Cu by means of nuclear emulsion technique. The angular distributions were measured from 14° to 161° at an interval of 5° in the laboratory system. The differential cross sections, in the ratio to the Rutherford cross section, have a minimum at about 85° in both cases, but at large scattering angles the cross section for Ni increases linearly, while there is a maximum at about 130° in the case of Cu. The results are in essential agreement with those of Bromley and Wall.

§ 1. Introduction

Bromley and Wall[1] investigated the elastic scattering of 5.25 Mev protons from Co, Ni, Cu and Zn, and discussed the angular dependence of the deviation from the Rutherford scattering. They found two characteristic features in the angular dependences. One was that the distribution had a minimum at about 85° in the relative cross sections in all cases, and the other was that it showed large deviations from the Rutherford scattering at large angles. As to the latter feature, the measured differential cross sections at large angles were larger than those expected from the Rutherford scattering in the case of Ni(Z=28) and Zn(Z=30), while they were smaller for Co (Z=27) and Cu(Z=29). They tried to explain these situations by the use of the complex potential well model[2], and succeeded in the case of Ni but did not in the case of nearby elements with the same parameters. Because of many adjustable parameters involved in the formula of this theory, it seems to be possible to obtain a considerable agreement between the experimental results and calculated values. Since the measured angular dependences seem to be different corresponding to target spin, Bromley and Wall suggested as an alternative possibility that if one assumed the spin dependent nuclear interaction, the different tendency might be explained.

It may be expected that the spread of the beam energy is sufficient to cover many levels of the compound nucleus in medium weight region such as Ni and Cu, and still the spacing of the lowest level of the target nucleus is large enough to allow an adequate resolution for the elastically scattered protons. We attempted to obtain further informations on the elastic scattering of protons by medium weight nuclei at incident energy of nearby Coulomb barrier height. The natural Ni and Cu targets were bombarded by 5.7 Mev proton beam from the 44-inch Osaka University cyclotron[3], and the elastically scattered protons were detected by nuclear plates.

§ 2. Experimental Arrangement and Procedure

The focused proton beam from the recently built cyclotron has been used for this work. The experimental arrangement is schematically illustrated in Fig. 1. The emergent beam from the cyclotron was passed through the wedge shaped magnet, placed at about 2 meters from the deflector exit, and was focused at the center of a scattering chamber set at about 5 meters from the magnet. The 60 cm diameter scattering chamber made of aluminium was used, and the scattering angles were measured by a precise goniometer. A collimating slit system defined the beam with an angular divergence of ±0.2°, forming an energy spread of about 50 kev, and the area of beam spot on the target was 4 mm × 10 mm.

The proton beam was collected by a negatively biased Faraday cage with a small magnet which suppressed the secondary electrons. The scattered protons were detected by Fuji ET-6B nuclear emulsions which were alike, in character, to Ilford C2. The thickness of the emulsion was 70 μ and the plates were put in a plate camera with plate holders spaced at an interval of 5° from −9° to −74° and from 6.5° to 161.5° in the laboratory system, and the glancing angles of the plates were 7.5°±0.1°. As shown in Fig. 2, the plate camera was set in the scattering chamber, and the centering was accurate within ±0.2 mm.

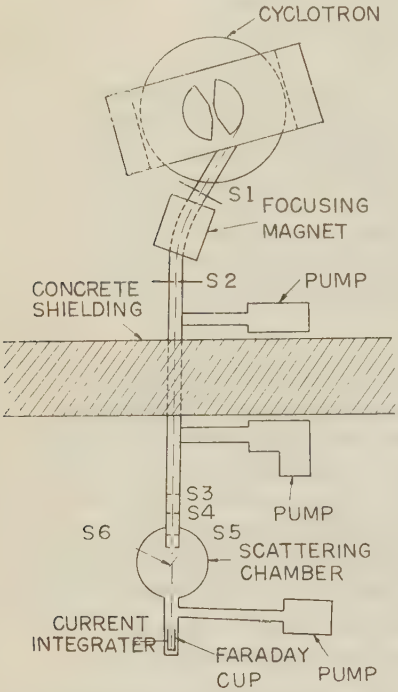

Fig. 1. The schematic illustration for present experimental arrangement.

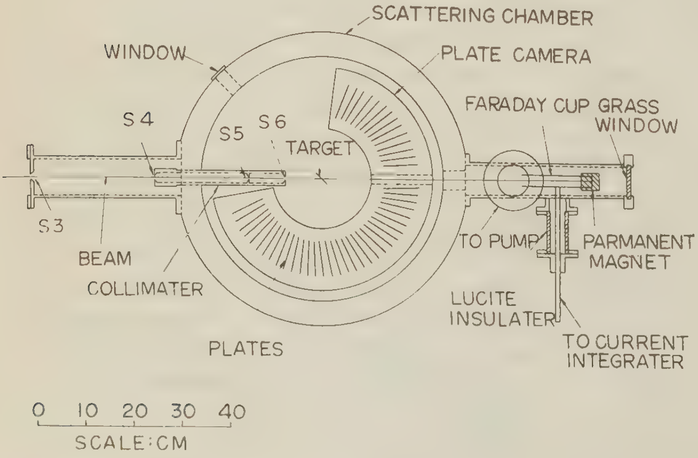

Fig. 2. The schematic diagram of the scattering chamber setting the plate camera.

The number of proton tracks in the emulsion was counted by using a microscope equipped with a ×40 objective and ×10 eyepieces. The microscope had an ocular microscope disk inserted in one eyepiece. Since the numbers of the elastically scattered protons at small angles were very large, the exposure at small angle plates was made about one-tenth in intensity of that of large angles by the shutter in front of the camera. A target equipped in the stainless steel holder with an area of 15 mm×15 mm, was set at 45°±1° to the beam direction, and the target was placed at the center of the scattering chamber with an accuracy of about±0.2 mm. The angular resolution of this work was about ±0.8°. The overall alignment was done within ±0.2°, and the geometrical errors were estimated to be about 1%.

The energy of the cyclotron beam was measured to be 5.7±0.1 Mev by the range of the elastically scattered protons from gold in C2 emulsion. It was believed that the energy used in both targets was the same within the spread of 0.1 Mev.

The Ni foil 1.5 mg/cm^2 thick was prepared by electroplating from an aqueous solution onto a polished plate of stainless steel. After it was peeled off from the backing, it was baked in vacuum. The Cu foil of 0.8 mg/cm^2 was prepared by evaporating onto a flat surface of sodium-chloride crystal, and then the crystal was dissolved into water.

§3. Results and Discussions

Our attempt was to measure the relative values of the differential cross sections, not to measure the absolute values. Since the Rutherford scattering is predominant at small angles, they were normalized to the Rutherford cross section at small angles. The number of the tracks observed in each plate was about one thousand, but about four thousand tracks were counted in the plates at small angles for which the normalization was done.

Since there are no excited levels below 500 kev in both elements except Ni^{61} (1.25% in natural), the resolution of our experiment was sufficient to distinguish the elastic peak from the inelastic one. The typical range distribution of the scattered protons from Ni target is shown in Fig. 3. For the first excited states at 1.45 Mev (2+) for Ni^{58} (67.76%) and at 1.33 Mev (2+) for Ni^{60} (26.16%), the proton groups could not be resolved. The similar spectrum of the scattered protons by Cu is shown in Fig. 4. Each level of Cu isotopes was not resolved in this experiment as shown in Fig. 4 because of their low intensities.

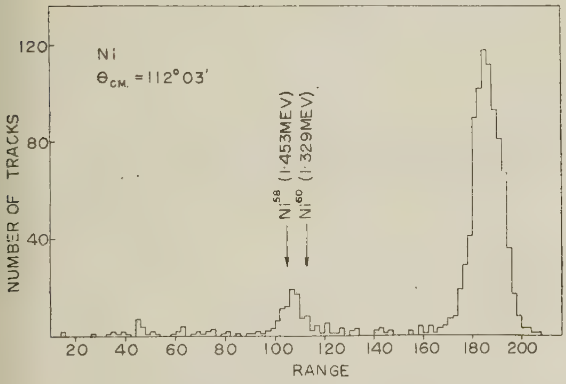

Fig. 3. The typical range distribution of the scattered protons from Ni at a center of mass angle of 112°03′. 1 div. = 1.2μ.

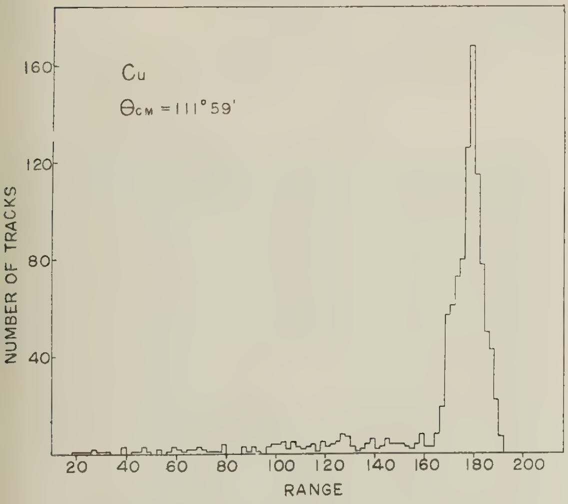

Fig. 4. The typical range distribution of the scattered protons from Cu at a center of mass angle of 111°59′. 1 div. = 1.2μ.

The amounts of the target impurities in both elements were negligible, but there was an appreciable background due to elastic protons which had escaped from the emulsion surfaces. The correction for this effect amounted to 4% of the elastic proton group. This correction was estimated by a preliminary measurement on the elastic scattering of protons from carbon by the same apparatus, because the inelastically scattered protons from carbon could not be detected energetically in our experiment. It is expected that the relative errors of the cross sections are about ±5%. The errors of the cross sections in the ratio to the Rutherford scattering are estimated to be ±12% because of the uncertainty of the beam direction.

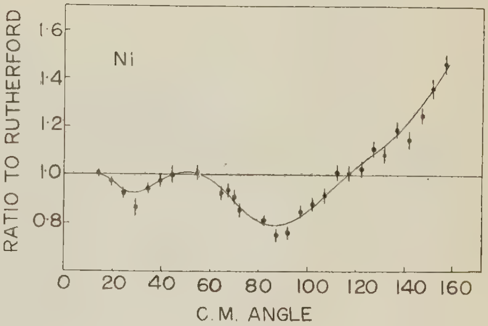

Fig. 5. Ratio of measured cross section in the center of mass system to the Rutherford for Ni.

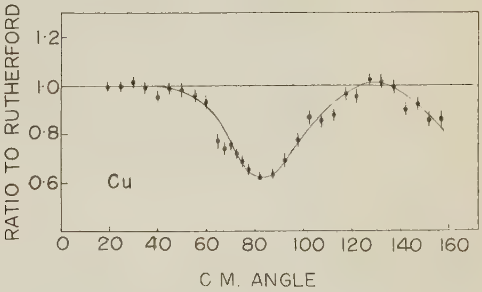

Fig. 6. Ratio of measured cross section in the center of mass system to the Rutherford for Cu.

The angular distributions obtained are shown in Figs. 5 and 6. As is seen in these figures, the angular dependences of the deviations from the Rutherford scattering are quite similar to those of Bromley and Wall. In the case of Ni, the shape of the measured angular distribution is in agreement with the calculated values by Saxon and Melkanoff$^{1)}$. Although the incident energy of our experiments (5.7 Mev) differs from that of Bromley and Wall's experiments (5.25 Mev), the present results are quite similar to theirs. The behavior of the angular dependences obtained by Schneider$^{4)}$ (6.0, 6.5 and 7.0 Mev) and Goldman$^{5)}$

(6.5 Mev) are also not so different from ours. Consequently, for Ni and Cu, it may be concluded that the behavior is not sensitive to the incident energy in these region.

Acknowledgments

The authors gratefully acknowledge the encouragement of Professor S. Kikuchi, Professor T. Wakatsuki, and Professor S. Yamaguchi who gave us kind advice throughout the course of this investigation. We also wish to express our appreciation to Fuji Film Corporation for the preparation of nuclear plates.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 12, No. 6, JUNE, 1957

Geometrical Theory of Convex Molecules in Non-Uniform Gases

By Taro KIHARA

Department of Physics, Faculty of Science,
University of Tokyo

(Received February 26, 1957)

Geometrical theory of convex molecules in uniform gases (T. Kihara, Revs. Modern Physics, **25** (1953) 831, **27** (1955) 412) is generalized to that in non-uniform gases when molecules are represented by rigid convex bodies without any additional intermolecular force. For this representation collisions between heavy molecules and light spherical molecules are treated exactly. Shape and size of several molecules are determined from diffusion coefficient. A " geometrical approximation " is suggested for more general cases.

§ 1. Introduction

After Enskog and Chapman¹⁾ had developed the kinetic theory of transport phenomena in dilute gases, several transport coefficients were calculated²⁾ for typical spherically symmetric intermolecular potentials and were compared with observation. The result was satisfactory for monatomic molecules. For non-monatomic molecules on the other hand there is no satisfactory treatment yet.

In 1950 Isihara³⁾ proved a geometrical identity for convex bodies and pointed out the fact that the identity is useful for treatment of molecular interaction in *uniform* gases and liquid-solutions. His work was improved and generalized by the present author⁴⁾. Owing to the generalization it became possible to treat the second virial coefficient for polyatomic molecules in a neat and simple manner.

Recently the author noticed that Hadwiger⁵⁾, a mathematician, had independently proved the same identity also in the year 1950. His result is constituted by three identities, one of which is the same as Isihara's. The chief objective of the present article is to show that the second identity by Hadwiger can be applied to molecular interactions in *non-uniform* gases.

It is to be noted that Curtiss⁶⁾ is developing a kinetic theory of non-uniform gases by use of the convex-body model of molecules. Owing to great difficulties of treating collisions between two convex bodies, however, he does not seem to have succeeded in obtaining a result capable of comparison with observations.

In this article a direct and simple proof of Hadwiger's relations and other necessary formulas will be given first. The former is an extension of the proof by the author of Isihara's identity. After preparing necessary tables, our mathematical results will be applied to transport phenomena, chiefly to diffusion; the shape and size of several polyatomic molecules will be determined as a result of comparison with observations.

§2. Geometry of Convex Bodies

A body is called convex if any segment whose end points are inside lies entirely in that body.

Let us choose a coordinate origin O inside a (fixed) convex body and take coordinates of polar angles θ and φ ($0 \leq \theta \leq \pi$, $0 \leq \varphi \leq 2\pi$). For any direction (θ, φ), there is one and only one plane which is in contact with the convex body and whose normal from the origin is in the direction (θ, φ). This plane is named the supporting plane in the direction (θ, φ); the perpendicular distance from the origin to the supporting plane is called the supporting function, when it is considered as a function of θ and φ. The supporting function will be denoted by $H(\theta, \varphi)$. Let us further denote by M the supporting function integrated over all directions,

$$M \equiv \int_0^{2\pi}\int_0^{\pi} H(\theta, \varphi) \sin\theta d\theta d\varphi \ . \qquad (1)$$

We shall later see that M is the mean curvature integrated over the whole surface of the convex body.

Let us first assume that convex body has a smooth surface and that each supporting plane has a contact of first order with the convex body. Let $\boldsymbol{r}(\theta, \varphi)$ be the radius vector from the origin to the contact point of the body with the supporting plane in the direction (θ, φ); compare Fig. 1(a). Then by use of the unit vector $\boldsymbol{u}(\theta, \varphi)$ in the direction (θ, φ) we have

$$H(\theta, \varphi) = \boldsymbol{r}(\theta, \varphi) \cdot \boldsymbol{u}(\theta, \varphi) \qquad (2)$$

and

$$M = \iint \boldsymbol{r} \cdot \boldsymbol{u} \sin\theta \, d\theta d\varphi = \iint \boldsymbol{r} \cdot \left(\frac{\partial \boldsymbol{u}}{d\theta} \times \frac{\partial \boldsymbol{u}}{\partial\varphi}\right) d\theta d\varphi \ . \qquad (3)$$

The surface area S and the volume V of the convex body are given by

$$S = \iint \left|\frac{\partial \boldsymbol{r}}{\partial\theta} \times \frac{\partial \boldsymbol{r}}{\partial\varphi}\right| d\theta d\varphi$$

or, since $(\partial \boldsymbol{r}/\partial\theta) \times (\partial \boldsymbol{r}/\partial\varphi)$ is parallel to $\boldsymbol{u}$,

$$S = \iint \boldsymbol{r} \cdot \left(\frac{\partial \boldsymbol{r}}{\partial\theta} \times \frac{\partial \boldsymbol{r}}{\partial\varphi}\right) d\theta d\varphi \qquad (4)$$

and

$$V = \frac{1}{3} \iint \boldsymbol{r} \cdot \left(\frac{\partial \boldsymbol{r}}{\partial\theta} \times \frac{\partial \boldsymbol{r}}{\partial\varphi}\right) d\theta d\varphi \ . \qquad (5)$$

Now we consider two convex bodies labelled A and B and in each body choose a coordinate origin O_A and O_B. The volume, the surface area, the M-value, and the $\boldsymbol{r}$-function will be denoted by

$$V_A, \quad S_A, \quad M_A, \quad \boldsymbol{r}_A(\theta, \varphi)$$

and

$$V_B, \quad S_B, \quad M_B, \quad \boldsymbol{r}_B(\theta, \varphi) \ ,$$

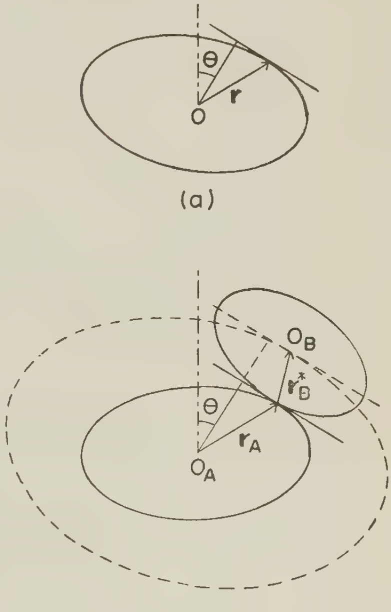
respectively. Keeping O_A and the orientation of A fixed, and keeping the orientation of B also fixed, let us move B around A keeping contact from outside. Then the locus of O_B forms the surface of another convex body, named AB, whose $\boldsymbol{r}$-function is

$$\boldsymbol{r}(\theta, \varphi) = \boldsymbol{r}_A(\theta, \varphi) + \boldsymbol{r}_B^*(\theta, \varphi) \ ,$$

with

$$\boldsymbol{r}_B^*(\theta, \varphi) \equiv -\boldsymbol{r}_B(\pi - \theta, \pi + \varphi) \ ,$$

see Fig. 1(b).



(a)

(b)

Fig. 1. Convex bodies and their supporting planes.

The volume of the last convex body AB,

$$V_{AB}=\frac{1}{3}\iint(\boldsymbol{r}_B+\boldsymbol{r}_B^*)\cdot\left[\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}+\frac{\partial \boldsymbol{r}_B^*}{\partial\theta}\right)\times\left(\frac{\partial \boldsymbol{r}_A}{\partial\varphi}+\frac{\partial \boldsymbol{r}_B^*}{\partial\varphi}\right)\right]d\theta d\varphi,$$

will be first evaluated. Making use of the identity

$$\frac{\partial}{\partial\theta}\left[\boldsymbol{r}_B^*\cdot\left(\boldsymbol{r}_A\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)\right]+\frac{\partial}{\partial\varphi}\left[\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\boldsymbol{r}_A\right)\right]$$
$$=2\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)-\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{r}_B^*}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)$$
$$-\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_B^*}{\partial\varphi}\right)$$

we have

$$\iint\left[\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{r}_B^*}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)+\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_B^*}{\partial\varphi}\right)\right]d\theta d\varphi$$
$$=2\iint\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)d\theta d\varphi\,,$$

since the integral of the divergence expression vanishes. Making use of this relation and another similar one, we obtain

$$V_{AB}=V_A+V_B+\iint\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)d\theta d\varphi$$
$$+\iint\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{r}_B^*}{\partial\theta}\times\frac{\partial \boldsymbol{r}_B^*}{\partial\varphi}\right)d\theta d\varphi\,.$$

Up to this point the orientation of the convex body B has been kept fixed. The next step is to take the average with respect to the orientations of the body B. The integrand of the third term on the right-hand side can be replaced by

$$\boldsymbol{r}_B^*\cdot\boldsymbol{uu}\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right).$$

When $\boldsymbol{r}_B^*\cdot\boldsymbol{u}$ is averaged with respect to orientations of the body B, the value no longer depends on (θ,φ) and is equal to $(4\pi)^{-1}M_B$. The average value of the third term is therefore $(4\pi)^{-1}M_BS_A$. Thus the average value of V_{AB} becomes

$$<V_{AB}>_{\mathrm{AV}}=V_A+V_B+\frac{1}{4\pi}(M_BS_A+M_AS_B)\,. \tag{6}$$

The surface area of the convex body AB,

$$S_{AB}=\iint\boldsymbol{u}\cdot\left[\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}+\frac{\partial \boldsymbol{r}_B^*}{\partial\theta}\right)\times\left(\frac{\partial \boldsymbol{r}_A}{\partial\varphi}+\frac{\partial \boldsymbol{r}_B^*}{\partial\varphi}\right)\right]d\theta d\varphi$$

can be transformed in a similar way into

$$S_{AB}=S_A+S_B+\iint\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{u}}{\partial\varphi}\right)d\theta d\varphi$$
$$+\iint\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{u}}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)d\theta d\varphi\,.$$

Replacing

$$\boldsymbol{r}_B^*\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{u}}{\partial\varphi}\right)\quad\text{by}\quad\boldsymbol{r}_B^*\cdot\boldsymbol{uu}\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{u}}{\partial\varphi}\right)$$

and taking the average with respect to orientations of the convex body B, we obtain

$$<S_{AB}>_{\mathrm{AV}}$$
$$=S_A+S_B+\frac{1}{4\pi}M_B\left[\iint\boldsymbol{u}\cdot\left(\frac{\partial \boldsymbol{r}_A}{\partial\theta}\times\frac{\partial \boldsymbol{u}}{\partial\varphi}\right)d\theta d\varphi\right.$$
$$\left.+\iint\boldsymbol{u}\cdot\left(\frac{\partial \boldsymbol{u}}{\partial\theta}\times\frac{\partial \boldsymbol{r}_A}{\partial\varphi}\right)d\theta d\varphi\right].$$

The [ ]-bracket expression can be reduced to

$$2\iint\boldsymbol{r}_A\cdot\left(\frac{\partial \boldsymbol{u}}{\partial\theta}\times\frac{\partial \boldsymbol{u}}{\partial\varphi}\right)d\theta d\varphi\,,$$

which, by virtue of (3), is equal to $2M_A$. Hence the result is

$$<S_{AB}>_{\mathrm{AV}}=S_A+S_B+(1/2\pi)M_AM_B\,. \tag{7}$$

The third relation

$$<M_{AB}>_{\mathrm{AV}}=M_A+M_B \tag{8}$$

is easy to see.

After we have obtained these relations it is no longer necessary to assume that the convex body has a smooth surface and that each supporting plane has a contact of first order with the convex body.

The formulas (6), (7) and (8) were given by Hadwiger[5]. The proof given above is partly due to Minkowski.[7]

The particular case when the convex body B is a sphere of radius b is well known. A convex body formed by all points whose distances from A are smaller than or equal to b is called the parallel body of A in the distance b. Its volume, surface area and the M-value are respectively given by

$$V_b=V+Sb+Mb^2+(4\pi/3)b^3\,, \tag{9}$$
$$S_b=S+2Mb+4\pi b^2\,, \tag{10}$$
$$M_b=M+4\pi b\,, \tag{11}$$

where V, S, M on the right-hand sides are constants of the convex body A. These three relations are called Steiner's formulas.

According to Gauss' theorem on spherical representation the surface area S can be expressed in another form

$$S=\iint R_1\,R_2\sin\theta\,d\theta\,d\varphi$$

where R_1 and R_2 are the principal radii of curvature at $\boldsymbol{r}(\theta,\varphi)$. The surface area of a parallel body is similarly

$$S_b=\iint(R_1+b)(R_2+b)\sin\theta\,d\theta\,d\varphi$$

$$=S+b\iint(R_1+R_2)\sin\theta\,d\theta\,d\varphi+4\pi b^2\ .$$

Comparing (10) we obtain therefore

$$M=\frac{1}{2}\iint(R_1+R_2)\sin\theta\,d\theta\,d\varphi$$

or, again by use of the Gauss theorem,

$$M=\int\frac{1}{2}\left(\frac{1}{R_1}+\frac{1}{R_2}\right)dS\ . \tag{12}$$

The last relation indicates that M is the mean curvature integrated over the whole surface of the convex body.

Values of V, S and M for several typical shapes are given in an article of the author[4] and in Hadwiger's book.[5]

§ 3. Convex Cores of Molecules

For applications of the geometry of convex bodies to molecules in gases it is useful to define an appropriate convex core within each molecule. In order to determine the core of a molecule, it is necessary to have information about the interatomic distances (and bond angles if any) of the molecule. We prepare, therefore, Table I. Consulting this table we fix our cores as in Table II. The volume V_0, the surface area S_0, and the surface integral of the mean curvature M_0 of the core are also tabulated.

Table I. Interatomic distances

Molecules		Bonds	Distance in A
Hydrogen	H_2	H–H	0.74
Nitrogen	N_2	N–N	1.094
Oxygen	O_2	O–O	1.10
Fluorine	F_2	F–F	1.44
Chlorine	Cl_2	Cl–Cl	2.01
Carbon dioxide	CO_2	C–O	1.15
Acetylene	C_2H_2	C–C	1.20
		C–H	1.06
Boron trifluoride	BF_3	B–F	1.30
Boron Trichloride	BCl_3	B–Cl	1.74
Ethylene	C_2H_4	C–C	1.33
		C–H	1.087
(Angle H–C–H is $2\tan^{-1}\sqrt{2}=109°30'$			
Benzene	C_6H_6	C–C	1.39
		C–H	1.08
Methane	CH_4	C–H	1.093
Carbon tetrafluoride	CF_4	C–F	1.36
Carbon tetrachloride	CCl_4	C–Cl	1.755
Silicon tetrafluoride	SiF_4	Si–F	1.54
Silicon tetrachloride	$SiCl_4$	Si–Cl	2.01
Sulfur hexafluoride	SF_6	S–F	1.56

The values are chiefly taken from L. Pauling, *Nature of the Chemical Bond* (Cornell Univ. Press, Ithaca, New York 1948). The value for SF_6 is due to H. Braune and S. Knocke, Z. physik. Chem. B **21** (1933) 297.

Table II. The cores of molecules

Molecules	Cores	V_0 (A³)	S_0 (A²)	M_0 (A)
N_2	thin rod joining 2N's	0	0	3.44
O_2	thin rod joining 2O's	0	0	3.45
CO_2	thin rod joining 2O's	0	0	7.23
CCl_4	tetrahedron joining 4Cl's	2.77	14.23	16.43
SF_6	octahedron joining 6F's	5.06	16.86	16.29
C_6H_6	hexagon joining mid-points of C–H	0	19.4	18.2

§ 4. Application to Transport Phenomena in Gases

In order to apply our theory of convex bodies to transport phenomena in gases let a molecule be representated by a rigid convex body without additional intermolecular force. In the following the representing convex body will be called molecule for brevity.

Diffusion between heavy convex molecules and light spherical molecules can be treated exactly so far as Enskog-Chapman's first approximation is concerned. Here we assume that the heavy molecule does not greatly change its linear and rotational velocities when it collides with a light molecule.

The coefficient of diffusion D in general is inversely proportional both to the total number-density N of gas molecules and to an effective cross section Q of collisions between two unlike molecules,

$$D=\frac{3}{4N}\left(\frac{2\pi kT}{m^*}\right)^{1/2}\frac{1}{Q}\ . \tag{13}$$

Here m^* is the reduced mass of a pair of unlike molecules; kT is the Boltzmann constant times temperature. Values of D at 0°C, 1 atmosphere and values of Q defined by (13) are given in Table III. When the two diffusing molecules are spheres of radii a and b, Q is equal to

$$Q=4\pi(a+b)^2\ , \tag{14}$$

which is the surface area of a sphere of collision radius.

The coefficient of diffusion between heavy molecules and light spherical molecules can be

Table III. Coefficients of diffusion D at 0°C, 1 atm. and the effective cross sections Q in Eq. (13)

Gases	D (cm^2/sec)	Q (A^2)	$S_A+S_B+\frac{1}{2\pi}M_AM_B$ (A^2)
H_2-N_2	0.674	114	
H_2-O_2	0.697	109	
H_2-CO_2	0.550	138	
H_2-CCl_4	0.293	255	
H_2-SF_6	0.420	178	
H_2-C_6H_6	0.318	236	
N_2-O_2	0.181	150	147
N_2-CO_2	0.144	176	179
O_2-CO_2	0.139	175	173
O_2-CCl_4	0.0636	320	304
O_2-C_6H_6	0.0797	278	283
O_2-O_2	0.189	139	141
CO_2-CO_2	0.104	215	208

The values of D are taken from

S. Chapman and T. G. Cowling: *Mathematical Theory of Non-Uniform Gases* (Cambridge Univ. Press, 1953).

W. Jost: *Diffusion* (Academic Press, New York, 1954).

J. O. Hirschfelder et al.: *Nolecular Theory of Gases and Liquids* (John Wiley and Sons, Inc., New York, 1954)

obtained if we replace $4\pi(a+b)^2$ by the expression (10):

$$Q=S+2Mb+4\pi b^2 . \tag{15}$$

Here S and M are the surface area and the surface integral of mean curvature of a heavy molecule, respectively, and b is the radius of a light molecule. This substitution is understood as follows. When a heavy molecule collides with a light spherical molecule the center of the light molecule is reflected at the surface of a parallel body in the distance b from the heavy molecule, which does not move during the collision. Two surface elements of equal amount on the parallel body reflect, in the average, equal number of light molecules into each scattering angle. In other words each surface element is independent of the shape of the whole surface. Therefore, the effective collision cross section is determined only by the total surface areas of the parallel body in the distance b from the heavy molecule.

For practical applications it is useful to choose as the convex body representing the heavy molecule a parallel body of its molecular core. Denoting by S_0 and M_0 the surface area and the surface integral of the mean curvature of the core respectively, we let namely

$$S=S_0+2M_0a+4\pi a^2 ,$$

$$M=M_0+4\pi a ,$$

where a is a parameter indicating the distance from the core to the molecular surface. Hence the relation (15) becomes

$$Q=S_0+2M_0(a+b)+4\pi(a+b)^2 . \tag{16}$$

Table IV. Constants of rigid convex-body model of molecules determined from coefficients of diffusion at 0°C.

Molecules	a (A)	S (A^2)	M (A)
N_2	1.48	37.7	22.0
O_2	1.41	34.7	21.2
CO_2	1.50	50.0	26.1
CCl_4	1.99	129	41.5
SF_6	1.24	76.6	31.9
C_6H_6	1.68	116	39.3

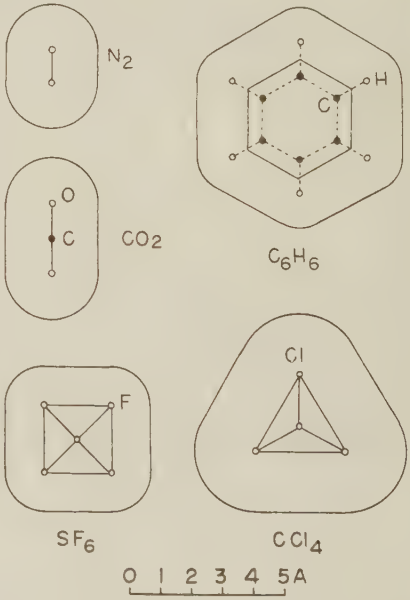


Fig. 2. Shape and size of molecules according to the rigid convex-body model determined from diffusion coefficients in hydrogen at 0°C.

The result obtained above can be applied to diffusion between hydrogen molecule (which may be assumed to be spherical) and several heavier molecules. From observed coefficient of self diffusion for hydrogen at 0°C we have $b=1.27$A. Then using the coefficient of mutual diffusion at 0°C, we can determine a of eral molecules. The result is given in ble IV and Fig. 2.

Thermal diffusion between heavy convex lecules and light spherical molecules can be ated similarly if the density of one of the mponents is much smaller than the density the other. (The last restriction is not nec- sary for ordinary diffusion,) For thermal fusion, however, our molecular model can used only at high temperatures, because the tractive part of the intermolecular potential ays an essential role at lower temperatures.

Collisions between two convex bodies in neral constitute a difficult dynamical problem ther than a mere geometrical one. Two lliding convex bodies rotate in a complicated anner, making several contacts in general; rrect treatment of this dynamical and atistical problem seems to be formidable. he present author, therefore, suggests a geometrical approximation" which is based on the assumption that the effect of mole- lar rotation vanishes in the average and the rmula (7) can be used. Thus, for the coef- cient of diffusion between A and B a sug- ested approximation to Q is

$$Q\approx S_A+S_B+(1/2\pi)M_AM_B\,. \tag{17}$$

Table III calculated value of the right-hand de are compared with observed values of the ft-hand side. Since equality holds within perimental accuracy our approximation seems to be close to the reality so far as rigid convex molecules are concerned.

Similar approximation to the viscosity η of a pure gas composed of rigid convex molecules with constants S and M and the mass m is

$$\eta\approx\frac{5}{4}(\pi kTm)^{1/2}\left(2S+\frac{1}{2\pi}M^2\right)^{-1}. \tag{18}$$

Statistical-Mechanical Theory of Irreversible Processes. I.

General Theory and Simple Applications to Magnetic and Conduction Problems

By Ryogo KUBO

Department of Physics, University of Tokyo

(Received March 2, 1957)

A general type of fluctuation-dissipation theorem is discussed to show that the physical quantities such as complex susceptibility of magnetic or electric polarization and complex conductivity for electric conduction are rigorously expressed in terms of time-fluctuation of dynamical variables associated with such irreversible processes. This is a generalization of statistical mechanics which affords exact formulation as the basis of calculation of such irreversible quantities from atomistic theory. The general formalism of this statistical-mechanical theory is examined in detail. The response, relaxation, and correlation functions are defined in quantummechanical way and their relations are investigated. The formalism is illustrated by simple examples of magnetic and conduction problems. Certain sum rules are discussed for these examples. Finally it is pointed out that this theory may be looked as a generalization of the Einstein relation.

§ 1. Introduction

The principal purpose of the present paper is to develop a general scheme for the calculation of kinetic coefficient, or admittance for external forces such as electric or magnetic susceptibility for alternating field, electric conductivity, heat conductivity and so on. The most common method traditionally employed to calculate such non-equilibrium quantities is to set up the so-called kinetic equation or transport equation for the molecular distribution functions. This will be solved for stationary or periodic conditions. It is however to be remineded that the kinetic equation is itself an approximation and cannot be derived without a certain condition which is rather strict and is not often satisfied.[1] For weakly interacting particles, it may be justified if the nature of interaction is appropriate. But certainly it is not always true, and we may not be able even to write down any equation of that sort.

On the other hand, the recent development of the thermodynamic of irreversible processes[2] indicates the possibility of constructing a general statistical-mechanical theory at least for those irreversible processes which are not far apart from thermal equilibrium. In fact, there have been a number of attempts in this direction[3]. A remarkable progress has been made by Kirkwood[4] wl showed that the friction constant, for instanc of a Brownian particle is determined by th correlation of forces acting on the particl This may be looked as a particular case the so-called dissipation-fluctuation theorem As was discussed from a general point view by Callen, Welton,[5] Takahasi[6] an others, the general admittance for an externa disturbance is related to the expectation the square of Fourier component of certai physical quantity which fluctuates in time thermal equilibrium. Thus it is shown tha as far as linear responses are concerned, th admittance is reduced to the calculation time-fluctuations in equilibrium.

This idea was used by the present autho as the basis of the theory of magnetic r sonance problem. In a previous paper[7] th author developed a quantum-mechanical theor of this and has shown a certain method practical application. A straightforward a plication of this theory was made by Nakan for the conduction problem. He showed th the simplest approximation of the fundament expression of conductivity gives the we known Grüneisen's formula.

A generalized form of Nyquist's theore can be easily derived by application of pe turbation theory either classical or quantu echanical. The complete conductivity tensor r a given frequency of applied electric field an be rigorously expressed in terms of ectric current components fluctuating spon- neously in equilibrium state[9]. We emphaze here that this expression is quite rigorous hough admittedly somewhat abstract. It is owever of great value, because the tradional theory of conductivity has not been ware of existence of such rigorous expresion (although the Heisenberg-Kramers disperion formula is an equivalent). The abstract ature of the formula may be compared to hat of general theory of statistical mechanics. he statistical mechanics can give a rigorous xpression for the equation of state in terms f partition function, but its calculation is not ecessarily easy.

This theory of electric conduction has been ctively discussed in last two years in Japan ince the appearance of our paper on magnetic esonance[7] and its application to conduction roblem by Nakano. Feynman also discussed his when he visited Japan in the summer f 1955. Also it has been discussed by Lax, Luttinger, Kohn and possibly by some others n the United States. Recently Mori[20] has ublished a paper on the same problem.

In the present paper, which will be the first art of a series of papers devoted to the evelopment of statistical mechanics of ireversible processes along this line and to its pplications, we shall examine in detail the mplications of this new method.

In § 2, we shall treat the response of a ystem to an external force by simple perurbation method. In order to make the idea learer we first discuss the classical case. Quantum-mechanical formulation is quite in arallel with this classical theory. However, we notice a difficult problem of quantumechanical observation which might disturb he natural development of the motion. It vill be pointed out that the logical basis f the whole theory is closely related to the rgodic properties of the system and the hysical quantities we are concerned with. This is discussed in § 3 in connection with the efinition of relaxation functions which desribe the relaxation of the system after renoval of external disturbance.

In § 4, the correlation functions are introduced which describe the time correlation of two quantities at different time points. The relation between the correlation function and the relaxation function is derived. This is somewhat complicated in quantum-mechanical case.

§ 5 is devoted to the application of general argument to simple examples of magnetic and conduction phenomena. This is mostly to illustrate the general idea. The symmetry of the relaxation and response functions is discussed in § 6. The Onsager's reciprocity is seen most clearly by this formalism. The complete form of fluctuation-dissipation theorem will be given in § 7 taking the example of conductivity tensor.

As an interesting application of the theory, some general rules for the admittance is discussed in § 8. The most general sum rule is mentioned with regard to the symmetric part of conductivity tensor. The integration of this over the whole range of frequency must be constant irrespective of the presence of interactions or magnetic field and at any temperature. Another type of sum rule is derived for the antisymmetric part of conductivity. An interesting sum rule for the magnetic problem is that the integrated absorption intensity of circular wave by magnetic media is directly related to the gyromagnetic ratio of magnetic particles.

In § 9, it will be pointed out that the theory may be looked as a generalization of Einstein relation which relates the mobility and the diffusion constant. The general nature of Einstein relation is thus most clearly revealed.

In the present paper we confined ourselves to such type of external disturbance which can be expressed definitely as an additional term in the Hamiltonian of the system. Thus the heat flow, or mass flow phenomena under the gradient of temperature or chemical potential is logically out of the frame of this treatment. This problem has been treated recently by Mori.[10] We shall, however, discuss this in a forthcoming paper from a somewhat different point of view.

We also have applied the present theory to the galvanomagnetic effect at high magnetic field[11]. This is an example for which the traditional transport equation has to be modified. Our theory will be reported in another paper.

§ 2. Response Function and Admittance of an Isolated System

Let us consider an isolated system, the Hamiltonian of which is denoted by $\mathscr{H}$. The dynamical motion of the system determined by $\mathscr{H}$ is called the "*natural motion*" of the system. We suppose that an external force $F(t)$ is applied to the system, the effect of which is represented by the perturbation energy,

$$\mathscr{H}'(t)=-AF(t)\,. \tag{2.1}$$

The motion of the system is perturbed by this force, but the perturbation is small if the force is weak. We confine ourselves to weak perturbation and ask for the response of the system in the linear approximation. The response is observed through the change $\Delta B(t)$ of a physical quantity B. The problem is now to express $\Delta B(t)$ in terms of the natural motion of the system.

First, we shall treat this in classical mechanics. We conceive a statistical ensemble which is represented by a distribution function $f(p,q)$ in the phase space. The *natural motion* is described by the equation of motion,

$$\frac{\partial f}{\partial t}=-\sum\left(\frac{\partial f}{\partial q}\frac{\partial\mathscr{H}}{\partial p}-\frac{\partial f}{\partial p}\frac{\partial\mathscr{H}}{\partial q}\right)=(\mathscr{H},f), \tag{2.2}$$

where p and q mean the set of the canonical moments and coordinates and the bracket means the Poisson bracket,

$$(A,B)=\sum\left(\frac{\partial A}{\partial q}\frac{\partial B}{\partial p}-\frac{\partial A}{\partial p}\frac{\partial B}{\partial q}\right). \tag{2.3}$$
